Index to Mechanical Engineering

Volume 54, January–December, 1932

(BR) denotes Book Review, (C) Correspondence, (Ed) Editorial

- Abbott, E. J., Firestone, F. A., and Durbin, F. M.
  - Reducing noise of machines 271
- Accidents
  - Automobile, fully preventable (Ed) 498
  - Automobile, some primary causes of 505
  - Industrial, prevention of (BR) 87
- Aerial Photography
  - New film for (Krypto-cyanine) 848
  - View showing 7200 sq. mi. of earth's surface 818
- Aerodynamics
  - Airfoils, inviscid flow past 862
  - Hydrodynamics and (BR) 231
  - Lift, increase of, devices for 513
  - Tail-surface flow in the spin 514
- Aeronautics
  - See also Aerodynamics; Airplanes
  - Drag of small streamlined bodies, measurement of 285
  - Progress in 848
  - Spinning, safety in 50
- Agriculture
  - Applications of electricify in farming operations 873
- Aircraft
  - Light alloys in 50
  - Use in warfare (Ed) 281
- Air Compressors
  - British 427
- Air Conditioning
  - Arrangement of centrifugal refrigerating system and cycle of refrigerant 656
  - Labus psychrometric chart 428
  - Railway trains, application to 796
- Air Cylinders
  - Rotating, proposed standard for 226
- Air Flow
  - See Flow of Air
- Air Lift
  - Theory of 794
- Airplane Carriers
  - Landing and storing naval airplanes on decks of mother ships, problems involved in 389
- Airplane Engines
  - Crankshafts, vibration characteristics of. 435
  - New fuel for 514
- Airplane Propellers
  - Hollow steel 50
  - Stroboscopic study of 221
- Airplanes
  - Clinogyre rotating-blade attachment for. 862
  - Construction, use of beryllium alloys in .. 214
  - Diesel engines for 726
  - Flight tests with control column giving warning of dangerous wing loads 500
  - Gyroplane, Wilford 862
  - Monoplane, Kohl tailless 500
  - Seaplanes, high-speed 427
  - Wing sections, super-high-load 213
- Air Preheaters
  - Boiler plant with 141
- Airships
  - Design, application of practical hydrodynamics to 427
  - Metal-covered (C) 72
- Alford, L. P., and Hannum, J. E.
  - Measuring operating performance by the kilo man-hour 821
- Allen, Oliver F.
  - U. S. Navy Diesel-engine requirements (C) 517
- Allner, F. A.
  - Hydroelectric developments and the correlation of hydro and steam power 695
- Alloy Steels
  - Dynamic strength and ductility of 133
  - Endurance properties in steam 51
  - Endurance properties, means of improving 133
  - Hardening by magnetic treatment 57
  - Notches, flaws, corrosion, etc., effect of .. 133
- Alloys
  - Beryllium, use in aeronautic construction 214
  - Fusible, in metal forming 52
  - Fusible, physical properties of (table) 52
  - High-temperature use, properties of alloys for 113
- Alloys (*continued*)
  - Iron-boron alloys and 18-8 steels with boron 574
  - Nickel 132
  - Thermal conductivities of (chart) 276
- Alumaweld
  - Solder for aluminum 51
- American Engineering Council
  - Progress report of its committee on the relation of consumption, production, and distribution 415
- American Society of Civil Engineers
  - Comment on its 80th birthday (Ed) 860
- American Society of Mechanical Engineers
  - Annual meeting, Dec. 5–9, 1932, program of 808
  - Boiler Code Committee. See Boiler Code Committee, Work of
  - Boiler Construction Code. See Boiler Code
  - Committee on economic status of engineers plans action 156
  - Fifty-second annual meeting 78
  - Lubrication research of 269
  - Organization, work of Calvin W. Rice in 5
  - Power test codes. See Power Test Codes
  - Presidential address of Roy V. Wright .. 20
  - Transactions papers, synopses of 65, 147, 223, 297, 439, 511, 583, 731, 799, 875
- American Standards Association
  - Work in last quarter of 1931 71
- Ammonia
  - Evolution of, in carbonization of coal 430
- Ammunition
  - Armor-piercing 490
  - Bullets. See Bullets
  - Tracer 491
- Angus, Robert W.
  - Hydraulics of open channels (BR) 591
- Applied Mechanics
  - Progress in 846
- Apprentice Training
  - In times of depression (C) 226
- Arkwright, Richard
  - His part in early days of the industrial revolution (with portrait) 677
- Armour Institute of Technology
  - Development plan of 841
- Asbestos
  - Yarns and cloths of 650
- Automobile Engines
  - Cast crankshafts and camshafts for 366
  - Design, improvements in 484
- Automobiles
  - See also Motor Trucks
  - Accidents, some primary causes of 505
  - Accidents with, preventable (Ed) 498
  - Air wheels vs. standard tires 483
  - Brakes, centrifugally cast drums for 724
  - Cars of 1932, features of 230
  - Crankcase draining of 789
  - Design, trend of 483
  - Diesel-engined 575
  - Dicsel engines for 726
  - Dual-power rear axle for 291
  - Gas for road vehicles 365
  - 1932 national automobile show in New York, notes on 230
  - Operating-cost and mileage studies 59
  - Packard twin-six, carburetion of 292
  - Speeding, costs of 653
  - Stopping distances for various speeds 653
  - Streamline body designed by Sir Dennistoun Burney 484
- Automotive Fuels
  - See Gasoline
- Aviation
  - Soviet Russia, data on 427

B

- Bailey, Alex. D.
  - The economics of electrical power supply 557
- Bailey, Neil P.
  - The measurement of surface temperatures 553
- Ballistics
  - See Bullets
- Banking
  - Branch banking defined 829
  - Weak spots in system and proposed remedies 825
- Banks
  - Bank of England, Bank of France, and Bank for International Settlements, views of 826
- Battleships
  - U.S.S. "Salt Lake City," view of 388
- Beams
  - I-beams, light, strength of 723
- Bearce, H. W.
  - Definition of the inch 689
- Bearing Metals
  - Porous bronze 108
- Bearings
  - Ball and roller, for sliding mechanisms .. 573
  - Bearing-temperature stresses, a possible criterion for 502
  - Journal, capillary lubrication of 108
  - Journal, overheating of, criterion for tendency toward 502
  - Lubrication of 434
  - Roll-neck, sleeve-type 364
  - Steel rings lined with lead bronze, tests on 294
  - Thin coatings of white metal deposited on mild-steel surfaces, atomization and fatigue of 294
- Belts
  - Action of gravity on (Lewis effect) 720
  - Endurance-testing machine for 438
- Berger, George G.
  - Economic lot sizes (C) 517
- Beryllium
  - Aeronautic construction, use in 214
  - Copper alloys for springs, use in 430
  - Production and applications (BR) 520
- Bigelow, Carle M.
  - Management essentials for recovery 749
- Bingham, Eugene C.
  - Mechanics of plastic bodies (BR) 305
- Blast Furnaces
  - Magnetogorsk, Russia ..... (Ed) 355, 461
- Blowing Engines
  - Large, performance of 346
- Boiler Code
  - Boiler Construction Code, Revisions and Addenda to 299, 370
- Boiler Code Committee, Work of
  - Interpretation of cases 74, 153, 302, 441, 516, 660, 878
- Boiler Feedwater
  - Priming, use of salts to reduce 59
- Boiler Firing
  - Dust and sulphur from powdered-coal firing 501
- Boiler Furnaces
  - Heat transfer by radiation in 576
  - Large stations, recent practice in 638
  - Smoke from, steam-air jets for abating .. 267
- Boiler Plants
  - First cost of steam-boiler plants 791
  - High-pressure, using brown coal 60
- Boilers
  - Benson marine boiler 138
  - Blast-furnace-gas-fired 868
  - Combination waste-heat and pulverized-fuel boiler unit 867
  - Combined rotary boiler and steam turbine 869
  - Critical-pressure 138
  - Drums, welded 222
  - Exhaust, on passenger steamships 789
  - Design factors affecting reliability and operation of boiler plants 506
  - High-pressure, for research work 251
  - Lancashire, modern installation of 141
  - Lancashire-type double boiler 729
  - Leakage, power test code for 77
  - Moderate-size, stokers for 791
  - Openings in cylindrical drums and shells, rule for determining (charts) 368
  - Priming, reduction of 59
  - Pulverized-coal-fired 216
  - Rotary type 853
  - Series operation of 729

Index to Mechanical Engineering

Volume 54, January–December, 1932

(BR) denotes Book Review, (C) Correspondence, (Ed) Editorial

- Abbott, E. J., Firestone, F. A., and Durbin, F. M.
  - Reducing noise of machines 271
- Accidents

  - Smoke from, steam-air jets for abating.. 267
- Boiler Plants
  - First cost of steam-boiler plants 791
  - High-pressure, using brown coal 60
- Boilers
  - Benson marine boiler 138
  - Blast-furnace-gas-fired 868
  - Combination waste-heat and pulverized-fuel boiler unit 867
  - Combined rotary boiler and steam turbine 869
  - Critical-pressure 138
  - Drums, welded 222
  - Exhaust, on passenger steamships 789
  - Design factors affecting reliability and operation of boiler plants 506
  - High-pressure, for research work 251
  - Lancashire, modern installation of 141
  - Lancashire-type double boiler 729
  - Leakage, power test code for 77
  - Moderate-size, stokers for 791
  - Openings in cylindrical drums and shells, rule for determining (charts) 368
  - Priming, reduction of 59
  - Pulverized-coal-fired 216
  - Rotary type 853
  - Series operation of 729

BOILERS (*continued*)
  Sludge as a source of danger in 576
  Steam generator for tangential firing 216
  Velox explosion type 506

BOOKS RECEIVED
  Brief notes on new books received by the U. E. S. Library 88, 160, 233, 306, 377, 441, 521, 592, 665, 737, 807, 883

BOOKS REVIEWED
  America's answer to the Russian challenge. By Robert Sibley 231
  Applied gyrodynamics—for students, engineers, and users of gyroscopic apparatus. By Ervin S. Ferry 737
  Behemoth: the story of power. By Eric Hodgins and F. Alexander Magoun 447
  Beryllium, its production and application 520
  Dynamics of engine and shaft. By Ralph E. Root 883
  Earthquake damage and earthquake insurance. By John R. Freeman 591
  Economic control of quality of manufactured product. By W. A. Shewhart 664
  Fundamentals of instrumentation 806
  Handbook of business administration. By W. J. Donald 157
  Hydraulics for engineers. By Robert W. Angus 447
  Hydraulics of open channels. By Boris A. Bakhmeteff 591
  Hydro- und aerodynamik (Handbuch der Experimental-physik vol. IV), edited by Prof. L. Schiller 231
  Industrial accident prevention 87
  Jobs, machines, and capitalism. By Arthur Dahlberg 317
  Mechanical fabrics. By George B. Haven 807
  Pathways back to prosperity. By Charles Whiting Baker 317
  Plasticity: a mechanics of the plastic state of matter. By A. Nadai 305
  Principles of organization as applied to business 87
  Proceedings of the fifth oil-power conference 664
  Quantity and economy in manufacture. By Fairfield E. Raymond 160
  Raise wages! By A. G. McGregor 736
  Sydney Harbour bridge 883
  Tables of rolling pressures and power requirements for rolling steel shapes. By F. Waldorf 447
  The paradox of plenty. By Harper Leech 317
  The physics of high pressure. By P. W. Bridgman 159
  The quest for power from prehistoric times to the present day. By Hugh P. Vowles and Margaret W. Vowles 159
  The work, wealth, and happiness of mankind. By H. G. Wells 882
  Wasserbauliche Modellversuche zur Klärung der Abflusserscheinungen beim Abschluss der Zuiderzee 520

BORING MACHINES
  Problems in design of 333

BORON
  Alloys containing, properties of 574

BRAKES
  Automobile, centrifugally cast drums for 724

BRASS
  Rod, free-cutting, machinability of 285
  Tubes, cold-drawn, bursting strengths of 219

BRIDGES
  Bayonne, over Kill van Kull (view) 532
  George Westinghouse bridge (view) 747
  Sydney harbor bridge (BR) 883
  Skew bascule bridge 650

BRILLHART, S. E.
  The manufacture of rubber-covered wires for telephone installations 405

BRONZE
  Be (beryllium-copper) 430
  Porous 108

BRYANT, O. N.
  Will economic stability suffice? (C) 879

BUILDING CONSTRUCTION
  Graph showing cost trends in 474

BUILDINGS
  Factory, taxable value of 473

BULLARD, J. E.
  Danger of government ownership (C) 589
  Invention, unemployment, and patent control (C) 303

BULLETS
  Accuracy and range, developments in by Ordnance Dept., U. S. A 487
  Markings on bullets and shells fired from small arms (C) 587
  National match, trajectories of 490
  U. S. caliber .30 ammunition, ballistic data for 489

BURGESS, GEORGE K.
  The late, appreciation of (Ed) 566

BURLINGAME, LUTHER D.
  Machine tools 323

BUSINESS
  Conditions. See Economics
  Cycles. See Economics
  Impotent (Ed) 280

C

CALORIMETERS
  Saturated-steam, new, details of 119

CAMMEN, LEON
  A chance for engineering progress 859
  Power requirements in rolling steel (BR) 447
  The saga of beryllium (BR) 520
  The transportation dilemma 533
  Will the boot straps stand the strain? (C) 734

CANADA
  Hydroelectric development in (C) 805

CANNON
  Cold working of 703
  Design, fundamentals of 703

CARBON
  Effect of ash on reactivity and combustibility of 431

CARBON DIOXIDE
  Solid, in industrial refrigeration 577

CARBURIZING
  Continuous gas process of 651

CARS, SUBWAY
  Dimensions, weights, and equipment of New York City subway cars (table) 43
  Improved, for New York's 8th Ave. subway 41

CASANOVA, ARRIGHI DE
  Tribute to French power-plant engineer (Ed) 649

CAST IRON
  "Migra" 215
  Promal (new type of) 133
  Remelted, tests of 215

CASTERS
  Swivel type of 435

CASTINGS
  Iron, permanent-mold 724

CEMENT
  Low-heat, for mass concrete 863
  Plants, grinding coal for use in 579
  Portland-cement industry in U. S., Canada, and the United Kingdom, comparative study of 211

CENTRAL STATIONS
  Brussels station, fire in 868
  Performance data of certain American stations (table) 636
  Practice in large modern American plants 635
  View of turbine room of Hell Gate plant of United Electric Light and Power Co. 820
  What does Pearl Street mean? (Ed) 718

CHEMICAL ENGINEERS
  Earnings of (Ed) 209

CHIMNEYS
  See Smokestacks

CHRISTIE, A. G.
  Central-station plant and performance 635
  Surplus power from industrial plants 771

CITIES
  Changes in age structure and composition of urban populations 835

CITY PLANNING
  Importance of human factor in 831

CLASSIFICATION
  Scheme for use with natural phenomena 805

CLAY
  Measuring plasticity of 504

CLINOGYRES
  Odier-Bessiere 862

CLOCKS
  Slow-motion electric motor for 500

COAL
  See also Pulverized Coal
  Ammonia, evolution in carbonization and gasification of coal 430
  Bituminous-coal industry, problems of (report of Pittsburgh conference) 85
  Bituminous coal, oil, natural gas, and water power, contest between 256
  Continuous carbonization of finely crushed coal by radiant heat 286
  Dust, self-electrification of 52
  Grinding mills for, tests in cement plants 579
  Industry, troubles of 49
  Solid, mechanism of combustion of 133

COAL-DUST ENGINES
  See Internal-Combustion Engines

COCKS
  Reduction in frictional resistance effected by changes in internal contour 476

COLUMNS
  Reinforced-concrete, investigation of 57

COMPTON, KARL T.
  Calvin Winsor Rice 5

COES, HAROLD V.
  Current problems of industrial management (C) 661

COKE OVENS
  Magnetogorsk, Russia 461

COLBY, Z. E.
  Comments on August "Mechanical Engineering" (C) 804

COLVIN, FRED H.
  Eight or Sixteen? (as base of measurement system) (C) 805

CONANT, WILLIAM S.
  Research must go on! (C) 375

CONCRETE
  Mass, low-heat cement for 863
  Mixes, cement-water ratio for 51
  Reinforced-concrete columns, investigation of 57

CONDENSATION
  Pure vapors 563
  Vapor-air mixtures 564

CONDENSERS
  Recent practice in large stations 639

CONDUCTION
  Heat, basic laws and data of 275

CONDUITS
  Salt Springs-Tiger Creek (view) 676

CONVECTION
  Film theory of 347
  Forced, problems, analysis of 410, 412
  Free, formulas for 347

COPPER
  Industry, troubles of 49
  Lake Balkhash copper works, Siberia 581

CORRESPONDENCE
  Letters from readers 72, 154, 225, 303, 375, 443, 517, 587, 661, 733, 803, 879

CORROSION
  Bonderizing process of preventing 568
  Effect of oxygen on gaseous hydrogen sulphide corrosion of tank steel 429

COSMIC RAYS
  Recent research in 846

COSTS
  Break-even chart for use in analyzing 759
  Mathematical analysis of 711

COWDRICK, EDWARD S.
  What's ahead in foreman training? 629

COYLE, DAVID CUSHMAN
  Public works and recovery 623

CRANES
  Overhead, handling car trucks with 45

CREAM SEPARATORS
  Noise rating of 273

CUNNINGHAM, JAMES D.
  The Armour Institute development plan 841

CUPOLAS
  Blast for, effect of excessive atmosphere moisture in 215

CURRENT MECHANICAL ENGINEERING LITERATURE
  Selected items from Engineering Index 89, 161, 234, 307, 379, 451, 523, 595, 667, 739, 811, 889

CUTTING METALS
  See Metals

CUTTING TOOLS
  Handbooks for users of, proposed series of (Ed) 861
  Metal cutting, experiments in 137
  New cutting materials, properties and limitations of 329
  Roughing tool for lathe, standard 710
  Skiving tools for formed parts 435
  Standard tests for 708
  Tool-mark patterns resulting from various machining and hand-tool operations, photomicrographs of 343
  Tungsten carbide 137
  Tungsten carbide tips with tantalum binder 365
  Widia (tungsten-carbide) 137

CYLINDERS
  Metal, thick-walled, cold working of 703

Y

YARROW, SIR ALFRED
  Obituary 227

Index to A.S.M.E. Transactions

Volume 54, 1932

The different sections of the Transactions are designated by symbols, the following being used: AER (Aeronautics), APM (Applied Mechanics), FSP (Fuels and Steam Power), HYD (Hydraulics), IS (Iron and Steel), MAN (Management), MSP (Machine-Shop Practice), OGP (Oil and Gsa Power), PME (Petroleum Mechanical Engineering), WDI (Wood Industries), RP (Research Papers), and RI (Record and Index). In this Index, except for references to the Record and Index Section, three numbers follow the symbol for the section; the first is the volume number, the second the paper number, and the third the page number. Thus AER-54-6-41 signifies that the material is found in the Aeronautics Section, vol. 54, paper no. 6, on page 41. In the case of the Record and Index Section of Transactions, there is no paper number, the entire section being numbered consecutively from page 1 to the end, so that the first number refers to the volume and the second to the page (RI-54-24).

(D) preceding other symbols in a reference denotes a discussion of a paper

[illegible]
American Society of
Mechanical Engineers
[illegible] 1932

Foreword

VOLUME 54 of the Transactions of The American Society of Mechanical Engineers contains 27 individual sections published during 1932 under the sponsorship of the Society's 15 professional divisions, as well as its annual Record and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and of its professional divisions and local sections, and were issued originally in pamphlet form. These pamphlets appear in sections, each section being sponsored by one of the Society's professional divisions. Other papers published by the Society but not included in the Transactions may be located by means of the Record and Index which forms a part of this volume.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on pages 89–91 of the Record and Index. Copies of the bound Transactions have also been set aside for sale.

The Record and Index of the A.S.M.E. for 1932 which forms a part of these Transactions, is the permanent record of the Society's activities for the year. It includes lists of committees, reports of meetings and committee activities, memorial notices of deceased members, as well as indexes of special A.S.M.E. publications and of *Mechanical Engineering*.

In this volume the papers of each section are grouped together and are numbered serially. The sections are arranged alphabetically. Each paper is designated by a symbol composed of key letters followed by the volume number and paper number. The letters refer to the section of the Transactions to which the paper is assigned. Thus AER refers to the Aeronautic section, IS to the Iron and Steel section, etc. The arrangement of the index and designations for locating material are explained at the beginning of the index.

THE PUBLICATIONS COMMITTEE.

Transmission of Visible, Infra-Red, and Ultra-Violet Radiation Through Fog

With Reference to Developing Aids in Fog Aviation

By S. HERBERT ANDERSON,[1] OCEANPORT, N. J.

Fog menaces all forms of transportation, particularly air travel. To study the visibility of beacons through fog, a laboratory method of producing fog was developed. Fogs of two types have been made with a range of densities corresponding to natural fogs in which the visibility varies from 20 ft. to 2000 ft. Transmission of radiation through these fogs has been measured, covering a wave-length range of 0.30 to 0.40 micron in the ultra-violet, 0.40 to 0.75 micron in the visible, and 0.75 to 2.6 microns in the infra-red parts of the spectrum. The conclusion is that the penetration of infra-red through fog is many times that of visible light, the ratio depending upon the distance and the nature of the fog, and consequently infra-red gives promise in developing aids for fog landing, especially in localizing a fog-obscured airport.

FOG, menacing and impeding, still hangs over all forms of transportation. On land, on sea, and in the air its risks still challenge the ingenuity of man. All of his skill is needed if he is to make travel more secure. Especially is this true of travel in the air. Here the pilot requires superior visibility to enable him to distinguish the landmarks, beacons, and signals on which the proper guidance of his plane depends. Here the menace of fog is directly proportional to the lack of that visibility so necessary for safe operation. With the development of aviation and the growth of interest in it, has come a corresponding recognition of the need for the study of fog penetration, with a view to diminishing its dangers. The last three years have witnessed a remarkable advance in these directions.

Prior to the investigation under discussion in this paper (autumn of 1928) only one paper dealing with measurements of fog penetration had appeared. Utterback[2] in 1919 measured the transmission of light through a laboratory-made fog. He used 11 bands of color between $\lambda = 0.46\mu$ and $\lambda = 0.63\mu$, and found a maximum of transmission for a wave-length range between 0.53μ and 0.59μ (corresponding to a color range from green to yellow). Granath and Hulburt,[3] of the Naval Research Laboratory, in 1929 reported their measurements through a natural fog for a range from 0.40μ (violet) to 3.00μ (infra-red). Their data showed the transmission to increase with wave length, thereby agreeing with King's[4] equation

$$I = I_o e^{-(a + b\lambda^{-4})x} \qquad [1]$$

in which I_o is the intensity of radiation in a clear atmosphere, I the intensity after passing through a distance x of fog, λ is wave length, and a and b are parameters. More recently Houghton and Straton,[5] of Massachusetts Institute of Technology, have presented experimental and theoretical investigations covering a range from 0.40μ to 0.70μ. They found a small maximum of transmission at 0.49μ. The work of Benford[6] and of Karrer and Tyndall[7] contributed to information on atmospheric transmission but very little on the specific problem of fog penetration. The results of these investigators will be discussed later.

A knowledge of the nature of fog enables one to make certain predictions regarding its effects on a beam of radiation projected from a searchlight or an airway beacon. Fog particles are minute spheres of water ranging in diameter from 1 to 10 microns (1 micron, μ, $= 10^{-6}$ meters $= 0.001$ mm.). The diameters of the most numerous particles in fogs occurring along seacoasts and the radiation fogs of interior lowlands are from 6 to 8 microns. Particles which make up smoke and haze are much smaller, 0.001 to 0.1 micron in diameter. In the "black" fogs found over industrial centers, both smoke particles and fog particles are present. In such fogs the particles are smaller than in sea fogs.

The attenuation of a beam of radiation in passing through a layer of fog may be attributed to four factors:

1. True absorption, including selective absorption
2. Scattering
3. Diffusion
4. Diffraction.

[1] Chief, Light Section, Signal Corps Laboratory, Fort Monmouth. Physicist for the Daniel Guggenheim Fund for the Promotion of Aeronautics, Inc., 1928–1930. Mr. Anderson received his Ph.D. from the University of Illinois, 1912. Member of the staff of the Department of Physics, University of Washington, 1912 to 1918 and 1919 to 1928. Commissioned First Lieutenant, Air Service, March, 1918. Assigned to Science and Research Section, Air Service, March, 1918, to March, 1919, and to Engineering Division, Air Service, March, 1919, to September, 1919. Was engaged in development and testing work of airplane instruments. Instructor in Air Corps Engineering School, McCook Field, Dayton, Ohio, during the summers of 1920 and 1926. Research Physicist for the Daniel Guggenheim Fund for the Promotion of Aeronautics, July, 1928, to July, 1930. Assigned to Wright Field, Dayton, Ohio, to work with the engineers of the Air Corps, U. S. Army, in developing aids for fog avigation. Physicist in charge of Light Section, Signal Corps Laboratories, Fort Monmouth, N. J., October, 1930, to date. Published papers on photoelectric phenomena, acoustics, X-rays, electric-arc characteristics; prepared the first editions of the Instruction Manual on Airplane Instruments and Manual of Aerial Navigation for the Air Corps, U. S. Army; preliminary report for the Daniel Guggenheim Fund for the Promotion of Aeronautics on the "Penetration of Light Through Fog," published in *Aviation*, May, 1930.

Presented at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

In *absorption*, the energy of radiation incident on the fog droplets is changed into some other form. It consequently disappears as radiant energy.[8] In *scattering*, *diffusion*, and *diffraction*, the radiation incident to the fog particles is turned aside or given a new direction. Thus the intensity of the beam suffers a loss. The physical processes by which this is accomplished in the three cases are quite distinct. In *scattering*, the particles become radiators, emitting light in all directions. The theory of scattering was set forth by Lord Rayleigh.[9] He showed the intensity of the scattered light to be given by

$$I_s = \frac{Kd^6}{\lambda^4} \qquad [2]$$

where K is a constant, d the diameter of the particle, and λ the wave length. The derivation of this formula assumed the diameter of the particle to be small compared with the wave length of incident light. Wave lengths of visible radiation range from 0.40μ to 0.75μ, and the most useful infra-red from 0.75μ to 2.0μ. Since the average diameter of droplets in a true fog is about 7μ—large as compared with the radiation wave lengths—Rayleigh scattering could not be expected to be important in the attenuation of radiation through fog. However, in haze, smoke, and small-particle fogs, where the particles are less than 1μ in diameter, the Rayleigh scattering must be considered a significant factor.

In *diffusion*, radiation is deflected from its original path by refraction and reflection. This is probably the most important cause for loss of energy in the transmission of radiation through fog.

In *diffraction*, there is a deviation of a ray of light, which is a function of particle size and wave length. The diffraction pattern produced by a group of fog particles of uniform size is a ring of rainbow colors, blue on the inside and red on the outside, about the source of light. This is called a corona. One sometimes observes it about the sun or moon, due to thin clouds in the high atmosphere. Very rarely is it seen in a ground fog; probably due to the fact that the great variety of sizes of fog particles causes an overlapping in the diffraction patterns. Under these conditions the effect of diffraction would be the same as diffusion.

The actual volume of water in a cubic meter of dense foggy air is extremely small, being 6 × 10^{-7} cu. m. or 0.6 cc. per cu. m. In order to obtain a layer of water 1 cm. thick (of any desired area), fog particles from a layer 16.7 km. thick would be required. Such a thickness of water would be opaque to infra-red radiations longer than 1.4μ, but transparent to visible and ultra-violet. Hence it must be concluded that true absorption is a negligible factor up to 1.4μ.

It appears, then, that the principal factors in the attenuation of visible radiation through fog are diffusion (due to reflection and refraction by fog particles) and possibly diffraction. There is no reason for believing these should show selective effects. Consequently, the problem of fog penetration with visible radiation did not appear a very promising one to the physicist.

Opposing these arguments, however, were persistent reports that neon lights and incandescent lights with yellow and orange filters exhibited greater visibility in fog than did white lights. It became desirable to secure, if possible, quantitative information on transmission of radiation through fog. Should any color be especially effective in fog penetration, this fact should be known and used in the designing of aviation lighting.

As the work progressed, the investigation was extended into the ultra-violet and infra-red regions, the total range covered being from 0.3μ to 2.6μ.

The unreliability of nature for furnishing fogs in the quantity and of the quality needed for such an investigation suggested the use of a laboratory method to expedite the research. Any information thus gained would be a valuable guide for field tests in natural fogs.

Design of Laboratory Fog Equipment

Principles of Fog Production. The design of laboratory equipment for the production of fog was made with a view to simulating as nearly as possible the processes in natural fogs. Hence, a brief statement of the principles involved will be given.

The essential conditions for fog formation have been known since the pioneer work of J. J. Thomson[10] and C. T. R. Wilson.[11] These are:

1 The presence in the air of condensation nuclei
2 A humid condition of the atmosphere.

The first condition is the more important, since the degree of saturation or supersaturation required for volume condensation depends upon the nature of the condensation nuclei. Wilson showed that in filtered air a fog could not be formed until a supersaturation of eightfold (800 per cent) was produced. The explanation of this is found in the fact that vapor pressure over a convex surface is greater than over a flat surface. The excess pressure is given by

$$\Delta p = \frac{2Td_v}{R(d_w - d_v)} \qquad [3]$$

in which

Δp = excess vapor pressure over a convex surface
T = surface tension of the liquid
R = radius of curvature of the surface
d_w = density of the liquid (water)
d_v = density of the vapor.

The foregoing equation shows that the excess pressure is inversely proportional to the radius. This means that if a droplet of water (for example, a fog particle) is present in the air, there is a tendency for the droplet to evaporate; the smaller the drop, the greater this tendency. If a drop is to be stable, the tendency to evaporate must be neutralized by some other force. A condensation nucleus supplies this neutralizing force.

The following table shows the magnitude of excess vapor pressure of water due to curvature:

Diameter of particle	Excess vapor pressure
1 × 10^{-3} cm.	2.8 dynes per sq. cm.
5 × 10^{-5} cm.	56.0 dynes per sq. cm.
2.8 × 10^{-8} cm.	100,000.0 dynes per sq. cm.

The pressure of saturated water vapor for a temperature of 10 deg. cent. (50 deg. fahr.) is about 12,250 dynes per sq. cm. The diameter of a large fog particle is about 1 × 10^{-3} cm. For a particle of this size, the excess vapor pressure, 2.8 dynes per sq. cm., is small compared with the vapor pressure of the space around it. Consequently, the tendency to evaporate is not large. However, if a particle has molecular dimensions (2.8 × 10^{-8} cm.), the excess vapor pressure is very large, 100,000 dynes per sq. cm. This is a little greater than eight times the saturated vapor pressure at 10 deg. cent. The foregoing explains the necessity for raising the supersaturation to eightfold in order to produce condensation in air free from dust, hygroscopic particles, and ions. Under such conditions, the volume vapor pressure must equal or exceed the vapor pressure of particles of molecular dimensions.

---

[8] Since heat radiation occurs at all temperatures, the fog particles will emit radiant energy. However, this will be so feeble and of such long wave length that it can be neglected as compared with the incident radiations.

[9] *Phil. Mag.*, vol. 41, p. 107, 1871.

[10] J. J. Thomson, "Conduction of Electricity Through Gases," 2d ed., p. 149 et seq.

[11] C. T. R. Wilson, Phil. Trans. of the Royal Society (London), vol. A-189, p. 265, 1897; vol. A-192, p. 403, 1899.

In an admirable paper Willet[12] has shown that fogs and clouds are formed in nature when the saturation is less than 100 per cent, and rarely when more than 107 per cent. Condensation with this relatively low vapor pressure is possible through the presence in the air of condensation nuclei. These may be:

1 Electric ions
2 Inert, irregularly shaped particles (smoke or dust)
3 Hygroscopic particles.

Electric ions act as condensation nuclei because the electric charge tends to neutralize the excess vapor pressure caused by curvature of the surface. It can be shown[13] that a particle having a unit ionic charge has a critical diameter, 1.26×10^{-7} cm., so that, should the diameter of the particles be equal to or larger than this, condensation will occur. If the particle be smaller, condensation will not occur. However, it was shown that saturation must be between fourfold and sixfold for condensation on electric ions. Since this is much greater than found in nature, it must be concluded that electric ions are not important in the formation of natural fogs.

Inert particles of dust and smoke act as condensation nuclei because of (1) flat areas over which the vapor pressure is equal to the saturated-vapor pressure of the air and (2) concave areas over which the vapor pressure is less than that of saturated-vapor pressure.

Hygroscopic particles have an attraction for water molecules. This force of attraction is opposite from the vapor pressure of the convex surface of the drop. Such particles are very effective condensation nuclei. Some such substances found in the air are sodium chloride (NaCl), magnesium chloride ($MgCl_2$), and sulphuric anhydride (SO_3). NaCl and $MgCl_2$ occur in the air over the ocean and along the seacoasts. These substances furnish the condensation nuclei of fogs for these localities. SO_3 is formed by the oxidation of SO_2. The latter is found generally wherever coal is burned. Around industrial centers other products of combustion and industrial processes form numerous hygroscopic particles.

Condensation nuclei are present in the air at all times in greater or less numbers. When a volume of air of high moisture content is cooled to the dewpoint or lower, a fog may occur. According to Willet,[14] the processes by which this is accomplished form a basis for classification. Only two types, more prevalent than others, will be mentioned here, viz., (1) radiation fogs and (2) advection fogs.

Radiation fogs occur most often at night, along river bottoms, in valleys, in cities, and around industrial centers. The conditions for the formation are:

1 A previous relatively high humidity, caused by daytime evaporation of water
2 A cooling of the lower strata of air at night by (*a*) radiation and (*b*) by contact with ground cooled by radiation after sundown; this results in a shallow temperature inversion
3 A fairly static condition of the atmosphere. Radiation fogs do not usually form with wind greater than 5 m.p.h. On the other hand, extremely calm air permits precipitation as dew. A slight turbulence bringing a large volume of air in contact with the ground slowly enough to permit cooling and rapidly enough to prevent complete precipitation is necessary.

The second type, advection fogs, occur (*a*) when a warm, humid body of air drifts over a cold surface and (*b*), more rare, when a warm, humid body of air comes in contact with a cold layer of air. Such fogs occur in the early spring and summer along seacoasts, i.e., along the New England Coast and the Pacific Coast. A further excellent example is the fogs off Newfoundland. Here the air from over the Gulf Stream drifts over the Labrador Current.

In the laboratory production of fog, condensation nuclei were introduced into an enclosure containing air saturated with water vapor. The size of the fog particles formed was controlled to some extent by the nature of the nuclei and the degree of supersaturation produced. The details will be described later.

The Fog Chamber. The fog chamber as finally developed and used is shown in Fig. 1. *C-C* is a length of standard steel steam pipe, 6 in. in diameter and 20 ft. long. It was closed at each end by a piece of plate glass. (For most of the tests Pyrex glass was used, since it has a uniform high transmission from 0.36 microns in the ultra-violet to 2.5 microns in the infra-red. For measurements in the ultra-violet and infra-red, plates of fused quartz were used.) The pipe was lined on the inside with a helical coil of copper tubing, $^1/_4$ in. in diameter, 12 turns to the foot. Through this coil hot or cold water could be circulated and by this means change quickly the temperature of the air in the pipe. The pressure could be increased or decreased by connections to an air-pressure line and a vacuum tank, respectively. From a water tank *W*, fitted with an electric heating unit, a 3-in. pipe *P-P* runs to each end of the fog chambers. Warm, humid air above the water could be circulated through the fog chamber by a small electric fan hung on the inside of the water-tank cover. A second electric fan was located inside the fog chamber. When this latter was running, a turbulence, similar to that in a natural fog, was produced. Valves *V-V*, at each end of the 3-in. circulating pipe, could be closed, thus shutting off the fog chamber from the water tank. The temperature of the air within the fog chamber was indicated by three thermocouples, one at each end and one in the middle. A fourth thermocouple, soldered to the exterior of the outside wall of the fog chamber, gave the temperature of the wall. A fifth thermocouple in the water tank indicated the temperature of the water.

Special precautions were taken to screen the light-detecting instrument from light reflected from the inside walls of the fog chamber. In the first place, the reflecting power of the inside walls was made very low. After assembling the equipment, the interior was sprayed with optical-black lacquer. While this was still sticky, soot from burning camphor gum was deposited on it. This produced a mat-black surface of very low reflecting power. In the second place, baffle rings were built into the temperature-control unit and so located as to prevent light reflections from reaching the observing end of the fog chamber.

Condensation nuclei were introduced into the fog chamber by a smoke injector *S*. Tobacco, burned in this injector, formed satisfactory nuclei. For large-particle fog magnesium chloride was mixed with the tobacco.

At the middle section of the fog chamber were three glass windows, 1 in. in diameter. Two of these were at opposite ends of a diameter and the third was at an angle of 30 deg. to the line of the other two. A beam of light from a small projector could be directed through the two windows opposite each other. Through the third window a microscope of low magnifying power

[13] J. J. Thomson, loc. cit.

[14] Willet, loc. cit.

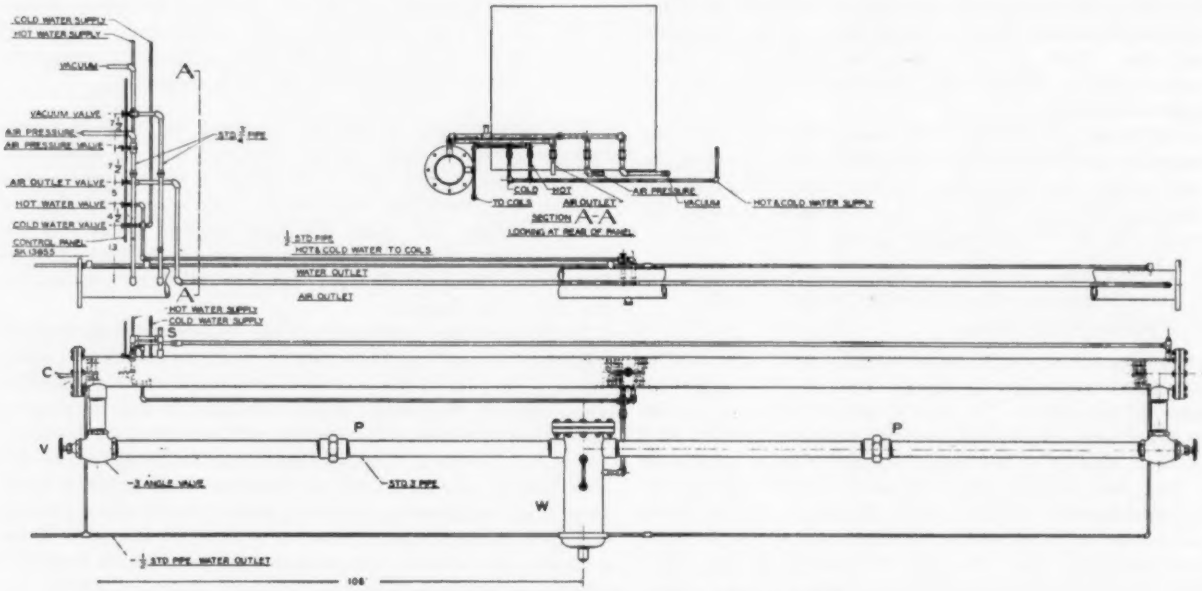

FIG. 1 DIAGRAM OF LABORATORY FOG CHAMBER

was directed on the fog particles illuminated by the light beam. Thus it was possible to make a qualitative observation on the number and size of the fog particles.

PRODUCTION OF FOG

Two kinds of fog were used in this investigation, which will be called (1) "small-particle" fog and (2) "large-particle" fog. The diameters of the most numerous particles in the small-particle fog were about 6 microns and in the large-particle fog about 8 microns.

The first step in the formation of both types of fog was the same, viz., the circulation of warm, moist air from the water tank *W* through the fog chamber. Condensation on the small windows at the center section indicated a saturated condition of the air. The end windows were kept slightly warmer than the rest of the fog chamber to prevent condensation there.

Small-Particle Fog. In the formation of small-particle fog, a large number of condensation nuclei were introduced by burning tobacco. The valves *V-V* were closed, the stirring fan was started, and the temperature was adjusted to 20 deg. cent. Shortly the testing light was completely obscured, indicating a change in the size of the particles. If the fog were watched through the microscope at the center section, the growth of these particles was easily observed. At first they were too small to be resolved by the low-powered microscope, but as the fog became stable the individual particles were distinguishable. Even though smoke particles were used as condensation nuclei, this fog must not be considered a smoke haze. It was definitely a fog in which the bulk of each particle was largely liquid water. The condensation took place from about 100 per cent saturation. This type of fog is probably similar to the black fogs found over industrial centers.

Large-Particle Fog. To produce large-particle fog, magnesium chloride was mixed with the tobacco, thus introducing hygroscopic nuclei of $MgCl_2$. The valves *V-V* were then closed, the stirring fan was started, and the temperature was adjusted to 20 deg. cent. In order to increase the moisture content of the air the pressure in the fog chamber was increased to 1.15 atmospheres. When a stable condition was reached, the air was suddenly expanded by opening the valve of the vacuum tank. An adiabatic expansion and cooling resulted in which the saturation reached about 150 per cent. A very dense fog was quickly formed, completely obscuring the testing light.

Both types of fog were very dense at first. They thinned out slowly, lasting from two to three hours, during which time measurements were made of the transmission of various bands of radiation.

METHOD OF MEASURING THE TRANSMISSION OF RADIATION THROUGH FOG

Source of Light. For the investigations in the visible and infra-red portions of the spectrum the source of light was a 200-watt, 6-volt, Mazda C incandescent lamp. The filament was specially concentrated, a single helix of seven turns, well adapted for projecting a narrow beam. By means of a lens projector a beam of radiation, limited by a circular diaphragm $2^1/_2$ in. in diameter, was directed through the fog chamber. The image of the filament was focused at the position of the light-detecting instruments, producing an illumination of 170 foot-candles and a corresponding beam candlepower of 70,000. The lamp was operated on a 15-volt d.-c. circuit, with a storage battery floating on the line. The current was kept at 28 ($\pm$ 0.1) amperes by a rheostat. Operating below the rated power of the lamp made possible a very constant source of light. The temperature of the filament, measured with an optical pyrometer, was 3000 deg. kelvin.

For the ultra-violet portion of the spectrum, the Mazda C lamp was replaced by a "sun lamp" *S-1*. With this type a mercury vapor arc about $^1/_4$ in. long was formed between electrodes of tungsten. The bulb of Corex-D glass transmits little or no radiation shorter than 0.28μ. However, it was better adapted to this work than a quartz mercury arc lamp, for it was possible to project a narrow beam from it. The glass projecting lenses were replaced by one of fused quartz.

Radiation Measuring Instruments. The intensity of the light emerging from the fog chamber was determined by photoelectric cells for the ultra-violet, visible, and near-infra-red parts of the spectrum, and for the infra-red of longer wave lengths by a thermoelement. Photoelectric currents were measured by a Leeds & Northup galvanometer with a sensitivity of 0.0005 microampere per mm. scale deflection. By using a shunt with the galvanometer, currents could be measured over a range from 1 to 1500.

Thus it was possible to measure transmissions of light somewhat smaller than 0.1 per cent. Preliminary tests showed that if the photoelectric cells were operated on a comparatively low voltage, the photo currents were proportional to the light flux on the cell for the range of illuminations used. (Subsequent to these tests the same results were published by Koller.[15])

A Hilger D-34 infra-red spectrometer, fitted with a linear thermopile, was used for isolating various bands of infra-red. The galvanometer was a Leeds & Northrup type HS, with a sensitivity of 20-mm. deflection per microvolt.

The comparison of a set of measurements taken at one time with those taken at another necessitated some means of measuring the transparency of fog. An arbitrary method was utilized. The photoelectric current (using the band of near infra-red 0.85μ) as obtained from cell 3, type UX-868, with Wratten filter 88A in front of it, was taken as a measure of fog transparency. Galvanometer deflections for all other bands of radiation were read at the same time as the deflections obtained with this band.

Bands of Radiation Used. Fourteen bands of radiation covering a total range from 0.30μ to 2.60μ were used in this investigation. Two were in the ultra-violet, four in the visible, and eight in the infra-red parts of the spectrum, respectively. The selection of these bands was governed by three conditions:

1. Each band should be as narrow as possible
2. One band should not overlap another
3. The radiation energy of each band should be sufficiently large to render possible an accurate measurement.

The first two conditions were imposed by the very nature of the problem. In order to determine the variation in transmission of various colors (bands of radiation) through fog, the measurements should be made for pure colors. Otherwise the results obtained would give transmission coefficients which might be misleading. It would be possible to secure pure colors (narrow bands) by using a spectrometer or monochrometer. However, should this be done, the third condition might be violated—the energy in each band would be too small for reliable measurement. It was found possible to use a spectrometer for isolating bands in the infra-red, but filters had to be used in the visible and the ultra-violet parts of the spectrum.

In Table 1 is given a list of the bands of radiation used, the width of each band, and the means of isolating each. In Fig. 2 the bands isolated by filters are shown graphically. The energies of the 0.3235μ, 0.360μ, and 0.4275μ bands were due largely to lines of the mercury-arc spectrum. The bands of the visible and near infra-red were cut out from the continuous spectrum of the Mazda C lamp.

The isolation of these latter bands was secured not only by the selective transmission of filters, but also by the spectral sensitivity of photoelectric cells. As much difference was found in the long wave-length limits of individual cells of the same type as existed between individual cells of different types. For example, the limit of cell No. 3, type UX-868, was 1.15μ and of cell No. 1, same type, was 0.825μ. This type had caesium sub-oxide as the active element. The limit of PJ-15, a pure caesium cell, was 0.70μ and of the Burt cell (sodium cathode) was 0.56μ. Practically all red and yellow filters had a high transmission (90 per cent or more) in the dark-red and infra-red to 2.5 microns. If the elimination of this radiation of long wave length was desired, some other filter had to be used with the yellow or red filter. One that would serve was a liquid filter of copper sulphate solution, cutting off radiations longer than 0.70μ. Such a filter, however, was not convenient. The proper selection of a photoelectric cell made possible a more simple accomplishment of the same result. For the band in the near infra-red (0.70μ to 1.15μ) the long wave-length limit was given by the cut-off of cell No. 3, UX-868. For the red band (0.60μ to 0.825μ), cell No. 1 of the same type gave the long wave-length limit at 0.825μ.

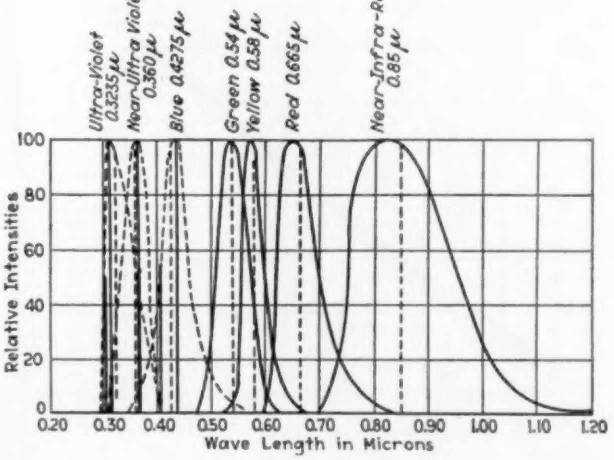

FIG. 2 BANDS OF COLOR IN ULTRA-VIOLET AND VISIBLE RADIATION ISOLATED BY FILTERS

Nearly every blue and violet filter had a transmission band in the red or infra-red. Such was the case with the theater blue (dark shade) and the red-purple ultra used to isolate the blue and near-ultra-violet bands, respectively. If such filters were used with a cell of the type UX-868, a large part of the photoelectric current would be due to the near-infra-red transmitted by these filters. In this work these filters were used with a PJ-15 (pure caesium) cell having a cut-off at 0.70μ. Hence the near infra-red was ineffective.

Isolation of only two bands in the infra-red by filters was found possible, one from 0.70μ to 1.15μ and the other from 1.10μ to 2.75μ. Preliminary observations showed that the

TABLE 1 BANDS OF RADIATION USED, WITH WIDTH OF BAND AND MEANS OF ISOLATING

[15] Koller, Jour. Optical Soc. of Am. and Rev. Sci. Instr., vol. 19, p. 135, 1929.

transmission through fog was much greater for the long wave-length band than for any others. Since this band was a wide one (1.65 microns), it seemed advisable to investigate in greater detail the transmission of the infra-red than would be possible by using filters. An infra-red spectrometer was tried and found suitable.

Method of Making Observations

As previously pointed out, the photoelectric current was proportional to the light flux incident on the cell. With a thermo-element the thermoelectric current was likewise proportional to the radiation flux incident on the element. Consequently, the percentage of transmission through fog of a certain band of color necessitated only the finding of the ratio between galvanometer deflections (for that band) with fog and with no fog.

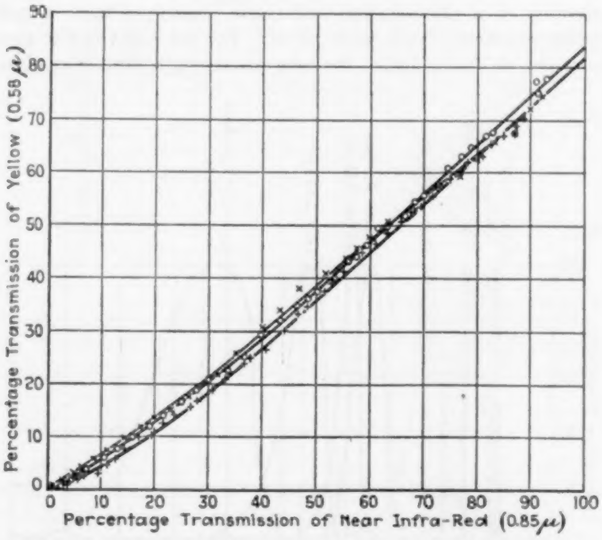

Fig. 3 Transmission of Yellow Light Through Fog

Three set-ups were required for each type of fog. In the first, observations were made on the ultra-violet band (0.3235μ), the near-ultra-violet (0.360μ), the blue (0.4275μ), and the near-infra-red (0.85μ). Part of the beam of light emerging from the fog chamber was concentrated by a quartz lens on the Burt cell. With filter No. 1 this isolated and responded to the ultra-violet band (0.3235μ). Another portion of the beam was directed on cell PJ-15 by means of a right-angled prism. With filter No. 2 before this cell, the near-ultra-violet band (0.360μ) was detected. With filter No. 3 the blue band (0.4275μ) was detected. A sliding filter frame made possible the quick changing of filters. By the use of a double-throw switch, either the Burt cell or PJ-15 could be connected to the galvanometer. A third part of the beam was directed by a second right-angled prism on cell UX-868 No. 3, with filter No. 7 before it. This cell was connected to a second galvanometer. Reference band 0.85μ was thus measured.

At the beginning of each series of readings the galvanometer deflection was taken for each band with the fog chamber clear. This deflection was called 100 per cent transmission. The fog was then produced. At first the fog was so dense that the galvanometer deflections were too small to be read. (This meant a transmission of less than 0.1 per cent.) As the fog slowly cleared, the deflections became readable, and the series was started. At a signal from one observer, the deflection due to the 0.85μ band was read simultaneously with the deflection due to the blue band (0.4275μ), then with the deflection due to the near-ultra-violet (0.360μ), and next with the ultra-violet (0.3235μ). This procedure was repeated again and again until the transmission through the fog reached about 95 per cent. Each series of readings consisted of from 75 to 250 individual observations. For each type of fog and each set-up at least three sets of readings were taken, and in some cases as many as five.

The second set-up was similar to the first. Filters Nos. 5 and 6 were used with cell UX-868 No. 1 to isolate the yellow (0.580μ) and red (0.665μ) bands, respectively. Filter No. 4 before cell PJ-15 gave the green band (0.540μ). The method of taking the readings was identical with the first set-up.

In the third set-up the greater portion of the beam was focused by a quartz lens upon the slit of the infra-red spectrometer. A small part of the beam was directed on the cell for detecting the reference band (0.85μ). As with the first set-up, the deflection due to the 0.85μ band was read simultaneously with that of each of the bands isolated by the infra-red spectrometer.

Interpretation of Measurements

Graphical Representation of Data. From each set of readings the transmissions were computed for each band of color and plotted against the corresponding transmissions of the near-infra-red band (0.85μ). Fig. 3 illustrates this procedure. Measurements with three fogs are represented, each curve being plotted from data obtained with a single fog. This figure indicates also the success attained in reproducing fogs of a given type.

Average transmissions were computed for each color from a set of curves such as Fig. 3 and plotted against those of the near-infra-red (0.85μ). These average curves for small-particle and large-particle fog are shown in Figs. 4 and 5, respectively. Since the transmission of the near-infra-red band is taken as a measure of fog transparency, the abscissas of these curves represent fog transparencies, dense fogs being at the left and light fogs at the right. All points on a vertical line (for example, at 5 per cent) represent a fog of given transparency. The points where the various curves cut this line show the relative transmissions of the different colors. Hence each set of curves is a graphical representation of (1) the transmissions of the various colors as a function of fog transparency and (2) the relative transmissions of the various colors for a fog of any given transparency.

The variation of transmission with wave length is shown to better advantage in Figs. 6 and 7. The curves of these figures were derived from the curves of Figs. 4 and 5, respectively. Here, each curve corresponds to a fog of given transparency. This is indicated at the right end of each curve, where the distance required to reduce the intensity of the near-infra-red (0.85μ) band to 0.1 per cent is given.

Discussion of Curves. The most noticeable feature of the curves of Figs. 6 and 7 is the greater transmission of infra-red radiation compared with that of other portions of the spectrum. This is in agreement with previous predictions, but is now shown for the first time in quantitative form. Consider, for example, in Fig. 7 the third curve from the bottom. This represents transmissions through a dense fog in which the intensity of the near-infra-red (0.85μ) was reduced to 0.1 per cent in 101 ft. The wave length for which the transmission is a minimum is 0.58μ, corresponding to yellow light. The transmission of this color through 20 ft. of fog is 15 per cent, while the transmission of infra-red of wave length 2.6μ is 87 per cent. The infra-red has 5.8 times the transmission of the yellow. Through 100 ft. of the same kind of fog, the contrast is more striking, the ratio of the transmission of the infra-red to yellow being 6500 to 1.

In small-particle fog the color of smallest penetrating ability is blue-green (0.475μ). Taking the third curve of Fig. 6, it is seen that the transmission through 20 ft. of fog is only 13.5 per cent, compared with 89 per cent for infra-red of wave length 2.6μ. The penetration of the latter is 6.6 times that of the blue-green. Through 100 ft. of fog of the same kind the ratio of transmission of infra-red (2.6μ) to blue-green (0.475μ) is 11,000 to 1.

The second feature of these curves attracting attention is the increase in transmission from the minimum in the visible to 0.30μ in the ultra-violet. This is contrary to the views generally held and is very surprising. However, a well-known fact tends to verify this—viz., that it is possible for a person to acquire a sunburn in a fog so dense that the sun is not visible. Since sunburn is caused only by radiations between 0.25 and 0.33 micron, ultra-violet must penetrate fog. Referring again to curve 3 of Fig. 7, it will be noticed that the transmission at 0.30μ is about the same as at 0.85μ, and about twice that of the yellow band (0.58μ) through 20 ft. of fog. Through 100 ft. of fog the ultra-violet (0.30μ) has a transmission 14 times that of the yellow (0.58μ). This fact suggests the possible value of ultra-violet in photography through fog and in signaling through fog.

The curves for small-particle fog, Fig. 6, do not show such a marked difference between the transmissions of the ultra-violet and the visible. Hence, in smoky fogs and hazes the ultra-violet would probably prove of little value.

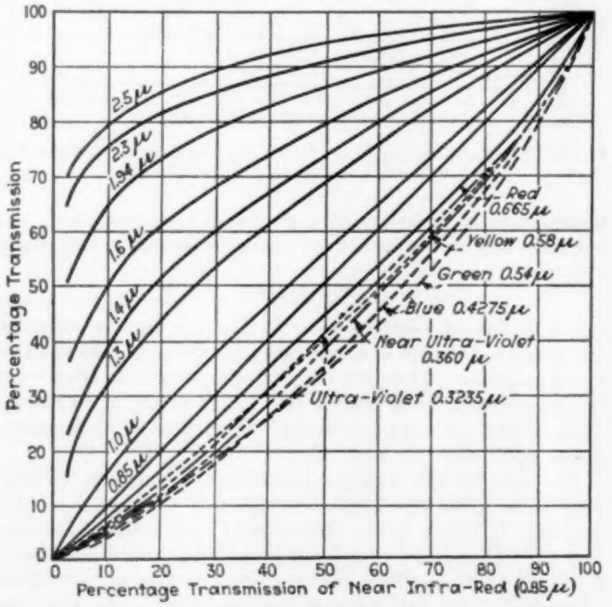

FIG. 4 TRANSMISSION OF RADIATION THROUGH SMALL-PARTICLE FOG

A general comparison of the curves of Figs. 6 and 7 shows that the transmissions of infra-red radiation through small-particle fog are somewhat greater than through large-particle fog. The difference is not great at any point, being largest for the most dense fogs. The ratio of transmissions is the largest for 1.4 microns.

In general, the transmission of the visible region is considerably less than in the infra-red or ultra-violet, the minimum occurring at some point in the visible. There is a difference in the position of this minimum in the two types of fogs. For the small-particle fog it occurs at a wave length of 0.475μ, corresponding to a blue-green color. For the large-particle fog it is at 0.58μ, or yellow color. This indicates a critical relation between the size of the particles and the wave length for which maximum absorption occurs. Further investigation in different types of fogs should be carried on to establish this relationship.

Law of Absorption of Radiation by Fog. If there could be established a law of absorption of radiation by fog which would enable us to compute the percentage transmission for a given band of radiation and a given distance, this would be of considerable value in the design of beacons for fog penetration. It is generally assumed that the attenuation of radiation by an absorbing medium is expressed by

$$I = I_o e^{-kx} \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

in which k is the coefficient of absorption, and the other symbols have the same meaning as in Equation [1]. The data presented by the curves of Figs. 6 and 7 show that in a fog the absorption coefficient k must depend upon the wave length, particle size, and concentration of fog particles. A satisfactory equation must take account of all these factors. In the King equation, which Granath and Hulbert found to agree with their data,

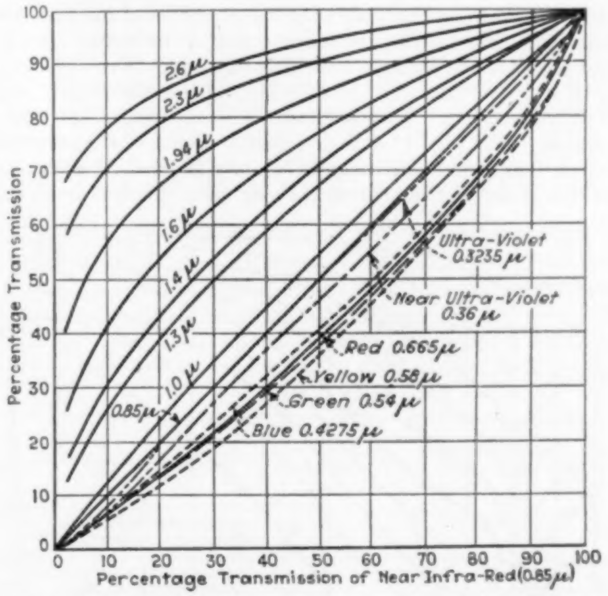

FIG. 5 TRANSMISSION OF RADIATION THROUGH LARGE-PARTICLE FOG

$$k = a + b\lambda^{-4} \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

This means that the attenuation is due to two factors: (1) an absorption, independent of wave length, expressed by the term a and (2) a scattering of radiation, expressed by the second term $b\lambda^{-4}$. This equation was derived by King to account for the absorption of the radiation of the sun by the earth's atmosphere. The parameters a and b have different values for clear and for dust-filled air. Furthermore, dust particles scatter radiation of wave lengths longer than 0.61μ, but not shorter. This critical wave length is probably a function of particle size.

Equation [5] has been tested, using data taken from the curves of Fig. 7. Coefficients of absorption k were computed from the transmissions and plotted against wave length. (Data for wave lengths shorter than 0.6μ were not used, as it is apparent the law of absorption must be different in the region $\lambda < 0.6\mu$ from what it is for $\lambda > 0.6\mu$.) Curves 1 and 3 of Fig. 8 were plotted from the coefficients of absorption computed from the curves 3 and 9, respectively, of Fig. 7. Then, values of the constants a and b were computed using the values of k corresponding to wave lengths 0.6μ and 2.6μ, respectively. Curve 2 is the theoretical curve corresponding to curve 1, and curve 4 corresponding to curve 3. The difference between the experimental and theoretical curves is large. Consequently it must be concluded that Equation [5] does not give the law of absorption in fog. In other words, the Rayleigh law of scattering does not apply for the attenuation of radiation in fog. The law was derived on the assumption that the scattering particles were small compared with the wave length of radiation. As has been already pointed out, fog particles have a diameter from 2 to 30 times that of the radiation used in this work. Hence the lack of applicability of the law is not surprising.

This conclusion is not in agreement with that reached by Granath and Hulburt. There may be three reasons for the difference. In the first place, Granath and Hulburt made their observations in very thin fogs (visibility 0.6 km.). This fact would indicate, not only that the concentration of fog particles was much less than in the fog chamber of the author's work, but also that the particles were of smaller size. Secondly, they used only two bands in the infra-red, with peaks at 1.4μ and 3.0μ, respectively. Both of these bands were broad and overlapped. (See Fig. 1 of their paper.) Hence the absorption which they found and assigned to wave lengths corresponding to the peaks of their curves may be quite different from the absorption of narrow bands located at the same wave lengths. The reliability of their measurements in the visible region is not questioned. However, the range covered (0.4μ to 0.6μ) is much too small to form a basis for any judgment. In the third place, a source of error which they point out is the absorption of water vapor. There are five absorption bands within the region in which their bands of radiation were located. The amount of water vapor in the air on clear days (used for determining 100 per cent transmission) was unquestionably much less than on foggy days. Hence, their absorption coefficients include the effect of water vapor as well as fog particles. In the author's work this source of error was eliminated. Measurements through the fog chamber were taken with the air saturated at 20 deg. cent. at all times. The transmission through the air clear of fog (which was taken as 100 per cent transmission with respect to fog) included the absorption of water vapor. Consequently, the absorption coefficients are for fog only.

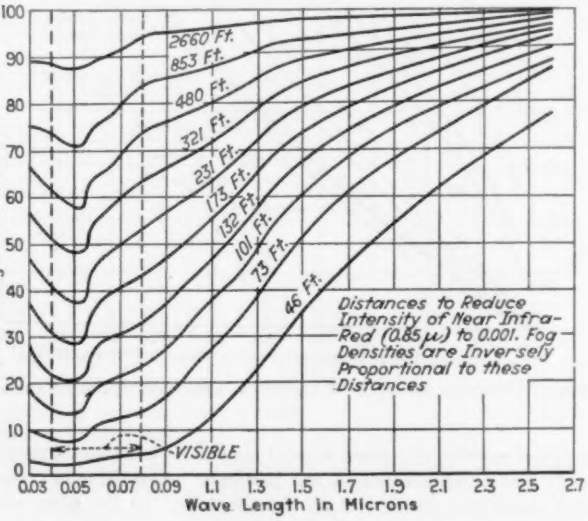

FIG. 6 TRANSMISSION OF RADIATION THROUGH SMALL-PARTICLE FOG AS A FUNCTION OF WAVE LENGTH (COLOR)

The most recent contribution to the theory of absorption of radiation by fog is that of Houghton and Straton.[16] Their equation for transmission is:

$$I = I_o e^{-2\pi a^2 NKx} \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

in which a is the radius of the fog particle, N the concentration (number of particles per unit volume), and K is a function of a and λ which oscillates about the value 1 for $a/\lambda < 6$ and becomes asymptotic to 1 for $a/\lambda > 6$. This equation has also been tested by the author's data. The lack of agreement is fully as great as with the King equation. Hence, it must be concluded that at present there is no satisfactory equation by which transmission of radiation through fog can be computed, and one must rely on empirical data such as presented in this paper.

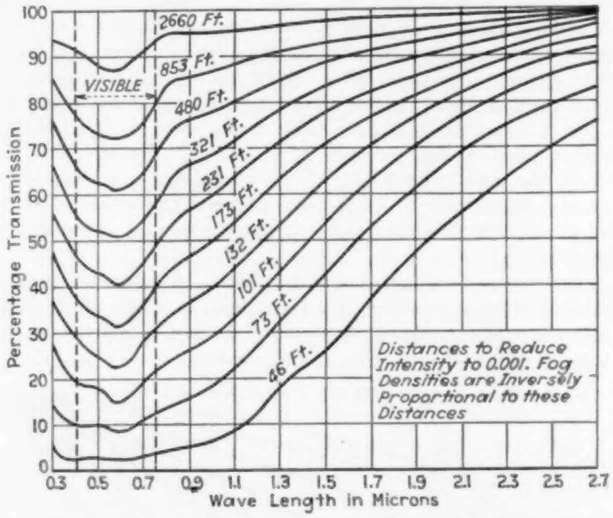

FIG. 7 TRANSMISSION OF RADIATION THROUGH LARGE-PARTICLE FOG AS A FUNCTION OF WAVE LENGTH (COLOR)

APPLICATIONS

Use of Colored Light in Fog. In the introduction attention was called to the need of investigating the value of colored lights in fog avigation. Does any band of color, especially effective in fog penetration, exist within the visible range of radiation? This question can now be answered. Unfortunately, the measurements made show no such color.

The basis for this negative answer is well shown in Table 2. This table gives the respective distances through dense fog necessary to reduce the transmissions of various bands of radiation to $^1/_{10}$ per cent. For large-particle fog, the values are 83 ft., 78 ft., 73 ft., and 79 ft. for blue, green, yellow, and red lights, respectively. No one color is predominantly better than the others. With small-particle fog, the distances are 69 ft., 71 ft., 81 ft., and 88 ft. for blue, green, yellow, and red lights, respectively. With this type of fog the red is somewhat more effective than the other colors, penetrating a distance 1.27 greater than the blue. This advantage is not large enough to be of any great value. In the lighter fogs, the differences in transmissions for the various colors are less than in dense fogs. Hence it may be concluded that there is no band of color of visible light which is especially effective in fog penetration.

This conclusion is in agreement with that of observers whose data were obtained in natural fogs. Granath and Hulburt found the distance required to reduce the transmission of red light (0.65μ) and of blue light (0.45μ) to $^1/_{10}$ per cent to be 1.4 km. and 1.2 km., respectively. The ratio of these distances is $1.4/1.2 = 1.165$. Their observations were made through an exceedingly light fog (probably small-particle fog), visibility 0.6 km. Using data from the uppermost curve of Fig. 6 of this paper (representing a thin, small-particle fog), the corresponding distances are 1350 ft. and 1050 ft. for red and blue lights, respectively. The ratio is 1350/1050 = 1.287. The difference between this ratio and that of Granath and Hulburt is not large and can be accounted for by the difference in fog densities.

---

[16] Houghton and Straton, loc. cit.

Breckenridge and Nolan,[17] of the Bureau of Standards, made a study of the "Relative Visibility of Luminous Flashes From Neon Lamps and From Incandescent Lamps With and Without Red Filters." Their observations were on relative visibilities rather than intensities. However, their conclusions are the same. They found that, under any weather condition, the neon lamp and the red-filtered incandescent lamp had no greater range of visibility than white light.

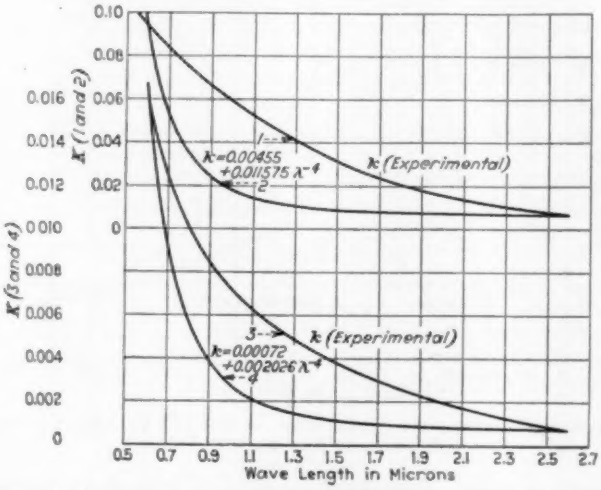

FIG. 8 COEFFICIENT OF ABSORPTION AS FUNCTION OF WAVE LENGTH

Other factors than the percentage of intensity transmitted determine the visibility of light, such as these:

1 The relative sensibility of the eye for various colors
2 The effect of contrast.

In Fig. 9 is shown the relative sensibility of the eye for monochromatic radiation (pure spectral colors). This figure shows that the normal eye is most sensitive to yellow-green light (0.555μ) and that the sensibility falls off rapidly toward each end of the spectrum. The eye is approximately 10 times more sensitive to the yellow light (0.58μ) used in this investigation than to the red (0.665μ) and 25 times more sensitive than to the blue (0.4275μ). This means that in order to have red, yellow, and blue light sources which would appear of equal brightness to the eye, the intensity of the red would have to be 10 times that of the yellow and the blue 25 times that of the yellow. Since the data in Table 2 show little variation in the energy transmission of blue, yellow, and red light through fog, one must conclude that the eye sensibility is a more important factor than the relative transmissions of visible colors.

The matter of contrast may be just as important. The value of neon lights for advertising signs is well recognized. This value is probably due to the contrast of the neon color with the white lights of the streets. Breckenridge and Nolan found it somewhat easier to pick up the flashes from red and neon lights than from the white light beacon, especially when other white lights were in the field of view. The factor of contrast as applied to aviation lighting is one that should be given careful study. Contrast is more important for low intensities of light when the visibility is near the threshold.

It must be concluded from present information that white light beacons are just as effective as colored beacons. If future studies based on eye sensibility and contrast show that certain colors have decided advantages, it will be necessary to develop a light source emitting those colors so that the efficiency and intrinsic brilliancy are comparable with those of the tungsten incandescent light.

Use of Ultra-Violet Radiation in Fog Photography. As previously pointed out, the transmission of the ultra-violet between 0.30 and 0.40 micron is greater than that of the visible, and about the same as that of the near-infra-red between 0.70 and 0.80 micron. This is true for large-particle fog, but not for small-particle fog. The near-infra-red region has been used very effectively in long-distance photography. By using "extreme red sensitive" film (sensitized with kryptocanine) and a Wratten 89A filter, Captain Stevens secured good negatives showing objects 270 miles distant. The band of radiation used with the combination extends from 0.68μ to 0.79μ. Since the transmission of the ultra-violet band (0.30μ to 0.40μ) through fog was about the same as that of this near-infra-red, the idea of using ultra-violet in photography through fog was suggested.

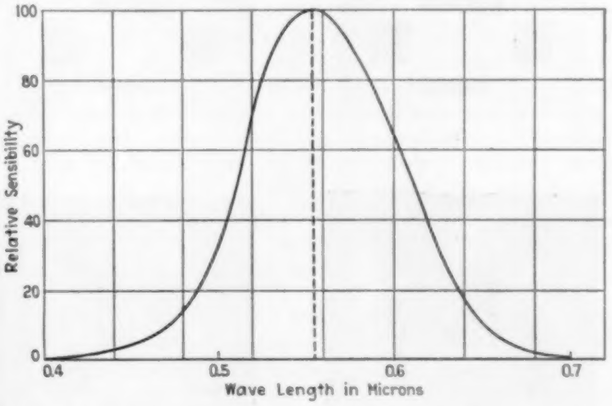

FIG. 9 RELATIVE SENSIBILITY OF THE EYE FOR MONOCHROMATIC RADIATION (PURE SPECTRAL COLORS)

In a limited way this was tested. As natural fog was not available, a laboratory fog was used. A target 22 in. by 28 in., made by pasting squares of black paper on white cardboard, was

TABLE 2 RESPECTIVE DISTANCES THROUGH DENSE FOG NECESSARY TO REDUCE THE TRANSMISSIONS OF VARIOUS BANDS OF RADIATION TO 0.1 PER CENT

Color	Center of gravity band	Coefficient of absorption: Large-particle fog	Coefficient of absorption: Small-particle fog	Distance in feet to reduce transmission to 0.1% (threshold visibility): Large-particle fog	Distance in feet to reduce transmission to 0.1% (threshold visibility): Small-particle fog

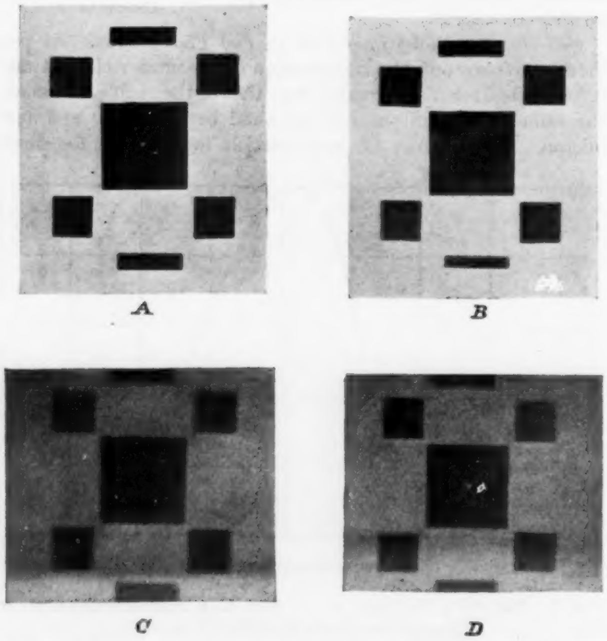
[17] Breckenridge and Nolan, Research Paper no. 78, Bureau of Standards Journal of Research, vol. 3, July, 1929.

illuminated by a quartz mercury arc and a sun lamp. Photographs of this target were taken through the fog with a band of ultra-violet light (0.25μ to 0.40μ) and a band of visible light (0.42μ to 0.50μ). Fig. 10 shows results from four negatives. Print *A* is a picture of the target with visible light, no fog; *B* was taken with ultra-violet light, no fog; *C*, visible with fog; *D*, ultra-violet with fog. The black areas in *B* are not quite as intense as in *A*. This evidently is due to some reflection of ultra-violet from the black paper. *D* is distinctly sharper than *C* and shows less general fogging of the negative. This photographic test appears to be a satisfactory confirmation of the results obtained with the fog chamber. In penetration of large-particle fogs, ultra-violet surpasses visible light.

It is not suggested that ultra-violet will give the same results in photography through fog that the near-infra-red gives through a hazy atmosphere. Conditions in the two cases are not the same. In the latter the particles are very small, so that the light is scattered according to the Rayleigh inverse fourth-power law. When no filter is used, this scattered light fogs the negative and obscures the desired image. The deep-red filter absorbs this scattered light and transmits the long wave lengths emanating directly from the object photographed. In large-particle fog absorption is due to other factors. Hence an ultra-violet filter is not as effective in fog as a deep-red filter in haze. However, the ultra-violet filter does isolate a band penetrating fog better than visible light, so that sharper negatives are obtained with it.



A B C D

Utilization of Infra-Red Radiation. As indicated previously, the most important result of this investigation is the discovery of the relatively large transmission of infra-red radiation compared with that of other colors. This suggests the use of infra-red for localizing a fog-obscured airport. The comparative quantities of infra-red and visible radiations penetrating fog are shown in Fig. 11. The upper curve shows the energy radiated from an ideal black body at 3000 deg. kelvin as a function of wave length. This represents approximately the energy distribution from a 1-kw. tungsten lamp (as used in an airway beacon). If an ordinate is drawn at $\lambda = 0.75\mu$, the area under the curve between 0.40μ and 0.75μ represents the energy radiated in the visible region, and the area under the curve between 0.75μ and 2.6μ represents the infra-red radiation. (If the lamp is mounted in a beacon projector, the actual proportions radiated will be somewhat different due to reflection coefficients of the mirror and absorption of the lens.) The ratio of infra-red radiated to visible is about 7 to 1. The lower curve is obtained by multiplying the ordinates of the upper curve by the respective transmission coefficients obtained from curve 3 of Fig. 7. The lower curve represents the relative amounts of energy penetrating a fairly dense fog. From this curve, the ratio of infra-red to visible is found to be 20 to 1. That is, from a standard airway beacon, 20 times as much infra-red as visible penetrates fog. Since the eye is not sensitive to infra-red, this is not utilized. However, if an infra-red receiver having the same relative sensitivity as the human eye can be evolved, the possibility of picking up the radiation from a beacon in a fog is at least 20 times greater than at present. This can be increased by the use of a beacon specially designed for infra-red radiation, such a beacon to be used in foggy weather.

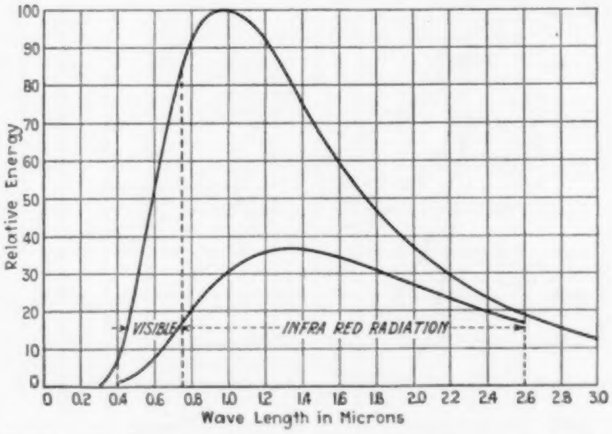

FIG. 11 COMPARATIVE QUANTITIES OF INFRA-RED AND VISIBLE RADIATIONS PENETRATING FOG

The author has designed and built such a receiver and has given it a limited test. The infra-red radiation can be detected by this instrument when the fog is so dense that it completely obscures the visible light from the projector.

An infra-red beacon has certain unmistakable advantages for localizing purposes, such as these:

1 The same methods of projection can be used as with light beacons and floodlights; thus there will be no difficulty in projecting intersecting beams or sheets of infra-red
2 Such infra-red beams will not be affected by local electrical disturbances, and there will be no interference with radio waves broadcast from nearby stations
3 The power source for infra-red beacons consists of standard electrical equipment, transformers, or motor-generator sets, which require a minimum of maintenance.

CONCLUSION

A laboratory method for the production of fog has been developed in which processes of formation of natural fogs were closely simulated. With this equipment fogs of two types have been made with a range of densities corresponding to natural fogs in which the visibility varies from 20 ft. to 2000 ft. Transmission of radiation through these fogs has been measured, covering a wave-length range of 0.30 to 0.40 micron in the ultra-violet, 0.40 to 0.75 micron in the visible, and 0.75 to 2.6 microns in the infra-red parts of the spectrum. From this investigation definite conclusions can be drawn regarding the value of the various regions of radiation in developing aids for fog avigation.

Conclusions.

1 Visible light is less effective than ultra-violet and infra-red radiation in fog penetration

2 The transmission of various colors of visible light through large-particle fogs is about the same for all colors. In small-particle fogs, the transmission of red light is about 25 per cent higher than other colors. This advantage is not large enough to be of any great value. In general there is no color of visible light especially effective in fog penetration. Hence colored beacons are of no greater value in marking airways than are white light beacons, as judged from the relative transmissions

3 In dense, large-particle fogs ultra-violet has a transmission greater than that of visible light. This has been verified by securing better photographs through fog with ultra-violet radiations than with visible light. The use of ultra-violet for photography through fog should be further investigated

4 The penetration of infra-red radiation through fog is many times that of visible light, the ratio depending upon the distance and the nature of the fog. Consequently, infra-red gives promise of great value in developing aids for fog landing, especially in localizing a fog-obscured airport.

Discussion

F. C. Breckenridge.[18] Dr. Anderson has covered a greater spread of wave length, a greater variety of fogs, and made more numerous observations than any other investigator in this field. The data he has accumulated will prove especially valuable in testing theoretical discussions of the problem.

It is to be regretted that Dr. Anderson has not given more definite data on the size of his fog droplets and the number of droplets per unit volume in his fogs. He mentions qualitative observations on the number and size of the fog particles and gives 6 microns and 8 microns as the approximate diameters of the droplets in his small- and large-particle fogs, respectively. In testing theoretical formulas it is important to know how much confidence may be placed in these estimates.

From the standpoint of fog flying, the significance of Dr. Anderson's work hinges entirely upon the degree to which his laboratory fogs reproduced natural fogs. More specifically, it depends upon the size of the fog particles, since a change in the number of drops per unit volume may be offset by an inverse change in the length of the light path. The particle size estimated agrees well with values determined by the meteorologists. If these estimates correctly represent the prevailing particle size, then the results should apply to natural fogs, and there is a conflict between these fog-chamber results and the results obtained with natural fogs by Granath and Hulburt. If, however, it is possible to assume that the average particle size in these laboratory fogs was smaller than those in Granath and Hulburt's natural fogs, then we can harmonize the results of the two researches, but in that case we are compelled to conclude that infra-red radiation less than 3.0 microns in wave length does not penetrate natural fog sufficiently for practical use. Evidently further data for infra-red transmission are needed.

In applying Dr. Anderson's remarks in regard to the sensibility of the eye, it is important to remember that he is measuring his radiation in energy units. If the radiation is measured in light units, as is usually the case in illuminating engineering problems, then the sensibility of the eye to radiation of different wave lengths enters into the rating of the light source and does not require further consideration.

E. O. Hulburt.[19] Dr. Anderson, as a result of his measurements of the transmission of light through artificial fog in a pipe 20 ft. in length, has concluded "that the penetration of infra-red radiation through fog is many times that of visible light, the ratio depending upon the distance and nature of the fog." This conclusion, if correct, would be of immense practical consequence. It is not, however, in agreement with our experiments (referred to in Dr. Anderson's paper). We experimented with the passage of light through about $^1/_4$ mile of natural fog along the Potomac River near Washington; the experiments were continued for nearly a year during various conditions of fogginess. We found, disappointingly enough, no appreciable increase in the transparency of the fog as the wave length of the light was increased from the visible red to about 3μ in the infra-red.

It seems probable that the discrepancy between our experiments and Anderson's is to be attributed to the fact that we used natural fog and he used artificial fog. Further experiments would be necessary to find out about it. The writer should like to emphasize very strongly that one cannot with safety extrapolate measurements on artificial fogs in a 20-ft. pipe to derive conclusions about the passage of light through 1000 ft. or more of natural fog. Furthermore, the facts that the sun is sometimes red at sunset, that distant lights are sometimes reddened, and that photography with light of the longer wave lengths often gives pictures free from the veiling effects of haze indicate that in haze the longer wave lengths are often transmitted more favorably than the shorter ones. But, again, one cannot with safety take these facts to mean that the same thing is true of fog, for this involves the doubtful assumption that the optical characteristics of haze are the same as those of fog.

Wesley L. Smith.[20] Dr. Anderson's paper very ably confirms the observations of those of us who have flown through all of the varying weather conditions. As early as 1925 the writer had decided that lights were of little use under severe weather conditions.

No mention is made of the type of detector that it may be necessary to use with ultra-violet or infra-red radiation. The writer would like very much to hear from Dr. Anderson on these possibilities.

Author's Closure

Mr. Breckenridge and Dr. Hulburt both have raised the question as to whether measurements of the transmission of radiation through a laboratory-made fog can be applied to a natural fog. Such a procedure is legitimate if the size of the particles in the natural fog is the same as in the laboratory-made fog. This is apparent from the following consideration. The transmission of radiation through any attenuating medium can be expressed by

$$T = \frac{I}{I_0} e^{-kx} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad [4]$$

The coefficient of absorption k is a function of the radius of the particles a, the wave length of radiation λ, and the number of particles per unit volume N. So far, no satisfactory formula for this function has been obtained. However, all formulas suggested involve N to the positive first power. This is the simplest and most reasonable assumption. Hence, kx in Equation [4] can be replaced by

---

[18] Photometric Section, Bureau of Standards, Washington, D. C.

[19] Superintendent, Heat and Light Division, Naval Research Laboratory, Washington, D. C.

[20] Chief Engineer, National Air Transport, Inc., Washington, D. C.

$$kx = k'Nx \qquad [6]$$

where

$$k = f(a,\lambda) \qquad [7]$$

Hence we may write Equation [4] in the form

$$T = e^{-k'Nx} \qquad [4a]$$

From this it is apparent that the transmission for a given wave length will be the same through two fogs of *different* lengths and concentration of particles, provided the particles are of the same size and the product Nx is the same for the two fogs.

An example will clarify this point. It is possible to compute the number of fog particles per cubic centimeter formed in the large-particle fog (8 microns in diameter), using the mass of excess water vapor per cubic centimeter resulting from adiabatic cooling and the mass of an individual fog particle. This comes out to be 40,000 particles per cc. Using $x = 20$ ft. (length of the fog chamber),

$$Nx = 800{,}000$$

For a distance of 1000 ft. through a fog of the same particle size and having the same transmission, $N = 800$. This is a reasonable value for a dense natural fog, judging from the meager data available. Observations by Wells and Thuras (see bulletin No. 5, 1916, U. S. Coast Guard) give a value for N in a heavy sea fog of 1200 particles per cc.

The author agrees with Mr. Breckenridge that definite information of the size and number of droplets per unit volume would add materially to the value of this investigation. Unfortunately such information is extremely difficult to obtain. The values for the diameters of the fog droplets (6 microns for the small-particle fog and 8 microns for the large-particle fog) were secured in the following manner. Through one of the small windows at the middle section of the fog chamber a small metal rod was inserted. This was insulated from the walls and charged to a high voltage. A few fog particles were attracted to this rod and lodged on it. With a micrometer microscope the diameters of such particles were measured. The number of particles observed was infinitesimal compared with the total number. Hence, this method gives only an approximation of particle size.

Possible explanations of the discrepancy between this work and Dr. Hulburt's have already been given. As he suggests, the only satisfactory way to settle the questionable points is by further measurements.

The author is in complete agreement with Dr. Hulburt in his contention that we cannot apply the laws of transmission through *haze* to *fog*. Fog particles are of a different order of magnitude, being 100 to 1000 times larger than haze particles. The phenomena of absorption and scattering are entirely different in these two kinds of disperse media.

Replying to Mr. Smith's query as to the type of detector for infra-red radiation, we have laboratory instruments (such as a thermopile and sensitive galvanometer) capable of measuring very minute quantities of infra-red radiation. But the design and construction of a robust, reliable instrument suitable for airplane installation is a difficult matter. The most feasible method seems to be the use of a photoelectric cell of infra-red sensitivity coupled to a vacuum-tube amplifier. The limitation to the development of an instrument of this type is the small infra-red sensitivity of photoelectric cells which are available at present. Much progress has been made in this direction within the past year, and hence the ultimate development of a satisfactory infra-red detector seems not far off.

A Radio System for Flying and Landing Aircraft in Fog[1]

By H. DIAMOND[2] and F. W. DUNMORE,[3] WASHINGTON, D. C.

While scheduled air transportation has been immeasurably aided by the provision of radio-direction facilities on the fixed airways, interruption of scheduled flying is still the rule whenever the landing field lies in an area completely inclosed by fog. The results secured by the development of instrument flying and of radio navigational aids to point-to-point flying are then nullified through the lack of means for safe landing under adverse conditions of visibility. The rigorous maintenance of scheduled flying by day or night requires the removal of this last great hazard to the reliability of air travel and transportation. This paper describes a radio system of blind landing aids, developed by the Aeronautics Research Division of the Department of Commerce at the National Bureau of Standards, which gives good promise for the solution of this difficult problem. The results already obtained with this system indicate that it will soon be ready for use under the severe conditions encountered in commercial air transportation. The system has been developed to be adaptable for use in conjunction with the radio navigational aids already being provided for point-to-point flying on the civil airways of the United States, and for this reason requires a minimum of additional equipment both on the ground and on the airplane.

A GENERAL idea of the operation and use of this system for flying and landing aircraft in fog may be had by reference to Fig. 1, which is a three-dimensional view showing the location of the ground transmitting equipment. Referring to Fig. 1, the 2-kw. directive radio beacon with large loop antennas, shown at *A*, is the main radio range beacon provided for point-to-point flying on the fixed airways. This beacon is normally located just off the airport (so that the loop antennas may not constitute an obstruction to flying), and serves to direct an incoming airplane to the vicinity of the airport. This beacon may be either of the aural or the visual type. A medium frequency receiving set is used on board the airplane for receiving the beacon course indications. One of the most important functions of the beacon is its use as a homing device. It not only directs an airplane along the airway route, but, in addition, indicates when the airplane is passing directly over the beacon tower, by means of a zero-signal zone effect. Utilizing this zero-signal zone, it is possible to locate the beacon to within 100 to 1000 ft., depending upon the altitude of the airplane.

Before reaching the beacon tower, the pilot has learned the wind direction at the landing field, either through the Government weather broadcast or by two-way communication with the ground. Upon receiving the zero-signal indication when directly over the tower of the main beacon, the pilot retunes his medium-frequency receiving set to the frequency of a low-power (200-watt) runway localizing beacon shown at *B*. This localizing beacon operates on the same principle as the visual-type radio range beacon for the airways. Using small loop antennas so that it may be located at one edge of the field without constituting an obstruction, it directs a course along the runway most suitable for landing (under the particular wind conditions then existing).[4] Knowing the geography of the field, i.e., the location of the main beacon relative to the desired runway, the pilot then uses his navigational instrument (such as the magnetic compass, etc.) for orienting himself along that runway. The course indications received from the runway localizing beacon greatly facilitate this maneuver.

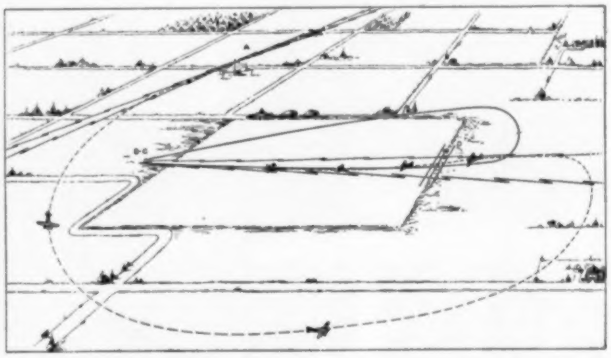

Fig. 1 Three-Dimensional View Showing Radio System for Flying and Landing Aircraft in Fog

Lateral position is thus given to the pilot by means of the runway localizing beacon *B* for the purpose of keeping the airplane directed to and over the desired landing-field runway. It is now necessary to provide means for vertical guidance which will direct him along a safe landing path, and also for longitudinal guidance to inform him that he has arrived at the boundary of the landing field. Vertical guidance is given by an inclined ultra-high-frequency radio-beam transmitter located at *C*. This landing beam operates on a frequency of the order of 100,000

[4] At a landing field having two runways, perpendicular to each other, two localizing beacons are necessary so that the pilot may land approximately into the wind. But one runway beacon will, however, be operated at a given time.

kilocycles and is directed at a small angle above the horizontal. It is used in such a way as to provide a very convenient gliding path for the landing airplane. Longitudinal position is given by a boundary marker beacon located at the edge of the landing field (*D*, Fig. 1) and operating on the same radio frequency as the runway localizing beacon. When crossing the boundary of the landing field, the pilot receives a distinctive aural signal from the marker beacon.

Description and Operation of Ground and Airplane Equipment

Before going into a detailed analysis of the use of the system by a pilot in order to effect a landing in dense fog, it is necessary to describe briefly the ground and airplane equipment employed and the manner of operation of this equipment.

Runway Localizing Beacon. This is a 200-watt, double-modulation, visual-type beacon, using modulation frequencies of 65 and 86.7 cycles, respectively. The beacon apparatus is housed in a two-story shed located on the border of the landing field and in line with the runway along which the course is to be directed. (See Fig. 2.) The transmitting set and machinery are shown on the first floor and the transmitting loop antennas on the second floor. These antennas consist of seven turns of wire wound on wooden frames 6 ft. high by 8 ft. in length.

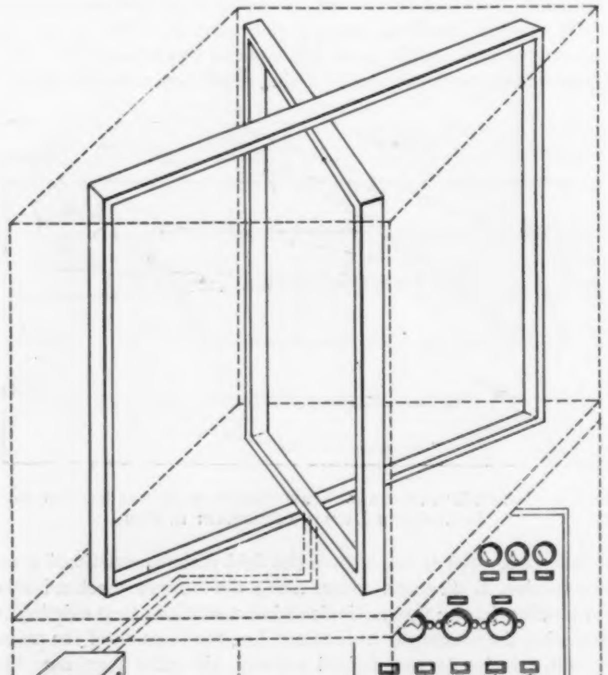

Fig. 2 Runway-Localizing Beacon Set-Up, Showing Location of Loop Antennas, Transmitting Set, and Power Equipment

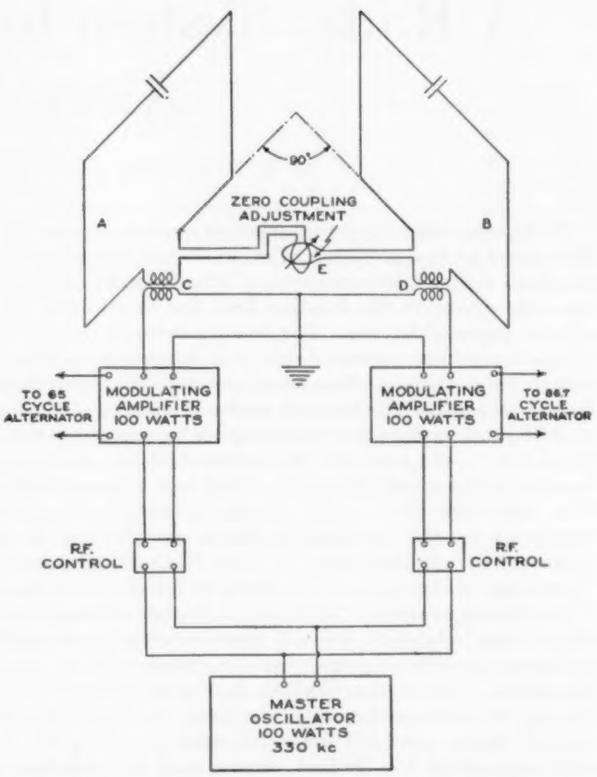

Fig. 3 Transmitting Circuit Arrangement for Runway-Localizing Beacon

The transmitting circuit arrangement is shown in Fig. 3. To simplify apparatus, the transmitter is coupled to the antenna system through two coupling transformers, *C* and *D*, rather than by means of the goniometer employed in the usual radio range beacon set-up. The variometer *E* serves to neutralize any residual inductive coupling between loop antennas *A* and *B*.

Referring to Fig. 3, the two loop antennas, crossed at 90 deg., carry currents of the same radio frequency but modulated to two different low frequencies, 65 and 86.7 cycles, respectively. These antennas are so oriented that the vertical plane containing the axis of the desired runway bisects the angle between the two antennas. An airplane flying in this plane therefore receives equal signals from the two antennas. On either side of this plane the signal received from one antenna is greater than from the other. On the airplane, a visual course instrument indicates to the pilot the relative received signals from the two antennas and, consequently, the relative position of the airplane with respect to the runway.

Boundary Marker Beacon. The boundary marker beacon operates on the same radio frequency as the runway localizing beacon. It employs a horizontal open antenna consisting of a horizontal wire, approximately 6 ft. above the ground and 200 ft. long, extending across the runway at the edge of the landing field. The pilot receives an aural signal beginning at about 100 ft. on one side of the boundary line and ending the same distance on the other side. Since a vertical-pole antenna is employed on the airplane, this signal is interrupted for a brief interval directly over the landing-field boundary line because of the zero-signal zone effect.

The transmitting set employs two low-power transmitting tubes excited alternately from a 500-cycle plate-supply transformer and feeding a common oscillatory circuit, coupled to the horizontal antenna. The tube filaments are also supplied from the 500-cycle source through a suitable winding on the 500-cycle transformer. Due to the alternate excitation of the transmitting tubes, the resultant modulation has a frequency of 1000 cycles, which is the aural signal heard by the pilot.

Receiving System for Localizing and Marker Beacon Signals. The receiving system on the airplane is as shown in Fig. 4. The medium-frequency receiving set normally employed for the reception of the weather broadcast and radio-beacon services is also used for receiving the signals from the runway localizing and marker beacons. The localizing beacon, being of the visual type, permits the use of automatic volume control in its reception. This is quite essential, since the pilot, in making a landing, is concerned with so many things that the burden of close manual adjustment of receiving-set sensitivity must be eliminated.

FIG. 4 CIRCUIT ARRANGEMENT FOR RECEIVING RUNWAY-LOCALIZING BEACON AND MARKER BEACON SIGNALS

The volume-control device operates through rectification of the alternating voltage across the course-indicator terminals and application of the rectified voltage, after filtering, as a negative biasing voltage on the grids of the radio-frequency amplifying tubes of the receiving set. An increase in the input voltage to the receiving set normally tending to increase the voltage across the indicator terminals is therefore accompanied by an increase in the negative bias on the radio-frequency amplifying tubes, and consequently by a reduction in the receiving-set sensitivity such as to maintain substantially constant voltage across the course indicator.

The provision of this automatic volume-control device makes possible the addition of an important instrument on the airplane instrument board, giving the pilot information as to his approximate distance from the localizing beacon transmitter. Since increasing input voltage to the receiving set is accompanied by increasing negative biasing voltage on the grids of the radio-frequency amplifying tubes, the deflection of a direct-current milliammeter connected in the plate circuit of these tubes will decrease as the airplane approaches the beacon transmitter. This meter may therefore be calibrated directly in approximate distance from the transmitter. Its operation is of considerable assistance to the pilot in maintaining a constant radius when circling the localizing beacon (during the process of finding the desired runway), and also in giving the pilot sense of approach to the landing field, once he has oriented himself along the runway.

A filter circuit is connected in the receiving set output to direct the aural signals (1000 cycles) received from the boundary marker beacon to the pilot's head telephones, and the double-modulation signal received from the runway localizing beacon to the visual course indicator. The automatic volume control is connected across the course-indicator terminals, and consequently is actuated only by the localizing beacon signals. The 1000-cycle marker beacon signal is therefore permitted to vary through a minimum even though the receiving-set output voltage (in so far as the course indicator is concerned) is maintained substantially constant.

The course indicator may be either the reed indicator type, in which case the runway course indications received by the pilot are as shown in Fig. 5 or the zero-center pointer instrument type shown in Fig. 6. In the latter arrangement, the pointer remains at the zero mark when the airplane is on the course and swings to right or left as the airplane deviates to the right or left of the course. This instrument is operated by a reed converter, i.e., a reed indicator in which, besides the set of driving coils for operating each reed from the received beacon signals, a set of pick-up coils is provided for each reed. The motions of the two reeds induce alternating voltages in the two pick-up coils, which are proportional to the reed-vibration amplitudes, and consequently to the intensities of the two low frequencies constituting the received beacon signal. The induced alternating voltages are rectified by means of copper-oxide rectifiers and the rectified voltages applied in opposition to the terminals of the zero-center instrument which the pilot sees. The pointer-type instrument is preferable for landing purposes, since it offers the advantage of combining the runway course indicator with the landing beam indicator into a single convenient landing instrument which will be described below.

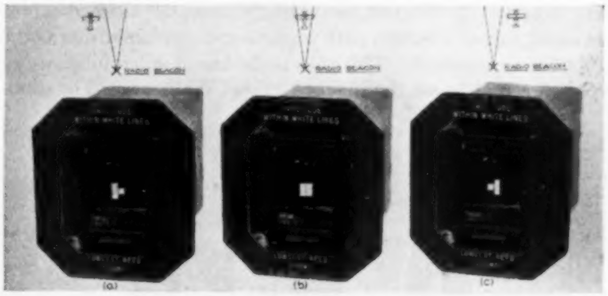

FIG. 5 COURSE INDICATIONS AS RECEIVED ON VIBRATING-REED COURSE INDICATOR

(*a*, unequal reed amplitudes, airplane off course to left; *b*, equal reed amplitudes, airplane on course; *c*, unequal reed amplitudes, airplane off course to right.)

The Landing Beam. The function of the landing beam is to furnish a pilot with the necessary vertical guidance to permit landing under conditions of no visibility. It consists essentially of a horizontally polarized beam directed at a small angle above the horizontal, this angle and the degree of directivity being so adjusted that a predetermined line of constant field intensity on the under side of the beam will mark out just the proper gliding path, clearing all obstructions and convenient for landing. In the set-up at College Park, Md., the beam is transmitted on a frequency of 93,700 kc. (3.2 m.) and is oriented in the same horizontal direction as the course of the runway localizing beacon. On the airplane, a horizontal dipole antenna feeding a detector-amplifier-rectifier unit is employed for receiving the landing beam

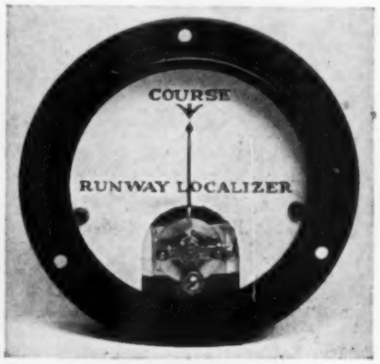

FIG. 6 POINTER-TYPE LOCALIZING-BEACON COURSE INDICATOR

signal. As will be evident below, the receiving equipment constitutes essentially a vacuum-tube voltmeter arrangement for exploring the field intensity in different portions of the landing beam.

(1) Method of Using the Landing Beam. Reference to Fig. 7 will show how suitable indication of absolute height above ground is secured by means of the landing beam. The vertical space pattern of the inclined ultra-high-frequency landing beam is clearly indicated in this figure. The airplane is readily directed approximately into the vertical plane containing the axis of the beam by means of the course indications from the runway localizing beacon. It does not, however, fly along the inclined axis of the beam, but on a curved path whose curvature diminishes as the ground is approached. This path is the line of equal intensity of received signal below the inclined axis of the beam. The diminution of intensity as the airplane drops below the inclined axis is compensated by the increase of intensity due to approaching the beam transmitter. Thus by flying the airplane along such a path as to keep the received signal intensity constant, as observed on a microammeter on the instrument board, the pilot comes down to ground on a curved line suitable for landing. If the airplane rises above this line of equal intensity of received signal, the microammeter deflection increases, while if it drops below this line the microammeter deflection decreases.

Several important advantages obtain for this method of furnishing altitude indication. The landing path may be so directed as to clear all obstructions. The pilot following the landing path is automatically kept above obstructions and no longer needs a thorough knowledge of the terrain in order to effect a safe landing. Secondly, the landing path may be of different shape to suit different landing fields. This is of particular importance in getting into a small field. A third advantage lies in the fact that in the act of following the landing path, the pilot automatically "levels off," thereby facilitating a normal landing, albeit somewhat fast. A fourth advantage is that the landing path may begin at any desired altitude within a rather wide range (500 to 5000 ft.).

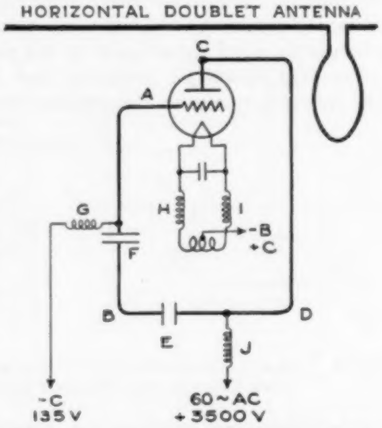

FIG. 9 CIRCUIT ARRANGEMENT OF 93,700-KC. LANDING-BEAM OSCILLATOR

(2) Directive Transmitting Antenna System. An ultra-high frequency was chosen for the landing-beam transmitting system in order to secure the attendant reduction in size and simplicity of equipment. Of a number of directive antenna systems studied, the arrangement developed by Unda and Okabe, and described by Yagi, for the production of horizontally polarized directed beams, was found most suitable. A photograph of the directive antenna array, as set up at College Park, is shown in Fig. 8. This is housed in a shed for protection against weather. The ultra-high-frequency source (93,700 kc.) is coupled to the horizontal doublet *A* (made of $^1/_4$-in. copper tubing), which serves as the radiating antenna and is accurately tuned to the frequency of the source. About 0.8 m. behind the radiating antenna is placed a reflecting antenna *B*, also a horizontal doublet, tuned to a frequency somewhat lower than the frequency of the source. At approximately every meter in front of the radiating antenna, horizontal doublet directing antennas *C* are placed. These are tuned to a frequency somewhat higher than that of the source. This array of antennas is supported on a horizontal wooden structure *D*, approximately 2.75 m. above the ground, and pivoted on the vertical support *E*. To obtain the vertical directive characteristic shown in Fig. 7, the wooden structure *D* is tilted approximately 8 deg. above the horizontal.

(3) The Ultra-High-Frequency Transmitting Circuit Arrangement. The necessary power output on the high frequency used is secured through the use of a 500-watt three-element tube (General Electric ZP-2) in the oscillatory circuit shown in Fig. 9. The small air condenser *E* is of a capacity about equal to the interelectrode grid-to-plate capacity of the tube. The plate inductance *CD* and the grid inductance *AB* are placed between this condenser and the tube, the leads making the shortest possible connections between these elements of the circuit constituting the inductances. Condenser *F* is of relatively large capacity and is necessary only as a safety measure in case of flashover of condenser *E*. *G*, *H*, *I*, and *J* are suitable choke coils to keep the oscillatory current out of the power-supply leads.

Fig. 10 shows the 500-watt tube and associated apparatus, including the horizontal doublet radiating antenna. The tube is operated with 3500 volts of 60-cycle frequency on the plate and a negative grid bias of about 135 volts. The tube circuit is tuned

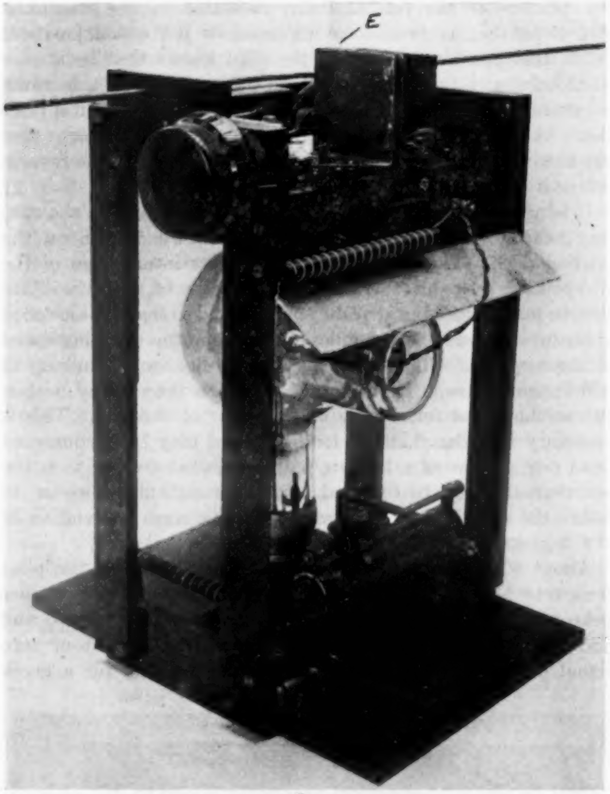

FIG. 10 ELECTRON-TUBE OSCILLATOR AND RADIATING ANTENNA FOR THE 93,700-KC. LANDING BEAM (AS SHOWN AT *A*, FIG. 8)

to the desired frequency within narrow limits by moving one of the plates of condenser *E* by means of an insulated adjustment screw. The frequency has proved sufficiently stable for use without external means for frequency control, due in part to the fact that but one broadly tuned circuit is used at the receiving end. The 60-cycle modulation facilitates audio-frequency amplification at the receiving end.

(4) The Receiving System. The receiving circuit arrangement (see Fig. 11) uses only two tubes without regeneration. This receiving circuit requires no adjustments on the part of the pilot. The tuning is fixed. Even the volume control is dispensed with, since the path followed during the use of the receiving set constitutes a line of constant field intensity of the directed beam.

A 224 heater-type screen-grid tube is employed for the detector, to afford the necessary high amplification without undue microphonic noises. To obtain good efficiency it is necessary to connect the detector tube directly in the center of the horizontal doublet antenna. The radio-frequency portion of the circuit (i.e., the detector) is confined to the section above the four radio-frequency chokes. The four leads running from the lower side of these chokes carry either direct current or the received audio modulation. The detecting portion of the receiving circuit is external to the airplane, being mounted in a streamline weatherproof box about 14 in. above the top wing. The doublet antenna is in the form of two copper rods housed in wooden streamlined supports projecting from the streamlined detector box. The streamlined detector box and antenna system are arranged to plug in electrically to the supporting upright on the wing, a five-terminal plug making the necessary connections. The supporting upright also makes a plug connection to a socket in the wing. The rest of the apparatus, which includes the audio amplifying tube and transformer, oxide rectifier, *A* and *B* batteries, and indicating instrument, are located within the airplane.

Fig. 12 at *A* shows an inside view of the streamlined detector box. The amplifier-rectifier unit is shown at *B*. The oxide rectifier shown eliminates one tube, and has been found perfectly stable in its operation at the low frequency employed.

The rectified output current from this receiving set is fed to a direct-current microammeter constituting the landing beam indicator. (See Fig. 13.) To facilitate its use, this instrument is mounted on its side so that the pointer moves vertically instead of horizontally. During landing, the deflection, to be kept constant (corresponding to the desired glide path), is chosen at half-scale reading, the instrument pointer being then in horizontal position. A rise of the pointer above this position indicates that the airplane is above the proper landing path, while the reverse is true if the pointer falls below its horizontal position. The indications of the position of the airplane relative to the landing path are thus made readily comprehensible.

(5) Combined Landing Instrument. The use of the landing system described herein has been greatly facilitated by the combination of the runway-course-indicating instrument shown in Fig. 6 with the beam-indicating instrument shown in Fig. 13 into a single instrument, as shown in Fig. 14. Two perpendicular reference lines are provided on the face of the combined instru-

(The detector is shown at *A*, the amplifier rectifier unit at *B*, and the horizontal doublet antenna at *C*.)

ment, the vertical reference line corresponding to the position of the runway and the horizontal reference line to the proper landing path. The pointers of the runway-course indicator and the landing-path indicator are arranged so that they cross each other, the former moving to the right or left of the vertical reference line and the latter above or below the horizontal reference line. The position of the point of intersection of the two pointers thus gives, through a single reading, the position of the airplane with respect to the runway and proper landing path.

(6) Complete Radio Equipment Required on the Airplane. The complete radio equipment required on the airplane by the radio system of blind flying and landing aids described in this paper is indicated by Fig. 15, which is self-explanatory.

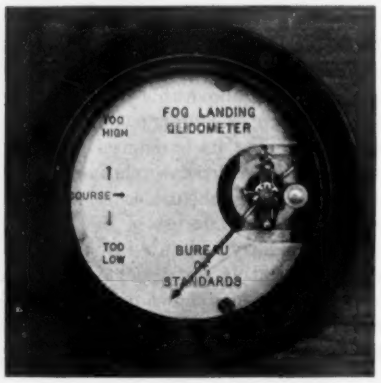

Fig. 13 Landing-Beam Indicator Used on Pilot's Instrument Board

(This is to show the position of the airplane relative to the proper landing path.)

Use of the Radio System of Blind Landing Aids

Method of Making a Landing. Let us now consider the operations required on the part of the pilot in making a blind landing. It is assumed that the information necessary for maintaining the airplane in stable flight is available through the use of suitable flight instruments. The medium-frequency receiving set is tuned to the frequency of the main radio range beacon (say, 280 kc.) and indications as to the correct course leading to the vicinity of the airport observed on the course indicator. Since automatic control of volume is provided, these course indications are available to the pilot without manipulation on his part.

Upon receiving the zero-signal indication when directly over the tower of the main beacon, the pilot retunes the medium-frequency receiving set to the frequency of the localizing beacon (say, 330 kc.) and throws a switch which places the landing-beam receiving set in operation. These are the only adjustments of radio equipment required of the pilot during the entire landing maneuvers. By watching the distance indicator the airplane may be made to circle the field on a fixed radius. An altitude specified by the control officer at the field by means of radiotelephony is maintained. This circular flight is continued until orders are received to land. The vertical needle in the combined instrument, Fig. 14, now furnishes information as to the landing-field runway direction, the provision of automatic volume control again relieving the pilot of the necessity for adjusting the receiving set sensitivity for variations in the distance between the airplane and the localizing beacon transmitter. The pilot next orients himself along the desired runway, using the runway beacon course indications, together with his compass indications and his knowledge of the geography of the field. The airplane may be kept at any altitude within, say, 500 to 5000 ft. From time to time the pilot glances at the rough-distance indicator and endeavors to get on the runway course at a point approximately 5 miles distant from the landing field. He now directs his airplane along the runway course and in the direction of the landing field, by navigating until the vertical needle of the combined instrument, Fig. 14, is over the central circle on the instrument face. When approximately half the distance to the field is covered, the pointer of the landing-beam indicator in the combined instrument begins to rise to midscale, or horizontal position. When this position is reached, the pilot knows that he is at a point on the gliding path. To follow the gliding path he must maneuver the airplane to keep this pointer in a horizontal position. A pointer position above the central circle indicates that the airplane is above the proper landing path, while the reverse is true if the pointer swings below this circle.

It is necessary now that the pilot keep accurately on the runway beacon course, at the same time following down on the landing path. This is done by holding the intersection of the two pointers over the central circle. (See Fig. 14.) To facilitate this, he may reduce the airplane engine speed so that the air-speed indicator registers about 5 miles above the normal landing speed of the airplane. This also helps during the actual landing, as will appear below. The accuracy to which the runway beacon course should be followed is of the order of ±3 deg. This is necessary in order that the landing beam may be encountered head on; otherwise, a landing path somewhat steeper than the one desired would be followed. It is not difficult, however, to follow the course to the necessary accuracy, since a deviation of ±1 deg. may be observed on the combined instrument.

About 100 ft. from the landing-field boundary line the pilot begins to hear a 1000-cycle signal from the boundary marker beacon. This signal increases rapidly, decreases to zero, and then passes through another maximum. The instant of zero signal defines the landing-field boundary line, and for a given field informs the pilot that he is at a definite distance above ground. He may now throttle down his engine to landing speed and maneuver his airplane to follow the landing path accurately to the point of landing.

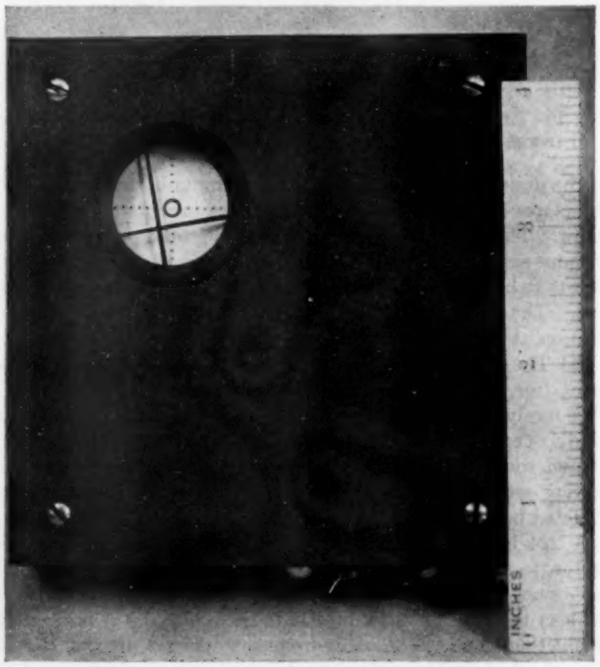

Fig. 14 Combined Instrument Giving Indication of the Position of the Airplane Relative to Both the Runway and the Landing-Beam Path

(The position of the intersection of the pointers shows the location of the airplane, the vertical dotted line represents the runway, and the horizontal dotted line the proper landing path. In the photograph the indication is that the airplane is to the left of the runway and below the proper landing path.)

Expansion of System to Take Care of Wind Direction. A number of possible arrangements of the system ot blind landing aids outlined above, whereby wind direction may be taken into account, are available. The problem is to determine the most economic arrangement; for example, it has been suggested that the localizing beacon and landing-beam transmitters may be buried in the center of the field and oriented into the wind at all times by remote control from the operations office, or even automatically. Aside from the technical problems involved, the provision of a sufficiently large waterproof room with sturdy roof construction level with the surface of the ground, so that an airplane might roll over it, seems economically unfeasible. In addition to the consideration of costs, the arrangement noted is open to the objection that the landing-beam transmitter would require special adjustment in each new position of orientation. The shape of the landing path should be convenient for landing and at the same time insure the clearance of all obstructions. Since the obstructions are quite different when coming into the average landing field from different directions, the need for the adjustment of the landing-beam transmitter is apparent.

Perhaps the most feasible arrangement is the one shown in Fig. 16. The transmitting equipment for both the localizing beacon and landing beam is so simple that the duplication shown appears warranted. It is estimated that the commercial cost of the complete installation would not exceed $15,000. An obvious advantage is that the equipment once set up remains in permanent adjustment.

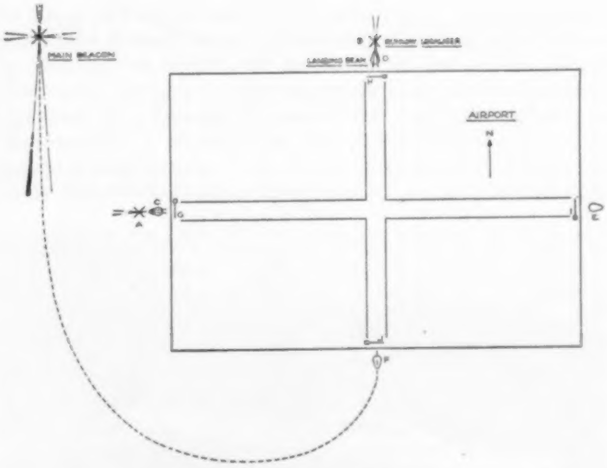

FIG. 16 SYSTEM OF BLIND LANDING AIDS NECESSARY TO TAKE CARE OF WIND DIRECTION ON A TWO-RUNWAY FIELD

Referring to Fig. 16, the beacon arrangement shown is for a two-runway field. Two runway localizing beacons, *A* and *B*, and four landing beam transmitters, *C*, *D*, *E*, and *F*, are required. Four boundary marker beacons, *G*, *H*, *I*, and *J*, are necessary. At any given time but one localizing beacon, one landing-beam transmitter, and one boundary-marker beacon are in operation, being so chosen as to require landing into the wind.

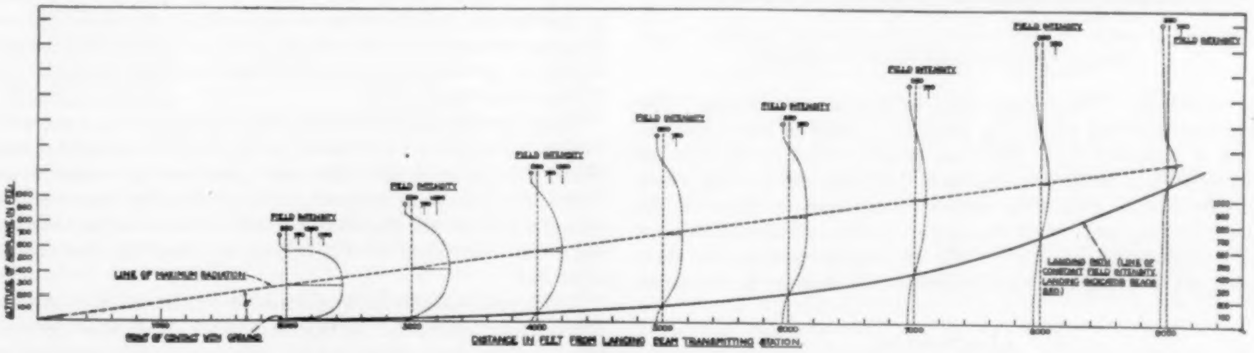

FIG. 17 LANDING GLIDE PATH

In Fig. 16 the wind is from the north, and the airplane is shown landing into the wind, using runway-localizer beacon *B*, landing-beam beacon *D*, and boundary-marker beacon *J*.

Practical Applications. The practicability of the radio system of blind-landing aids described has been partially demonstrated in numerous test flights on the Aeronautics Branch experimental airplanes. Fig. 17 shows the landing glide path as found by actual flight tests at College Park, Md. No difficulty has been experienced in following both the runway-localizing beacon and the landing-beam indications simultaneously. Arrangements are now being made for actual blind-landing tests, the results of which it is felt will completely demonstrate the feasibility of the system.

Even in its simplest arrangement (see Fig. 1), which does not take care of wind direction, this system should have numerous applications to scheduled flying. It should successfully prevent practically all interruptions to scheduled service due to dense fog, since fog is rarely accompanied by strong winds. Under special conditions of low visibility (for example, when the airport has a

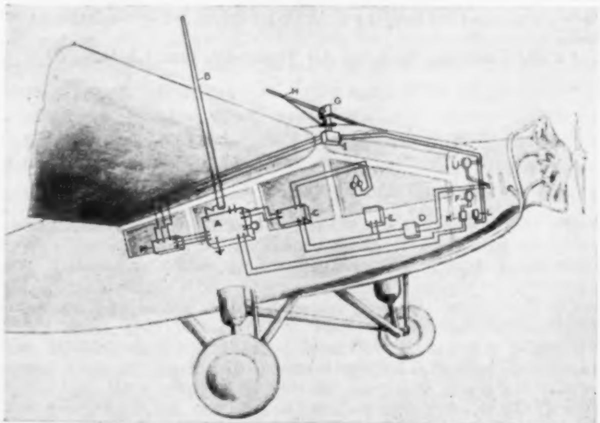

FIG. 15 COMPLETE AIRPLANE INSTALLATION SHOWING RADIO EQUIPMENT REQUIRED TO MAKE USE OF THE RADIO SYSTEM OF BLIND FLYING AND LANDING AIDS

(*A*, medium-frequency receiving set for voice and beacon signals; *B*, 6-ft. vertical-pole antenna; *C*, filter unit for separating voice and beacon signals; *D*, tuned-reed converter; *E*, automatic volume control for beacon signals; *F*, rough distance indicator; *G*, landing-beam receiving-set detector unit; *H*, horizontal doublet antenna for landing-beam receiving set; *I*, landing-beam receiving-set amplifier unit; *J*, combined landing instrument; *K*, pilot's control unit for medium-frequency receiving set; *L*, pilot's control and test unit for landing-beam receiving set; *M*, *A*, *B*, and *C*, batteries.)

ceiling of 100 ft. or more) the system may be used as an aid to landing regardless of wind conditions. A particularly interesting application consists of the use of this system for complete or partial blind landing on seadromes or on airplane carriers, where the landing deck can at all times be oriented into the wind. Such a proposed seadrome, with main beacon *A*, runway-localizer beacon *B*, fog-landing beam *C*, and boundary-marker beacon *D*, is shown in Fig. 18. A large number of conditions exist where a partial use of the system described appears practicable. The runway-localizing beacon, in particular, seems to have possibilities of extensive use. This was demonstrated in the tests at Mitchel Field, under the auspices of the Guggenheim Fund, where a special landing altimeter was employed in conjunction with the localizing beacon. With the expansion of the system to take care of wind direction, as shown in Fig. 16, it is felt that the last great obstacle to flying under any conditions of weather is overcome.

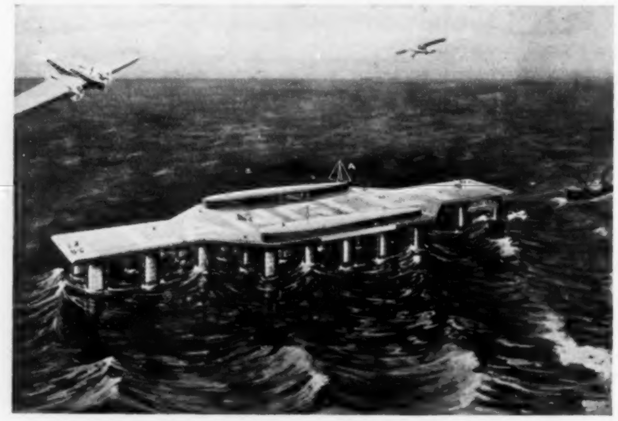

FIG. 18 METHOD OF APPLYING BLIND FLYING AND LANDING RADIO AIDS TO PROPOSED ARMSTRONG SEADROMES

Discussion

H. N. WILLETS.[5] The Bureau of Standards is to be complimented on the energetic steps it is taking to further the use of radio equipment now being flown by transport lines so that in addition to the two-way radio-telephone service the pilot may have the advantage of directional aids.

The present two-way radio-telephone system provides full control of the plane by the ground personnel, and the installed beacon transmitters of the aural type lay out a definite radio path that the pilot may follow. The recently developed anti-static headphones enable the pilot to use the full sensitivity of his equipment without being subjected to the discomfort of static shocks. There still seems to be a question as to whether the reed type of indication is preferable to the aural type, but in recent tests where visual transmission was uninterrupted when the voice transmission was broadcast this would indicate a desirable development.

The present installed two-way radio-telephone equipment on the transport lines will lend itself to visual indication when this system is perfected.

It may not be generally appreciated, but within the last year the air-transport companies have installed over a hundred of their own ground radio-telephone transmitters and the investment for this apparatus is over $1,800,000.

WESLEY L. SMITH.[6] This radio landing beam seems to supply the missing link that is necessary for the regular scheduled operation of airplanes through any weather conditions. With the aid of the present flight instruments and the radio range beacons along the airways, we have been able to fly our planes on schedule whenever we could be assured of some visibility beneath the clouds at the destination.

There are still some problems of coordination of this aid with the other aids that we now have, but having flown on this landing beam, the writer is sure that these problems are simple ones. This system can be developed to be more accurate than a pilot's eyesight and he will therefore be able to make better landings using the beam than he will be able to when the visibility is unlimited.

It is hoped that this landing beam can be installed soon at some commercial airport, such as that at Newark, N. J., where ground fogs are prevalent, so that as many pilots as possible can have an opportunity to try the beam. It is only by putting these things into regular use that we get them fully developed, and there is a very great need for landing aids under ground-fog conditions.

AER-54-3

General Maintenance and Suggestions for Lowering Overhead

By H. C. DOWNEY,[1] MITCHELL FIELD, N. Y.

When an airplane crashes, it is easy to set fire to it and write it off, but the author contends that half of the wrecked planes, except where they have been badly burned, may be salvaged and rebuilt. He gives many details of where and how this may be done. The value of constant inspection is emphasized, and the paper describes in detail many points sometimes overlooked. Special tools for difficult repair jobs are outlined.

PLANES crash occasionally, as all well know. The first impulse in the case of an airplane crash is to junk the wrecked machine. It is so easy to set fire to a wrecked plane, with gasoline on it, that no doubt many planes have been burned up, with no salvage, which could have been rebuilt at a small percentage of the cost of a new machine. It would probably be good news to the insurance companies if more of them were repaired. With the exception of a plane that has been consumed by fire, there are few wrecks that cannot be rebuilt. The question is of course whether they can be rebuilt economically. The author has several times rebuilt planes successfully that other people thought advisable to junk. At least half of the total number of wrecked airplanes can be rebuilt without undue cost and at a profit to the operator.

It is not intended to infer that people have not been conscientious in the matter of salvaging wrecks. On the contrary, they have been overconscientious. They seem to feel that, even though a member does look all right, there may be some hidden defect that will fail later on, whereas if they knew more about materials they would not be under this impression.

It can be said without qualification that inspection is the most important function in the operation of airplanes other than the actual piloting. During actual flying operations, all parts cannot be seen, but during overhaul everything must be scrutinized for cracks or wear. Control cables should be replaced. Electrical wiring also should be replaced. Care should be taken that control parts do not rub. Welds must be inspected for cracks. Bent members should be replaced or trued up. Bearings must be checked for clearance. Rigging must be accurate. Corroded parts must be replaced or otherwise repaired. Propellers must be balanced and checked for blade angle. Landing gears must be trued, and if of the oleo type, the oleo chambers must be inspected.

Those who have been concerned with the overhaul of aircraft have very often noted that the old wooden-frame airplanes were capable of taking shocks that would have caused failure in a metal structure. Wood is capable of sustaining great loads for a short time with no more damage usually than elongated bolt holes. In the same circumstances steel would probably have failed altogether. Now that we have oleo landing gears, the airplanes are not so likely to be subjected to great shock.

The reason that wood stands up so well is that, for the same strength and weight as steel, wood presents more bulk and consequently more surface to take up the load. This is also true of duralumin, but to a lesser extent.

In the service there is a large turnover in aircraft and a great amount of salvage, but the services are concerned with obsolescence as well as with depreciation. Indeed, obsolescence is a more serious problem than depreciation, since the military services must constantly encourage manufacturers to improve performance and to keep abreast of the developments in other parts of the world.

In commercial service, obsolescence of type would of course enter into the matter, but not nearly so much as in the fighting service. It is thought therefore that a much greater amount of repair and working would be done. There appears to be no reason, other than obsolescence, why aircraft should not be reworked and overhauled many times during the life of the craft, up to perhaps as much as ten years. There have been cases in the service where airplanes were in operation for as much as seven or eight years and in some isolated instances as much as ten years. During this time, naturally many parts were changed, and possibly different engines were installed.

When an engine is overhauled several times, the custom in the service is for the engine to retain its identity under a certain number until such time as the upper half of the crankcase is cracked or otherwise damaged and worn, when it is written off.

Rigging

One of the most interesting phases of overhaul work, and perhaps the least understood and appreciated, is the rigging department. In spite of the attempts of designers to eliminate the rigging feature and its attendant troubles, it still is with us, since even on a rigid-wing monoplane we must rig our controls if the airplane is to handle properly. We probably shall always have a certain amount of rigging to do on aircraft, since adjustments to controls are indispensable and inevitable.

Some rather peculiar things happen to ailerons. The author recalls that once in Panama we set up a DH at the depot, with new wings and ailerons out of stock, and proceeded to test-fly it. Test pilots reported that it had most abominable aileron control. The author flew it and found that they were right.

Rigging was checked from one end to the other, but no error

---

[1] Lieutenant Downey was born on Oct. 4, 1894, at Dobbs Ferry, N. Y. He was educated at Dobbs Ferry High School and New York University. Was graduated from Air Corps Engineering School, at McCook Field, Dayton, Ohio. Worked as mechanic, draftsman, and engineer for Gallaudet Engine Corp., 1915; Aeromarine Plane and Motor, 1915; Standard Aircraft Corp., 1916; Chas. F. Willard, 1916. Designed and flew flying boat, 1916–1917; entered Army Air Service, 1917; commissioned as Second Lieutenant, Air Service, 1918; worked for Curtiss Aeroplane and Motor Corp., 1919; participated in bombing of German naval vessels off Virginia Capes in 1921; made several long flights testing earth inductor compass while at McCook Field, 1924; Engineer Officer, France Field, Canal Zone, 1928–1929; Assistant Engineering Officer, Mitchell Field, 1931. Has flown 3000 or more hours on all types.

Presented before a meeting of the Metropolitan Section, New York, N. Y., Feb. 25, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

was found anywhere. The usual trouble in a case like this is due to warped trailing edges on ailerons, but these were found perfectly straight.

This airplane caused a great amount of trouble for awhile, until finally the difficulty was located. There were two kinds of DH wings in stock. One kind had little filler strips between the ribs at the rear spar where the aileron was attached, while the other did not. Likewise, the ailerons in one case had these strips, and in another type they did not. These strips were only $^{3}/_{16}$ in. thick, and there was hardly any noticeable difference in the wings and ailerons when assembled. Nevertheless when the wings without the strips were assembled with ailerons that had the strips, or vice versa, the resulting difference in the air flow was so great that one could not bank the plane without using both hands on the control.

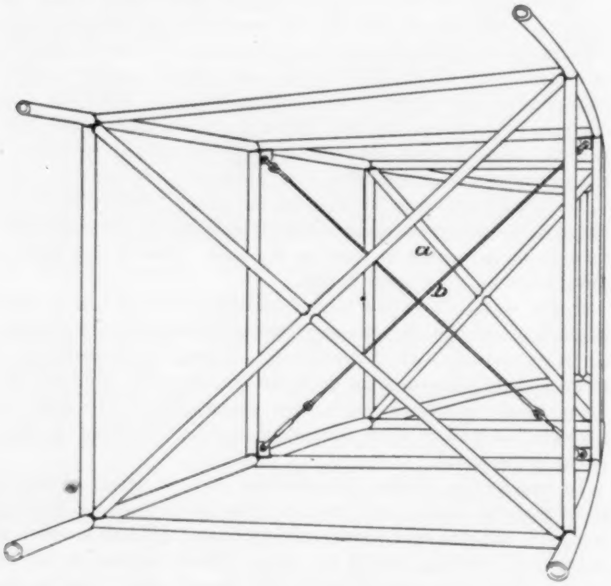

Fig. 1 Method of Reenforcing Bomber Fuselage Against Torsion
(*a*, X-brace of tubing; *b*, X-brace of aircraft cable.)

In another case a problem was encountered on a certain amphibian plane. In the early stages of this plane the wings were constructed with plain dural ribs and wooden spars. These dural ribs corroded rapidly to such an extent that the depot was forced to rebuilt the wings with wooden ribs. These were computed so that their design load factor was as high as before with the metal ribs.

We struck one snag, however. The metal cap strip on the original ribs was very thin where it passed over the spars. The wooden cap strip, in order to have the same strength, was $^{3}/_{16}$ in. thick. This of course changed the contour of the wing considerably. It was feared that the performance of this plane would be adversely affected by such a change.

Much thought was put on this matter. It was finally decided to go ahead with the job. The contour of the wing was changed so as to allow of this thickness at the spars. The rest of the contour was faired in accordingly. Upon completion of the change it was found that no difference whatever in the performance could be noted even with an increase of weight of about 60 lb. The reworked airplane was flown alongside of one with the original wings on it, and no loss of performance could be noted, although there may have been some slight loss.

Again, on a certain three-motored plane, it has been found that the balance, cruising speed, and general performance were greatly improved by moving the wing engines forward about 2 ft. Although there were more powerful engines installed, it is believed that some of the increase in performance was due to the elimination of interference.

The engines were originally under the wing. On another three-motored plane, it was found that the speed was stepped up considerably by the installation of Townend rings on the wing engines and the raising of the wing about 9 in. Here again the improvement was no doubt due to the elimination of interference.

All this indicates, as has been proved in the wind tunnel, that any obstruction or abrupt change in section on a wing or other part will change the flow of air and cause power-consuming drag. In other words, no wing section in the light of our present knowledge is any good that does not give perfectly smooth air flow over its surfaces.

All of our practical experience to date appears to indicate that we must have rigidly braced, smooth wing surfaces that will allow of no flutter or flexibility.

However, it seems from various tests with slots at different places in the surface that these at certain large angles of attack appreciably increase the lift and may prevent the burble or stall.

It seems, therefore, that if we are to attain really large speed ranges that will make flying an easily acquired art, instead of a profession for highly trained men, we must study the bird's wing.

The bird appears to have a flexible wing that is variable in area as well as contour and camber, also allowing a number of slots in various places between the feathers. With this arrangement they are able to fly at high speeds and land lightly at very low velocities. Whether we will ever be able to duplicate this mechanically is a question, since it is a very difficult problem to build such a device light and strong enough.

Methods of Repair

To illustrate some of our other problems, the author will digress for a moment. On a certain bombing airplane of which we were operating a number, or attempting to, we had a series of exasperating troubles. At first, pilots complained that motors cut out badly in bumpy weather and also in banks. It was found that the upper or high engine always caused the miss in turns. It was therefore decided to equip all motors on these planes with fuel pumps. The system in use was a gravity system.

After this was corrected, it was found that the whole tail assembly vibrated and shimmied so badly that the pilots did not want to fly them any longer.

Therefore, after studying the problem, it was decided to stiffen up the fuselage in a certain manner, as well as reenforce the tail surfaces.

It is inadvisable to make a metal fuselage too rigid, for then synchronous vibration may cause resonance, which is worse than shimmying of the tail surfaces, for it causes a pound in the members that will drive a pilot to distraction.

In order to get stiffness and at the same time prevent resonance, the system shown in Fig. 1 was adopted. At every other station of the fuselage a rigid X-brace of steel tubing was welded in. At intermediate stations an X-brace of steel cable was installed. The effect of this was that the steel braces stopped the twist, but the cables at the intermediate stations damped out the vibration, so that resonance was not developed. The explanation is that the cables have a greatly different period of vibration from the steel members, and since they do not take loads in compression anyway, they naturally destroy the beat or rhythm of vibration and tend to quiet the structure. It was then found that landing-gear fittings on the fuselage were weak, and these were reenforced.

It also was found that pins on dural mechanisms did not have sufficient bearing surface. These bearings were bushed up with steel bushings and were given more bearing surface.

Other things developed. The windshields were of such design that, instead of sheltering the pilot, at certain times he was almost blown out of the cockpit. A new windshield was designed and fitted to these planes. It also was found that the impeller of the earth inductor compass was blanketed so that it would not generate. It was necessary to move this farther back on the fuselage to a position where it would be operated by the slipstream of the engines. Such are a few of the problems faced by the maintenance engineer.

Recently a certain anti-knock fuel was introduced to the service. This is apparently a very good commercial product and is quite popular, but as soon as we attempted to use it our spark-plug life dropped from about 100 hours to 40 hours, and we began experiencing corroded and stuck valves, broken valve springs, ruptured coils and condensers on magnetos, and various other difficulties. It appears that in the presence of the high temperatures developed in aircraft engines the anti-knock fluid shows a corrosive action which may be troublesome.

It may not be apparent how this could affect magnetos, but it is thought that the fluid corroded the spark-plug electrodes so much that there was a consequent overloading of the coils and condensers, eventually causing rupture of the insulation.

ENGINES

We find that we have to test our spark plugs very thoroughly, especially since we started using this special fuel. It is necessary to clean them quite often and to adjust clearances very closely. We then put them in a pressure cartridge and fire them with the aid of a booster device under from 80 to 125 lb. pressure, in order to insure that they will fire under compression in the engine; since increased pressure raises the resistance at the spark gap and may cause the plug to short-circuit through the mica insulation. This device is shown in Fig. 2.

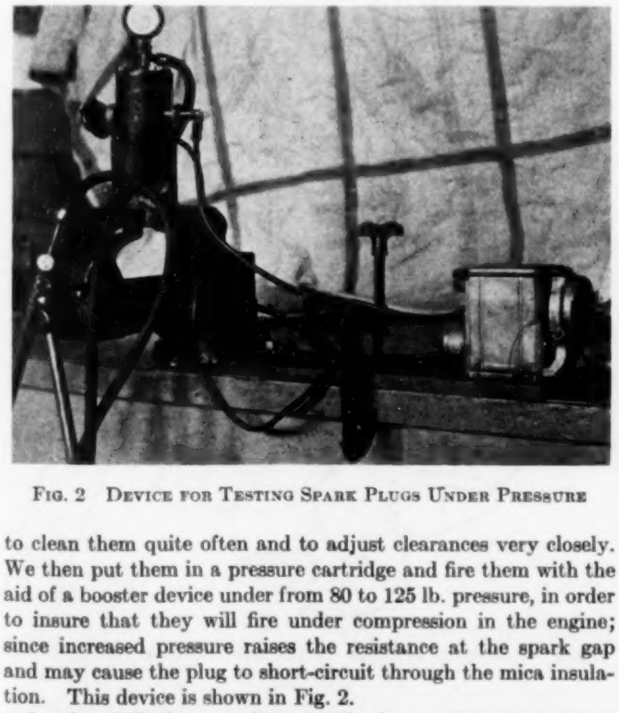

FIG. 2 DEVICE FOR TESTING SPARK PLUGS UNDER PRESSURE

Another difficulty experienced with the use of medicated fuel is sticking valves. A deposit of carbonized material collects on the valves stems after a time. There appears to be no good way to remove this unless the engine is taken down. In this connection it is thought that it might be advantageous to have a sliding sleeve incorporated over each valve stem, in order to insure operation if this condition occurs.

Sticking valves very seldom cause forced landings, but they are troublesome, since they cause an engine to miss, and unless corrected, this may necessitate the replacement of the valve because of burning. Altogether, it is an unmitigated nuisance.

It is suggested that to prevent this the aircraft-engine designers use a sliding sleeve with a flange at the bottom, as shown in Fig. 3, so that the valve will have over twice the bearing surface, and further, in case any particles of carbon collect on the valve stem, they will not prevent the operation of the valve, because it will ride on the outer guide. Further, with this arrangement, the protruding flange will prevent particles from collecting on the guide walls. Also it is thought that the clearance could be reduced, which would in itself prevent particles from collecting.

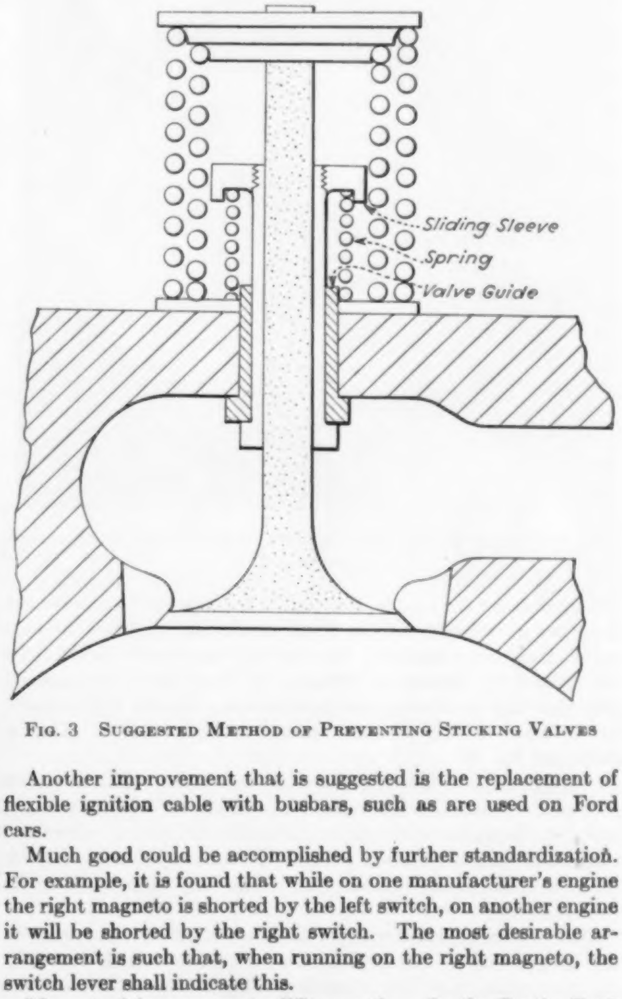

FIG. 3 SUGGESTED METHOD OF PREVENTING STICKING VALVES

Another improvement that is suggested is the replacement of flexible ignition cable with busbars, such as are used on Ford cars.

Much good could be accomplished by further standardization. For example, it is found that while on one manufacturer's engine the right magneto is shorted by the left switch, on another engine it will be shorted by the right switch. The most desirable arrangement is such that, when running on the right magneto, the switch lever shall indicate this.

Magneto drives appear to differ greatly. On the Curtiss D-12 we have the Oldham coupling, which is quite satisfactory, but on other engines we have various other devices, which means that magnetos are not interchangeable, even on engines of the same number of cylinders and same power.

Propeller hubs likewise are found to be of different types, and in cases where the hub is splined, the number of splines will differ. All this is disturbing, since one is required to stock a great number of parts, which means increased cost of operation.

Metal propellers must be checked carefully, especially when any vibration is present during flight. Very often these propellers will show good static balance and will track properly, but have faulty dynamic balance. This can be detected by balancing each blade separately over a knife edge. The center of gravity of each blade should of course be located at the same point in order to get proper weight distribution. If there is a difference in the location of the center of gravity between the two blades, there will be large unbalanced forces set up when the blades are in motion, hence the term "dynamic balance." Faulty dynamic balance may also be caused by a small difference in blade section between the two blades at like stations. This difference may not be apparent except under close measurement; nevertheless it will cause very rough operation.

Very often one wishes to check the timing of an engine in a plane. It may be found that the manufacturer has supplied a timing disk for the engine, but that it is necessary to remove the propeller in order to use the disk, and having removed the propeller, there is no means of turning the engine over slowly. To get around this annoying difficulty, we have made up a special disk that can be fitted to the front of the propeller hub in order to facilitate timing without removing the propeller. This is shown in Fig. 4.

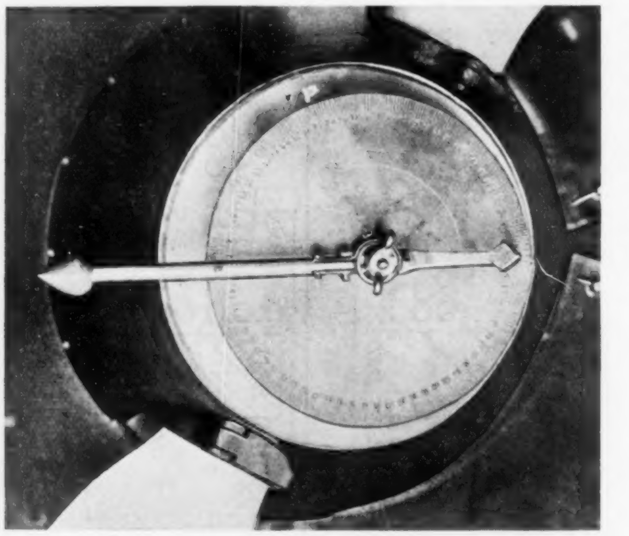

FIG. 4 TIMING DISK THAT CAN BE USED WITHOUT REMOVING PROPELLER

A suggestion for indexing the crankcase of the engine is shown in Fig. 5. With this arrangement it would be necessary to remove the propeller or to use a timing disk for setting valves and magnetos. An adjustable pointer is clamped to the propeller blade so that settings can be indicated directly from markings on the crankcase.

One of the greatest worries that maintenance men have is the danger of fire. An airplane is an AAA fire hazard, especially on the ground, for then there is no slipstream to blow the fire out if it does start. Further, when on the ground, men are usually working on them, removing or replacing batteries, wiring, or other parts. It is very easy to get an arc from a battery by grounding a pair of pliers between the battery post and the metal framework. There is always gasoline present in liquid, or worse yet, in vapor form. For this reason batteries should be located away from the engine compartment and the fuel lines.

Regulations against smoking should be rigidly enforced, for it is believed that 90 per cent of all aircraft fires are caused by someone dropping a lighted match in a pool of gasoline.

Fire extinguishers should be carried on all airplanes. Also portable extinguishers should be easily accessible in all hangars. All Army aircraft carry the pressure type, which sprays Foamite or some other similar product over the carburetors and the engine compartment.

In airplanes everything possible is done to prevent fluttering or vibration, and cable is especially susceptible to this, with resultant fraying and rupture of insulation. These cables must, however, be heavily insulated and also shielded, so that no radiation will be set up that will interfere with radio operation.

Many things can be done to increase accessibility and to reduce maintenance on aircraft engines. For example, if both spark plugs on vee engines could be placed on the outside of the cylinder, it would be a great help to the mechanics, for these spark plugs must be removed quite often for inspection and cleaning. Also it would be helpful if carburetors were placed on the outside of the blocks. At present on certain engines it is difficult to get at the carburetors, even for the simplest adjustments, and very often it is easier to remove the whole assembly than it is to attempt to adjust or to synchronize them while on the engine.

Magnetos are usually tucked away under other protruding parts where it is difficult to get at them. All this probably makes for lightness, but it also is conducive of delay in repair.

If accessories could be arranged as shown in Fig. 6, it would be a great aid to mechanics and might reduce the overhead for the operator. The magnetos are shown moved out somewhat so as to give the mechanic more room to get at them in adjusting them.

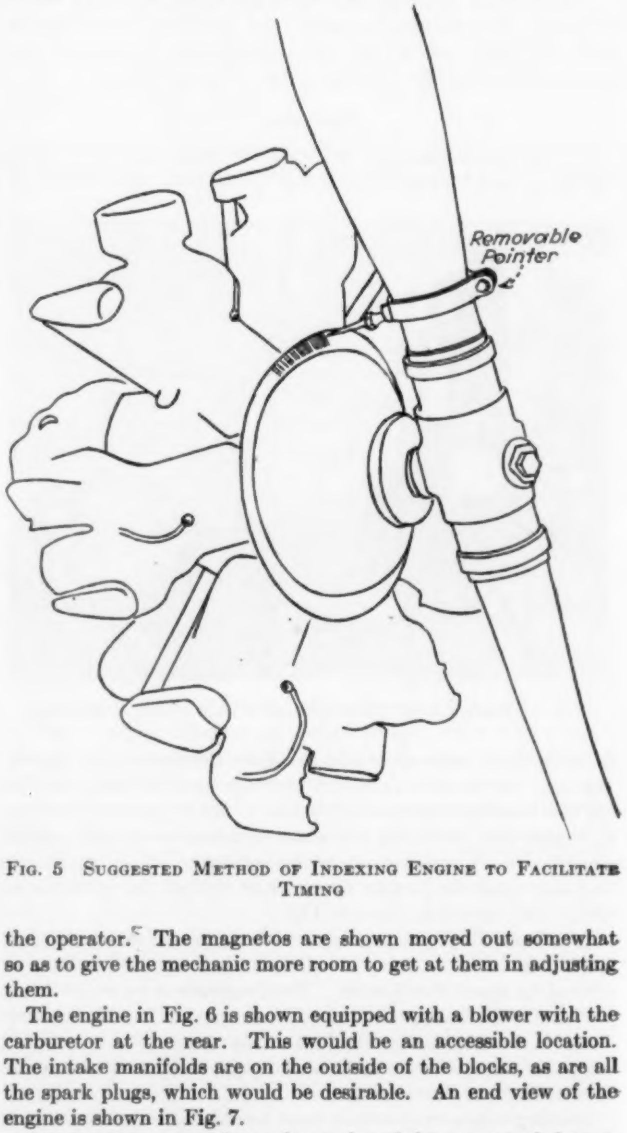

FIG. 5 SUGGESTED METHOD OF INDEXING ENGINE TO FACILITATE TIMING

The engine in Fig. 6 is shown equipped with a blower with the carburetor at the rear. This would be an accessible location. The intake manifolds are on the outside of the blocks, as are all the spark plugs, which would be desirable. An end view of the engine is shown in Fig. 7.

At present on a certain service engine of the water-cooled type, it takes fully four man-hours to change a set of spark plugs, or one-half day's work for one man. This is because the carburetors are on the inside of the vee, and they and their manifolding make it difficult to get at the plugs. From a military point of view this is not desirable; neither is it in a commercial sense, since it is most desirable for a military plane to be quickly serviced and also very desirable to have a commercial plane with low maintenance.

The suggested engine also has its starter and water, oil, and gasoline pumps at the rear, as well as the generator, at the rear between the blocks. These accessories would all be run off the same gear train at the vertical drive shaft from the crankshaft master gear. The magnetos are driven from the front crankshaft gear, and the propeller shaft through reduction gearing. The magnetos should run much cooler in this position.

There are of course other considerations which govern the location of these accessories. It is desirable to have plugs on the opposite sides of the cylinders to get good flame propagation, but it is thought that with proper combustion-chamber design they could all be located on the outside. There is the objection of exhaust gases entering the cockpits with exhausts led up from the inside of the vee, but it should be easy enough to conduct these gases off to each side over the tops of the cylinders.

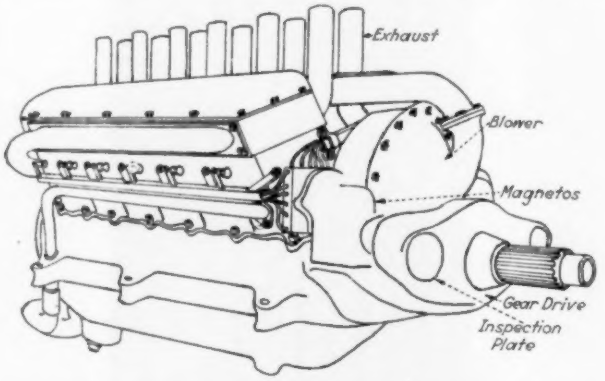

Fig. 6 Suggestions for Improving Accessibility
(Starter, carburetor, and generator are at the rear end; spark plugs are on outside block.)

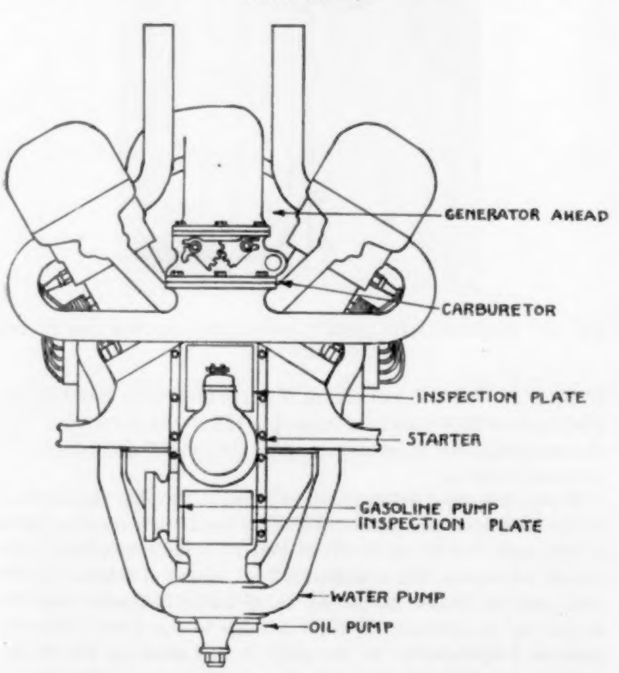

Fig. 7 End View of Suggested Engine

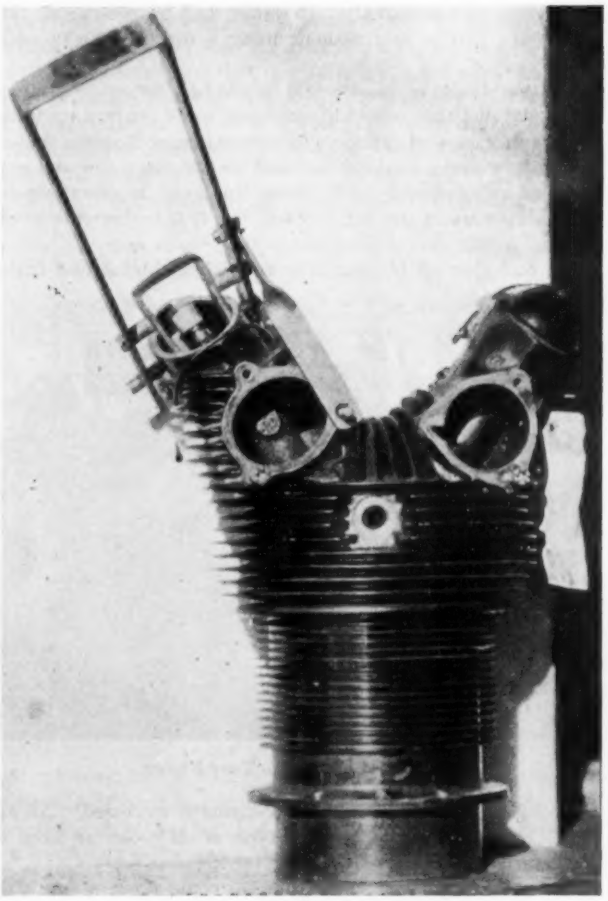

Fig. 8 Valve-Spring-Removal Tool

There are several inspection plates shown on the suggested engine. These are highly desirable when replacing parts or timing engines, in order to check gear backlash or shaft end play.

It is estimated that the maintenance time on such a design might be at least cut in half over the time on the present engines of the vee type.

It is true that the radial engine widely used in commercial service is very accessible, but it is thought that the vee-type engine will be used more in commercial work in liquid-cooled engines, as the speed of commercial aircraft is stepped up.

Present figures on service-type ships show that there is from two to four hours of labor required for every hour of flying. This figure, although it is much less than it was five years ago, is still thought to be much too high.

Many special tools are needed for maintenance of aircraft engines, but unfortunately it is found only too often that the tools supplied by the manufacturer are unsatisfactory. For example, we were forced to manufacture a valve-spring removal tool for a certain well-known air-cooled radial engine, since the one made by the factory was almost worthless. (See Fig. 8.)

A test bench for testing electrical accessories is shown in Fig. 9.

Another thing which some one might devise is a device which could be screwed into the cylinder to indicate the position of the No. 1 piston throughout the stroke with reference to the angular rotation of the crankshaft. It would then be possible to time the engine in the field without using a disk on the propeller hub.

Another device of value would be one to blow out or drain off water and dirt that collect in carburetors and get in the nozzles, thus causing several cylinders to cut out; since it seems that no matter how many strainers are used on the gas, water and sediment get in occasionally. No doubt this water is sometimes due to condensation in the engine itself, but it is bothersome nevertheless.

We find that oil is constantly running at higher and higher temperatures as the power of the engine is increased. All aircraft engines should have some type of oil cooler to keep oil temperatures down.

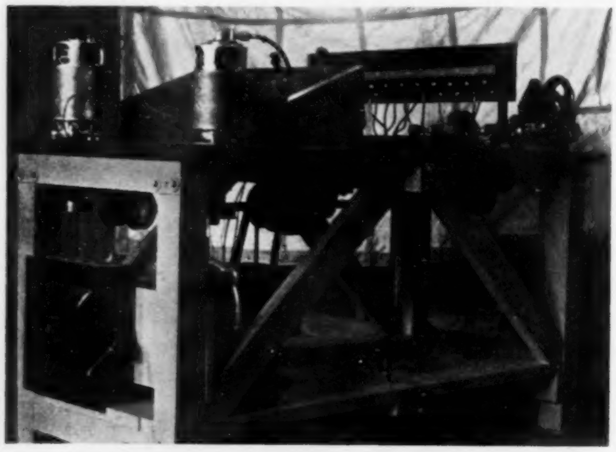

FIG. 9 ELECTRICAL TEST BENCH

An interesting development that has come along of late is the electric oil and water heater installation now used on Army aircraft. Hangars are difficult and also expensive to heat. Furthermore, there often are cases where it is necessary to land service planes in the winter time where there are no hangars. These heating units are inserted in the water manifolds, and also the oil tank can be coupled with an ordinary bayonet socket to a lighting circuit. They rapidly raise the temperature of the water and oil to about 60 deg. fahr. and hold it there. The water is heated by two 600-watt units, while the oil tank is heated by one 300-watt unit. We do not as yet know what maintenance troubles will be encountered with this installation, but the idea is promising. (See Fig. 10.)

Among the useful articles developed by the author at the Panama Air Depot was a tool for checking the main bearings on the Curtiss D-12 and other engines during the boring operation on these bearings.

Bearings on aircraft engines are either reamed or bored, and close measurements must be taken during the boring or reaming operations.

The inside micrometer is a delicate thing to use and liable to error. Therefore, the gage shown in Fig. 11 was designed, with the following points in view: First, it was desired to have a measuring device which would eliminate the inside micrometer; second, a device that would not be likely to get cocked in the bearing during the measuring operation (a fault which the inside micrometer is liable to), and, third, a device that would take only the minimum or high-spot measurement. It was also desired to have an instrument that would be more robust than the inside micrometer. The device shown can be inserted in the bearing and allowed to extend. The outside micrometer can then be used on it, or if desired the measurements can be taken directly from graduations on the gage itself. The gage may be made to read to 0.001 in.

It is an expanding device with two outside blocks machined to a curvature such that it will slip into the bearing in question. Between these outside blocks there is a sliding vee block which is operated by a knurled screw with graduations on the head. This device turned out to be very useful in the boring operations of Curtis D-12 main bearings.

Many other interesting problems come up in the overhaul and repair of aircraft.

For example, at the Panama Air Depot it was desired to replace some sections of longerons on the NBS-1, or Martin bomber, since the wood rotted away rapidly in that climate.

Reenforcement would be necessary at the splice, bearing in mind that glue in such a damp climate was a doubtful proposition.

The original longeron was of spruce, 2 in. square in section. We had some chrome-molybdenum steel strip available luckily, about the proper size, namely, 0.090 in. by 2 in., also some 0.125 in. by 2 in. We also had plenty of Army and Navy standard aircraft bolts of 2330 steel heat treated to 125,000 lb. per sq. in. The chrome-molybdenum steel was good for 90,000 lb. per sq. in. non-heat-treated.

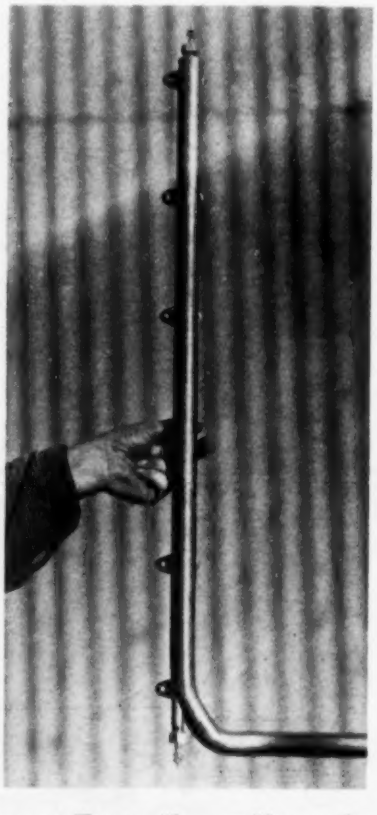

FIG. 10 ELECTRICAL HEATING UNIT FOR HEATING OIL AND WATER ON AIRPLANE

It was therefore determined, in order to develop the strength of the solid longeron at the splices, to reenforce with two plates of the steel, bolted as shown in Fig. 12. We found from competent references that a longeron 2 in. square of selected spruce was good for 10,000 lb. per sq. in. ultimate in tension and 750 lb. per sq. in. ultimate in shear parallel to the grain. In compression perpendicular to the grain it was good for 840 lb. per sq. in.

This problem is not quite as simple as might appear. The generally accepted best practice is to scarf the joint with a 1-in-12 slope, as shown in Fig. 12. Also the best practice is to stagger the bolts as shown. Since the longeron will be drilled for $^1/_4$-in. bolts, as shown, its strength in tension can be computed as follows:

$$[2(2) - 2(0.25)]\ (10{,}000) = 35{,}000 \text{ lb.}$$

Since the shearing strength for the bolts is given by competent authority as 3570 lb., it will need 10 bolts at each end of the scarf. The strength of the plates in tension will be:

$$2(2 - 0.25)\ (90{,}000)\ (0.09) = 28{,}350 \text{ lb.}$$

This is low. Ten bolts staggered and spaced 2 in. apart, as shown, should give a strength in longitudinal shear as follows:

$$[18 \text{ in.} - 10\ (0.25)]\ 1.5(2) = 34{,}875 \text{ lb.}$$

This is enough. A factor of 1.5 is used here, since it is thought the condition does not quite approach double shear.

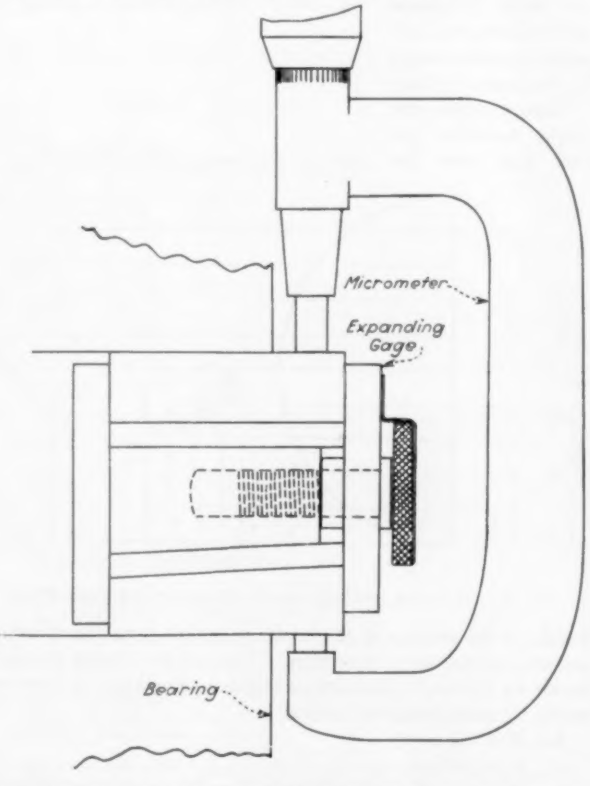

FIG. 11 METHOD OF MEASURING BEARINGS WITH AID OF EXPANDING GAGE

The straps will develop a strength on longitudinal shear as follows:

$$2[182 - 10(0.25)]\ 1.5\ (0.09)\ (60{,}000) = 251{,}110 \text{ lb.}$$

This is ample. As regards bearing strength of the steel plate against the bolts, we have the following: Value given for $^1/_4$-in. bolts against 0.09 plate is about 2200 lb. We have, then, 10 bolts in double bearing, which gives 10(2200) 2 = 44,000 lb.

As for shear perpendicular to the grain, it can be seen that the strength is far over the requirements.

It appears, then, that every case has been covered except compression and torsion. It is not thought necessary in this case to analyze for torsion, since the scarf is placed close to a strut point. As for compression parallel to the grain, it is known without going further that the steel is over-strength.

It is apparent, then, that it will be advisable to increase the thickness of the plate to $^1/_8$ in. in order to develop the strength in torsion. In another case it was found that the engine of a certain airplane could not be installed without the removal of some of its magnetos.

Since this was a nuisance and likely to throw the engine out of time, it was decided to install a removable section instead of the fixed member, which was in the way. This happened to be a member in tension supporting the engine bed. The method of reworking this is shown in Fig. 13. The strength of this material in tension non-heat-treated is about 90,000 lb. per sq. in. We installed two pairs of male and female clevises, which were welded and riveted as illustrated. The clevis pin was a tapered affair. Clevis and clevis pins were made of S.A.E. 2330 steel, also good for about 90,000 lb. per sq. in. in tension. Here we should develop the strength of the tube in tension on the clevis ends, also in double shear on the rivets and pins. This material machines very well too, and can be welded if handled properly.

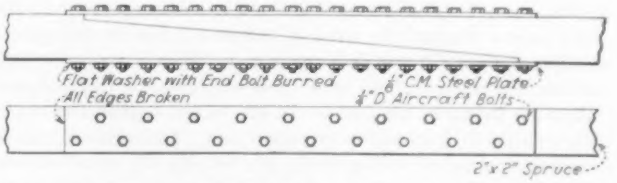

FIG. 12 METHOD OF SPLICING WOODEN LONGERON WHERE GLUE IS UNRELIABLE

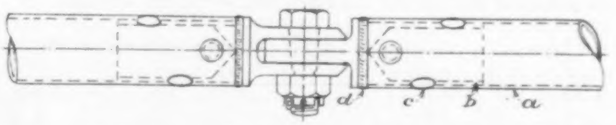

FIG. 13 METHOD OF INSTALLING CLEVISES ON REMOVABLE SECTION

(*a*, $1^1/_8$-in. outside diameter, 0.028-in. wall, chrome-molybdenum steel tube; *b*, 0.065-in. wall clevis of 2330 steel; *c*, mild-steel rivets, $^1/_4$ in. diameter; *d*, weld.)

To analyze this case, these clevises could either be welded or pinned, but a weld in tension as this would be a doubtful proposition, so it was decided to use pins and rivets, in connection with the weld. The cross-sectional area of the tube, if we used $^1/_4$ in. diameter pins, would be 0.19442 sq. in. = 2(0.25 × 0.058), for two drill holes for pins or 0.165 sq. in., which gives a strength in tension of 14,850 lb. It is probable that $^1/_4$-in. mild-steel rivets will be low in shear and bearing strength against 0.058 wall tubing, but we will depend on the weld to develop the rest of the strength. Of course, we could weld a sleeve on the tube to develop shear and bearing strength, but this operation would anneal the tube and reduce its strength in tension.

The clevis pin of course must develop a double shearing strength of about 1500 lb. An undercut taper pin will be used so that the job can be drawn up securely when finished, for it is undesirable to have any play in a member supporting an engine, as it may set up a heavy vibration.

Its average cross-section, then, must be 0.0165/2(9/6), since a shearing value of 60,000 lb. per sq. in. will be used. This works out as 0.124 sq. in., or close to $^3/_8$ in. in diameter.

Three mild-steel rivets will be used in each clevis, since this is a convenient arrangement. We will space these 120 deg. apart, as shown, because we do not want them in line, for then they may tear out more easily. Three rivets in double shear will develop a shearing strength of 6(1719), or 10,314 lb., according to competent references. This, of course, is low, but we will depend upon the welding to fill it out.

It is convenient to space these rivets down the tube $^1/_2$ in., 1 in., $1^1/_2$ in. This gives a mean of 7 to 8 in. of material in longitudinal shear. Then then develops as follows: 2(0.875) 1.5 (60,000)–15,750 lb., using the factor of 1.5 since, as stated, this condition is not considered quite equal to double shear. It follows, of course, that the walls of the clevis inside should be at least 0.065 in. in thickness, but that they should not be much thicker, since it will add weight and will cause unequal expansion and contract during the welding operation, due to the difference in weight of the metals being joined. This is a very important consideration in light structures such as airplane fuselages.

Another factor to consider is the size of the lugs at the clevis ends which will hold the large taper pins. The cross-sectional area from the end of the lug to the pin hole should be as follows: $A(1.5)\ (60{,}000) - 14{,}850$, or $A = 0.165$ sq. in. If we have a lug thickness of $^3/_8$ in. then we must have about $^7/_{16}$ in. of material between the pin hole and the end of the lug. Therefore, the radius of the lug end will be $^7/_{16}$ in. + $^3/_{16}$ in. = $^5/_8$ in.

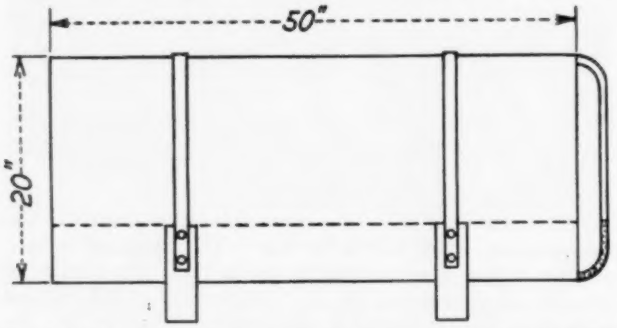

FIG. 14 METHOD OF INSTALLING AUXILIARY TANK, LAID ON ITS SIDE

We find, however, that the bearing strength of a $^3/_8$-in. pin against $^3/_8$-in. metal in thickness is somewhat low, about 13,360 lb., so we will increase the pin size to $^1/_2$ in., where we will get a value of 17,812 lb., from competent references. It appears, then, that we can safely use a pin with a mean diameter of $^7/_{16}$ in.; that is, $^1/_2$ in. at one end and $^3/_8$ in. at the other.

The rivets have a bearing strength of only 6(1378) lb., which works out as 8268 lb., which is, as was expected, low. We believe, however, that we can depend upon the weld to develop the necessary strength not available in the rivets. The matter of bearing strength depends largely upon the fit between the sleeve of the clevis and the inside of the tube. If this is a good fit, a high bearing strength will be developed. If it is not, the job will be very low in bearing strength. Therefore, we will make this job an especially good fit.

In a job like this, we do not deem it advisable to heat-treat the parts unless it is difficult to develop the strength without it. Heat-treated parts are likely to be brittle and to crack where subjected to vibration.

It is highly important, however, to incorporate fillets, as shown in Fig. 13, where there is a break in section, since sharp corners are likely to localize stresses and start cracks at these points.

Good workmanship, however, is really the prime requisite in things of this sort, since a job that has been properly calculated may easily fail because of sloppy fits and tool marks, or the parts may be overstressed in working.

Rivets must be fitted snugly, and such parts as the male and female clevises shown must match nicely, so that they will go together without forcing.

It may have been noticed in the foregoing computations that particular attention was paid to bearing stresses in the case of bolts, rivets, and pins. This is because failures of parts due to lack of sufficient bearing surface are common. Indeed, they are probably the most common of failures on aircraft.

In the construction and operation of airplanes and motor boats, one very often runs into very knotty problems that defy solution by ordinary means. Suppose, for example, that one desires to put in an auxiliary fuel tank for a long-distance flight, since the standard fuel tank will not suffice. Suppose further that there is sufficient room to install a cylindrical tank 20 in. in diameter and 50 in. long, which will be laid on its side as shown in Fig. 14. Again suppose it is important to know the supply of fuel with respect to height in the tank. In fact, it is very important in an airplane or even motor boat to know this, in order to estimate probable cruising range at any time.

Now, of course one might measure the fuel and note the height of the column of gas in the gage, but then this is laborious and amateurish in operation. This problem cannot be solved easily by the usual processes of trigonometry, but can be solved easily by integrating as follows:

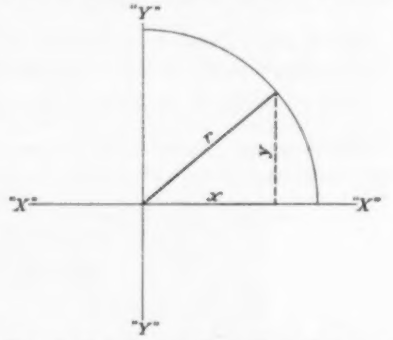

FIG. 15 DIAGRAM OF FUEL-TANK PROBLEM

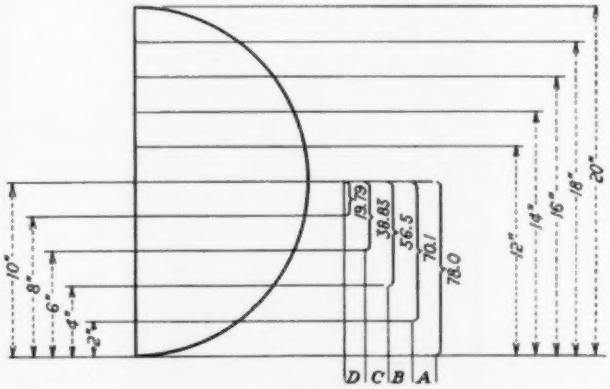

FIG. 16 METHOD OF CALCULATING CAPACITY OF FUEL TANK

Let D = diameter
r = radius
x = any distance subtended by a perpendicular y dropped to the X axis, as in Fig. 15.

Then:

$$y = \sqrt{(r^2 - x^2)}$$

We wish to know first the cross-sectional area of the tank by increments of heights of 2 in. After that, it will be easy to compute volume of the tank for every 2 in. of height. Therefore, we will integrate the area of one-quarter of the cross-sectional area, as shown in Fig. 16, between where x is zero and the various values of x.

Any table of integrals will show that the integral of $y = \sqrt{(r^2 - x^2)}$ is as follows:

$$\int \sqrt{(r^2 - x^2)}dx = \frac{x\sqrt{(r^2 - x^2)}}{2} + \frac{r^2}{2}\left(\sin^{-1}\frac{x}{r}\right) + c$$

The theory of the operation is that we compute the value of the integral for two values of x and take the difference, during which operation, of course, the constant c drops out, but in this case one value of $x = 0$, so that the subtraction is not actually carried out.

Substituting $x = 10$ in the following formula, we get:

$$\left[\frac{10\sqrt{(100 - 100)}}{2} + \frac{r^2}{2}\left(\sin^{-1}\frac{x}{r}\right)\right] = \frac{100}{2}\ (\sin^{-1} 1)$$

Substituting $x = 0$, we get zero, of course. Therefore, the area between $x = 0$ and $x = 10$ is 50(1.56), or 78.57 sq. in.

Substituting $x = 8$ and $x = 0$, we have

$$\left[\frac{8\sqrt{(100 - 64)}}{2} + 50(0.922)\right] - 0, \text{ or } 70.1 \text{ sq. in.}$$

Substituting $x = 6$ and $x = 0$, we get:

$$\left[\frac{6\sqrt{(100 - 36)}}{2} + 50(0.65)\right] - 0, \text{ or } 56.5 \text{ sq. in.}$$

Substituting $x = 4$ and $x = 0$, we get:

$$\left[\frac{4\sqrt{(100 - 16)}}{2} + 50(0.40)\right] - 0, \text{ or } 38.83 \text{ sq. in.}$$

Substituting $x = 2$ and $x = 0$, we get:

$$\left[\frac{2\sqrt{(100 - 4)}}{2} + 50(0.2)\right] - 0, \text{ or } 19.79 \text{ sq. in.}$$

Thus we have the areas computed as shown in Fig. 16. It is very simple, then, to determine what our gas reserve is for every 2 in. of height in the tank. Of course, the tank being symmetrical about its center lines, the volumes will be the same for each half.

We must now compute the increments in order by subtracting as follows:

$A = 78.54 - 70.1 = 8.44$ sq. in. for 2 in. of height
$B = 78.54 - 56.5 = 22.04$ sq. in. for 4 in. of height
$C = 78.54 - 38.83 = 39.71$ sq. in. for 6 in. of height
$D = 78.54 - 19.79 = 58.75$ sq. in. for 8 in. of height

Volumes, then, are as follows:

For 2 in. of height 2(8.44)50/231 = 3.65 gal.
For 4 in. of height 2(22.04)50/231 = 9.54 gal.
For 6 in. of height 2(39.71)50/231 = 17.19 gal.
For 8 in. of height 2(58.75)50/231 = 25.43 gal.
For 10 in. of height 2(78.54)50/231 = 34.00 gal.
For 12 in. of height 2(19.79)50/231 + 34.00 = 42.56 gal.
For 14 in. of height 2(38.83)50/231 + 34.00 = 50.81 gal.
For 16 in. of height 2(56.60)50/231 + 34.00 = 58.46 gal.
For 18 in. of height 2(70.1)50/231 + 34.00 = 64.35 gal.
For 20 in. of height 2(34) = 68 gal.

In the same manner, tanks of other curvatures can be integrated to determine their contents by increments of height.

Discussion

Walter C. Thee.[2] Lieutenant Downey clearly shows in his paper how overhead can be decreased, but in doing so, he showed also the absolute necessity of an officer in charge of maintenance to be well qualified for the position. A great aid in maintenance is to have a good supervisor that knows the fundamental principles of machine-shop practice and can apply them successfully and economically. He also must have a working knowledge of metallography, strength of materials, and dynamics of internal-combustion engines, as well as the fundamental principles of engines, ignition systems, propeller design, airplane rigging, and the application of fabrics and woodwork.

A good maintenance superintendent will increase the efficiency of an organization a great amount and will reduce the unit cost of maintenance so that salvaging of wrecks or reclamation of component parts will be economical.

The author stresses the importance of inspection. The functionalization of inspection has grown in our industries mainly because it has proved itself to be profitable. Inspection in regard to the operation of airplanes may be called an official examination of unit assemblies or parts to detect errors or flaws and to determine quality, accuracy, finish, and interchangeability. To accomplish this it is necessary to have a definite knowledge of particular facts obtained and shown to be correct by scientific research. When definite knowledge is established, a record should be made for the purpose of accumulating and preserving all data under one form so that a standard practice is established.

THE IMPORTANCE OF STANDARDS

The value of standard practice applied to the maintenance of airplanes is that it brings about a coordination of information and uniformity of instruction for the maintenance of one type of equipment in a single manner. Standard clearances, tolerances, and adjustments are specified and used as a basis to detect errors when inspections are made of airplanes or their unit assemblies and parts.

If we look at inspection in the light of Gantt's philosophy, it is evident that without standards there can be no inspection, for no one can see that a quality order is carried out if no quality order is issued, and a quality order to be such must contain standards quality. Furthermore, if standards for inspections are specified, definite information is furnished the inspector. An inspector's or any man's judgment is no better than his information.

OBSOLESCENCE, DEPRECIATION, AND AMORTIZATION DEFINED

In regard to the author's views on obsolescence and depreciation, the writer is heartily in accord with him. The principal factor that will determine when an airplane should be discontinued from service is obsolescence. Obsolescence can be divided into two major classifications: Obsolescence through change in design of product, which does not reflect on the value of the machine as a useful piece of equipment, but merely that the part which it was bought to produce was found to be of wrong design or to have short life; and obsolescence through an economic replacement.

The terms depreciation, obsolescence, and amortization are sometimes confused and used indiscriminately. Depreciation has been defined as the act of lessening or seeking to lessen the price or value, the reduction of worth, the gradual wearing out of equipment. Depreciation can be calculated in advance; it deals with the anticipated life of the equipment to produce for a given number of hours.

Amortization is the extrication of a debt, usually by means of a sinking fund. Wear and abuse do not necessarily enter into this meaning, but rather an anticipated life or fixed time in which to set aside funds to pay the debt.

Obsolescence is a measure of progress that reduces the value of the tool or machine on hand when improvements have been made in design or manufacturing methods that increased their efficiency or reduced operating costs or hazards. Obsolescence cannot be calculated like depreciation in accounting practice, as the former depends on research and can be divided into two major classifications:

1 Obsolescence through change in design of product
2 Obsolescence through an economic replacement.

MAINTENANCE VERSUS ENGINEERING DESIGN

The paper is not confined strictly to airplane maintenance, as at times the author has described problems involving the computation of design load factor relative to rebuilding wings with wooden or metal ribs and changing the position of the engines in order to improve the balance, cruising speed, and general performance. These problems should be charged to the engineering division and worked out by them rather than by the maintenance division. Placing such responsibility upon a division that specializes on problems involving design will accelerate the establishment of standard practice and centralize all records when definite knowledge is received.

Obsolescence is usually that lessening in value that is brought about by developments, inventions, and changes in the art that render airplanes, any part of its equipment, or whole sections of it uneconomical of use as compared with newer types available of greater efficiency.

Obsolescence has been defined as "going out of use," which definition represents a falling off in value of usefulness of a thing from causes outside of the thing itself as distinguished from the effect of wear or physical deterioration.

Wear and tear is a form of depreciation, and the one regularly recognized in accounting practice is that due to the elements, to abrasion, accidents, accelerated usage, and the like. Wings can be repaired, struts replaced, new bearings installed, cylinders reground, and bushings replaced. Experience has shown that where obsolescence has not set in or is operating and the equipment is kept in reasonably good operating condition for the work that it is called upon to regularly perform, it is then maintained at from 80 to 85 per cent of its original functioning condition. The principal factor which will determine when an airplane or any of its units should be discontinued from service is obsolescence.

The causes of obsolescence that will have a tendency to affect maintenance and the continued use of airplanes are:

1 The development of an extensive change in the method of manufacture
2 The making of a substitution of materials
3 Newer planes of the latest type will give the same or better performance more economically
4 A newer or modern plane may reduce (*a*) the hazard to the operator and passengers or (*b*) the hazard of fire
5 More rigid equipment may give greater required safety.

SIMPLIFICATION OR SPECIALIZATION REDUCES OVERHEAD

Maintenance of airplanes can be simplified only by specializing on the various routine repair operations that are required in service, applying the fundamental principles of industrial organization now used by the manufacturers to produce airplanes in mass quantities, and observing the laws of manufacturing management, as described by L. P. Alford.[3] In order to apply these laws or fundamental principles of industrial organization and management to the maintenance of airplanes, repairs must be made in mass quantities. Small local service stations should confine their work to the facilities, qualified personnel, and adequate equipment available. By this it is not meant that small local service stations should have a large force of expensive skilled mechanics and a complete assortment of expensive shop equipment, unless they can be economically operated and the volume of work for each machine warrants its purchase and installation.

HOW MASS PRODUCTION CAN BE APPLIED TO MAINTENANCE

The fundamental principle of the organized system of maintenance of airplanes is based upon qualified personnel and adequate facilities with which to do the work. In order to keep overhead down to an absolute minimum, to hire qualified personnel, and to operate adequate facilities economically, maintenance should be simplified and divided into five phases or zones of maintenance in order to make specialization possible. In each of these phases or zones there are three distinctly different elements; namely, personnel, the tool equipment, and supplies.

ORGANIZATION OF AIRPLANE MAINTENANCE

The zones of supplies should extend from spare parts carried on airplanes to the centralized stockage in airplane maintenance depots. The zone of maintenance functions to extend from the work of the pilot or individual airplane mechanic to the major operations of reconstruction shops or factories where the airplane or equipment is manufactured.

The work of airplane maintenance and handling of aeronautical supplies will be so graded in the zones of maintenance as to remove all maintenance facilities—i.e., service station and warehouse operations—from the field of operations of airplanes and especially of large fleet operators of transport planes. The most extensive repair operations, requiring skilled mechanics, always limited in number, the expensive and elaborate shop equipment, and large stocks of airplane supplies should be centralized in airplane repair depots or factory service stations.

THREE ESSENTIAL ELEMENTS OF MAINTENANCE

There are five natural zones or phases of maintenance. In each of these zones there are the following three distinctly different elements: (1) The personnel, (2) the shop and tool equipment, and (3) airplane supplies. Throughout the five zones, the three elements, personnel, equipment, and supplies, will be graded in accordance with the character of maintenance to be performed.

FIVE ZONES OF MAINTENANCE AND THE FUNCTIONS OF EACH

The functions and responsibilities of each of the five phases or zones of maintenance should be as follows:

(*a*) *First Zone—Airplane Pilots' or Airplane Mechanics' Maintenance.* This embraces cleaning, waxing, greasing, servicing, tightening (bolts and screws), making ordinary running repairs and minor adjustments, such as oil changed, pushrods greased, cleaning strainers, gas, and oil lines, changing plugs, and adjusting tappets, that can be accomplished with the tool kit and the spares usually carried on the airplane. It is in this phase or zone of airplane maintenance that the little things are done from day to day in the way of maintaining the plane and engine. It is at this time that preventative maintenance is applied, and if done correctly it will do more to lengthen the life of the plane and engine than will any other one thing. This phase of maintenance also includes the keeping of up-to-date accurate log books in which are recorded for each engine the total number of hours since overhaul of the engine then in service. With this data, there is also recorded for each engine the time it has run since the several routine operations required in service have been performed, such as oil changed, valves checked, pushrods lubricated, magnetos checked, and strainers cleaned.

(*b*) *Second Zone—Periodic Inspection.* This will embrace periodic and systematic inspection to insure thorough and constant maintenance, with enforcement and correction of the first phase of maintenance. The first and second phases or zones, together, will form "preventative maintenance," for which the official in charge of the airplane or fleet of airplanes is directly responsible. The repairs undertaken will be limited to those that can be accomplished economically and satisfactory by local personnel, repair facilities, and stock of spares that may be available. It is at this phase of maintenance that log books for both plane and engine are carefully checked. This system of maintenance should require each plane to carry an inspection form on which is recorded in abstract form the total operating time of the plane and all engines, with any other special information the log books contain on that particular ship or its engines. A careful check should be made on this inspection form to see that it contains the time each engine has run since the several routine operations required in service have been performed, such as oil changed, valves checked, pushrods lubricated, magnetos checked, and strainers cleaned.

---

[3] "Laws of Manufacturing Management," Trans. A.S.M.E., 1926, p. 393. Abridged in *Mechanical Engineering*, April, 1927, p. 301.

(*c*) *Third Zone—Unit Replacement.* This contemplates a removal of an unserviceable unit assembly in which a sub-assembly or part needs a repair and immediate replacement thereof by a similar serviceable unit assembly held in reserve of the third phase or zone stock or stocks of spare units. Unit replacement will be practiced in all cases unless it is unmistakably obvious that a minor repair or replacement of a sub-unit assembly or part is all that is required and that this repair or replacement can be made without removal of the unit assembly from the plane or without disassembly of the unit, and that the supplies required are on hand or quickly and readily obtainable.

The third phase or zone of maintenance further contemplates organization of unit replacement repair shops, in all airports or at replacement centers established in a territory relative to a number of very small airports.

In undertaking or authorizing third zone service station repairs where such repairs are not contemplated in the regular set-up, an airfield manager or service superintendent should consider the following:

(1) The mechanical personnel must be capable of performing the contemplated work without damage to the plane or assemblies.

(2) The service station and tool equipment required for the work must be on hand at the location where the repairs are to be made.

(3) The spare unit assemblies, spare sub-assemblies, or spare parts required in the work contemplated must be in immediate stock at the place where the work is to be done, or easily and quickly obtainable by shipment from the next higher zone of aeronautical supply vicinity. This availability must be established as certain before removal of an unserviceable unit assembly from a plane for the purpose of repair is justified.

(*d*) *Fourth Zone—Unit Repair.* This will embrace the "tear down" and repair of any or all unit assemblies. The fourth phase or zone work contemplates a balanced personnel organization composed of the various types of mechanics classified and qualified in accordance with the various trades, as electricians, welders, engine repairers, ship builders and carpenters, painters, and upholsterers, required to repair the various unit assemblies of the airplane involved. It contemplates the organization, operation, and maintenance of departments of the various types used in the trades referred to, and it also contemplates the extensive supply of spare unit assemblies, sub-assemblies, and spare parts required in unit repair operations. In all fourth zone service stations the three essential elements must be in balance, i.e., trade classified personnel, the service station and tool equipment, and the required supplies.

As a rule, these fourth zone shops will be concerned only with the repair of unit assemblies and sub-assemblies. When the repair of an airplane or airplanes is imposed upon the fourth zone shop, it will remove and replace unserviceable unit assemblies in accordance with the third zone principles and practice, absorbing the unit repair work in its normal operations. There should always be, however, physical separation between third and fourth zone operations because of the distinctly different objectives involved. The objective of a third zone service station is to return airplanes to service in a serviceable condition as quickly as possible. The objective of a fourth zone service station is excellent and efficient shop organization, a smooth-running program with work of first-class quality, and a high rate of production in view, measured in terms of the number of unit assemblies repaired and returned to stock each month.

Fourth zone shops reclaim all serviceable unit assemblies, sub-assemblies, and spare parts from airplanes and aeronautical equipment that are not considered economically repairable.

In the operation of fourth zone service stations, the work of repair of unit assemblies and sub-assemblies will be balanced with the territorial requirements on the one hand and the capacity of fourth zone service stations to turn out such required repairs on the other hand. In this connection, fourth zone service stations should evacuate work beyond their capacity of fifth zone repair depots to which they may be assigned for supply.

(*e*) *Fifth Zone—Reconstruction.* This covers three subdivisions, as follows: (1) This will embrace repair work that is really reconstruction and requires special expensive single-purpose tool equipment and special tool operators who regrind crankshafts and cylinders, remove and replace valve seats properly in the aluminum heads of the modern air-cooled cylinders, renew crankshaft bearings, rebuild instruments, carburetors, magnetos, and wings, and reset pitch of propeller blades and balance same. In addition to repair and manufacture, the fifth zone of maintenance embraces the reclamation of and salvage of airplanes, unit assemblies and sub-assemblies in order to replenish stocks from uneconomically repairable planes, that nevertheless constitute a source of low cost supply of serviceable or economically repairable unit assemblies, sub-assemblies, and parts. It also includes assembling of units, sub-units, and planes.

(2) Whereas a large percentage of supplies of the fourth zone is in spare unit assemblies and sub-assemblies, the supplies of the fifth zone must embrace every individual part of such assemblies and sub-assemblies and the raw materials, i.e., steel, copper, alloys, wood, cloth, leather, wire, paints, etc., essential to aeronautical remanufacture.

(3) The fifth zone repair depots will cooperate in every way possible with fourth and third zone service stations assigned to them for supply so as to accomplish, between the three zones, the work of unit repair and unit replacement. Fifth zone repair depots will endeavor to maintain a smooth flow of supplies and reserve stocks through both the fourth and third zones. Whenever fourth and third zone work is imposed upon the fifth zone repair depots, such work will be performed in accordance with the principles and practices of third and fourth zone service stations. A physical separation, however, between third zone work of unit replacement and the higher zones of unit repair and unit reconstruction should always be maintained to protect fourth and fifth zone shops against the loss of man labor hours that always attends the repair of specific airplanes.

RELATION OF MAINTENANCE ELEMENTS TO PHASES OR ZONES OF MAINTENANCE

The three elements of maintenance, that is, personnel, shop or tool equipment, and supplies, should be graded throughout the five zones in accordance with the requirements of operating planes and fleets on the one hand, and on the other hand the necessity for maintenance organization, which requires the centralization of limited elements. The highly trained personnel required for the fourth and fifth zone work is always very limited. The shop and tool equipment used by such personnel is likewise limited; first, because of the large investment necessary in maintaining a fireproof building, in having specially designed equipment, in maintaining a large corps of technically trained mechanics, recoverers, and ship builders, and then in the need for carrying costly inventories of parts and supplies. The third element, "airplane supplies," embraces articles that have a high mortality and should be distributed in such amounts as will prevent exhaustion of stocks and dissipation of supplies that can be sent where needed and when needed only from centralized stocks. In the use and distribution of these three elements, incident to setting up the five zones of maintenance, the following resources are available:

(*a*) *Element of Personnel.* The first zone should include pilots, assisted by individual airplane mechanics, line or ground crews, who are qualified to care for airplanes. The prescribed functions being regular cleaning, waxing, lubricating, servicing, air, oil, water, tightening of bolts or screws, and emergency repairs.

The second zone should include field managers, flight superintendents, and especially selected line and ground crews trained and qualified to operate and maintain small fleets of airplanes of transport companies. The prescribed functions should be regular inspections, correction of errors or neglect in first zone work, assistance to airplanes that made forced landings, etc.

The third zone should include small maintenance organizations of general aircraft mechanics under a service superintendent qualified in airplane maintenance. The prescribed functions should be the removal and replacement of unit assemblies and exchange normally with fourth zone unit repair shops, and exchange with fifth zone shops whenever practicable.

The fourth zone maintenance should be limited to authorized factory service stations and will include large maintenance organizations of various trade classifications in the airplane industry. The prescribed functions should be repair of unserviceable unit assemblies in shop programs, based on "quantity production" methods and a quick return of repaired unit assemblies to reserve stock for third zone use. The personnel, in order to function properly and efficiently as well as economically in fourth zone work, will be balanced as to trade qualifications, in accordance with well-established fundamental principles of industrial organization and management.

The fifth zone maintenance should be limited entirely to factory personnel who may be augmented by the hire of highly skilled personnel qualified to reconstruct and manufacture airplanes, unit assemblies, sub-assemblies, and parts, or by unskilled personnel to be trained. The personel will consist of extensive manufacturing and airplane supply organizations of all trade classifications in airplane industry. The prescribed function should be reclamation of units and parts; salvage and remanufacture of airplanes, units and parts; extensive warehousing, storage, and issue.

(*b*) *Elements of Shop and Tool Equipment.* The first and second phases or zones of airplane maintenance should be limited to small kits of hand tools which come originally with every plane upon its leaving the factory, augmented in the second zone by such extras as may be carried at various airports.

The third phase or zone should be limited to such hand tools as are required to remove and replace unit assemblies and to such simple repair equipment as may be installed at airports, which is required for minor repairs incident to ordinary flying operation. In addition, the third phase or zone may have added work benches, vises, air compressor, paint-spray machine, high-pressure lubricating devices, hoisting jacks, traveling crane, electric grinders, drill press, welding outfit, riveting machine, and a limited addition of small hand tools, such as taps and die sets, airplane repair, and wood-working tools.

The fourth phase or zone should include the machinery and equipment required in service stations of the various trades connected with the airplane industry required to repair unit assemblies.

The fifth phase or zone should include similar but more extensive equipment required for the reconstruction and remanufacture of planes, units and parts, i.e., all machinery, tools, and facilities pertaining to the airplane industry.

(*c*) *Element of Airplane Supplies.* The first and second zone supplies should be limited to the few spare parts intended to be carried on planes and spare planes of transport companies or small fleets.

The third zone supplies should consist of a reasonable proportion of reserve stock of spare unit assemblies and sub-assemblies, and of a small stock of frequently required spare parts that do not require the disassembling of unit assemblies to install. Supplies of the third zone should be located in every large city where aeronautical service stations are established and where aeronautical activity is most prevalent.

The fourth zone supplies should include reserve stocks of spare unit assemblies and sub-assemblies and such stocks of spare parts required to repair unit assemblies and sub-assemblies.

The fifth zone supply will consist of centralized stocks of aeronautical supplies, including raw materials, spare unit assemblies and spare parts, stocks of machinery, equipment, tools, and accessories required to maintain airplanes.

NECESSITY OF A SUCCESSFUL STUDY AND STANDARDIZATION OF REPAIR OPERATIONS

An airplane mechanic should not be required to be able to rebuild an entire plane, any more than a factory mechanic should be required to build each unit and assemble an entire airplane. Prior to 1900, automobiles were built on the plan of having one man assemble the engine, and when he was through with it he proceeded to the axles and so on. Today there is a minute specialization in the manufacture of automobile[4] and airplane parts. Airplane repair operations should be studied more thoroughly and standardized so that the work can be simplified by specializing on unit repair operations with the resultant benefit to the airplane user.

The principal objective of the suggested scheme of maintenance as described is to make possible repairs of unserviceable material in mass quantities, thereby securing satisfactory work at a reasonable cost.

SUGGESTED LOCATIONS FOR ZONES OF MAINTENANCE

Until the volume of repairs warrants the establishment of fifth zone repair depots in various parts of the United States and foreign countries, reconstruction work, such as regrinding crankshafts, renewing main bearings, regrinding and honing cylinder barrels, rebuilding carburetors, magnetos, starters, generators, and instruments, should be done at the respective factories that produced them, where practically all of the necessary tools, equipment, supplies, and personnel are already available.

The major service stations for fourth zone maintenance and supplies should be located in the vicinity of such cities as New York, Cleveland, Chicago, St. Louis, Los Angeles, Fort Worth, and Atlanta.

The minor service stations for third zone maintenance and supplies should be located in every large city where aeronautical activity is most prevalent.

The first and second zone maintenance should be located and applied at every airport or flying field.

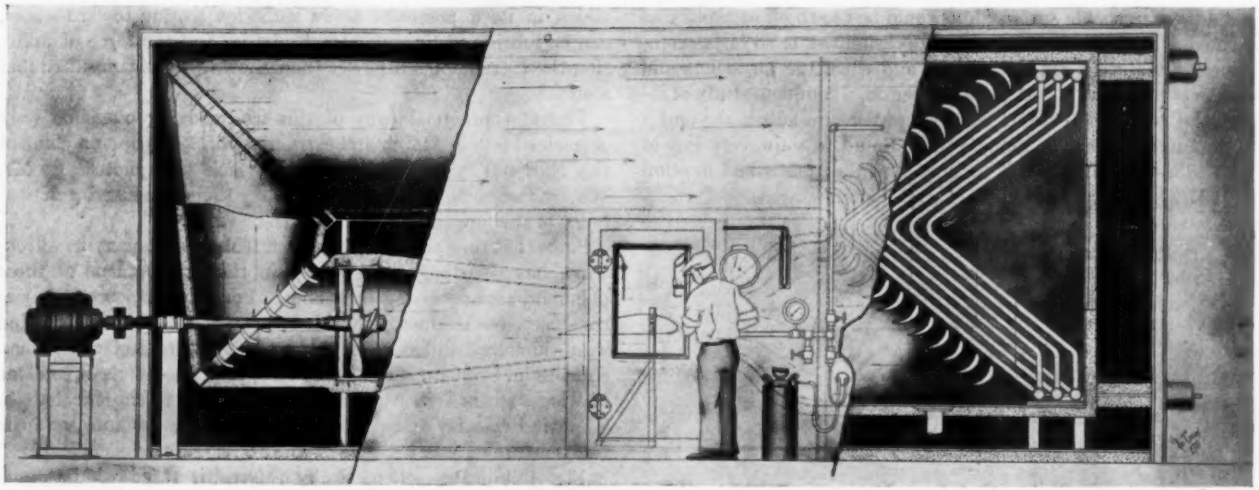

FIG. 1 REFRIGERATED WIND TUNNEL

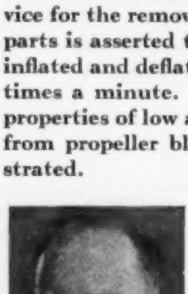
The Ice Hazard on Airplanes

BY WILLIAM C. GEER,[1] ITHACA, N. Y.

The problem of the formation of ice on airplane wings and propeller blades and of its prevention or quick removal is discussed in the paper. The most practical device for the removal of ice on the leading edges of airplane parts is asserted to be a rubber overshoe capable of being inflated and deflated with an air pump at the rate of three times a minute. A special oil mixture gives the rubber properties of low adhesion toward ice. The removal of ice from propeller blades has not been successfully demonstrated.



THE fact that there is an ice hazard need not be discussed in this presence. Every pilot who flies a mail route over the Alleghany Mountains or northwest of Chicago need not be told that over a considerable portion of the year he faces grave risk due to the accumulation of ice upon the leading edges of wings, struts, and other parts of his plane.

Nor does one need to enter into a discussion of the causes of the formation of this ice. Such men as Andrus,[2] Smith,[3] Scott[4] and Barnes,[5] Carroll and McAvoy,[6] and others have given far more thought to this problem than has the author and have published their conclusions.

A number of different chemical methods have been proposed and tried, the object being to prevent the formation of ice on airplanes. Of all of these methods, only one of them has given any indication of success. In principle this one consists of the use of a coating upon the airplane, which coating is composed of a material which, in contact with water, either solid or liquid, will lower its freezing point. This means that when a freezing rain comes in contact with such a coating, the freezing point will be lower and the rain will remain as water and not freeze as solid.[7]

However, the chemical principles involved indicate that a quantity of them must be present, and because the water will wash off appreciable amounts from minute to minute, this quantity must be large. Also, it is obvious that a plane may fly through a warm rain before it passes into an ice-forming area; and therefore either such soluble material may be removed before the need arises or some means must be provided under the control of the pilot by which he may replenish the material upon the surfaces where the ice may form. In the case of biplanes these surfaces are so numerous that an intricate system of pipes, tubes, or other equipment would be required, leading to an increase in weight of the plane and to greater complexity of the pilot's work.

Many attempts have been made to provide solid materials in the form of paint or varnish, the physical nature of these being such that the adhesion tension between a film of them and water, in solid or liquid form, might be so low that ice as formed would

[1] Research chemist. Mr. Geer was born in Ogdensburg, N. Y., and obtained secondary education in the normal school at Potsdam, N. Y., going then to Cornell University, where he took an A.B. degree in 1902 and a Ph.D. in 1905. At Cornell he specialized in chemistry and physics; then remained one year as instructor in chemistry, afterward joining the U. S. Forest Service as a specialist in the utilization of waste wood, also investigating extraction of turpentine and rosin from the waste pine wood of the Southern States. In 1907, he joined the staff of the B. F. Goodrich Company as chief chemist, remaining until 1925; he was a member of the Board of Directors and the Executive Committee and was Vice-President in charge of development and research. Retiring on account of health, after a period of travel and rest he built a small research laboratory and has since been engaged in private research, primarily in the rubber field.

Presented at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

not adhere to such a surface, but would be blown off as rapidly as formed. Without doubt, there are possibilities in so far as zero-adhesion materials are concerned; and when the physicists and chemists have conducted, if they ever do, a complete study of interfacial adhesion tensions between water as a substance and a large number of solids, many will be found to show very low or zero adhesion. It was this thought that the author had in mind in 1927 when his interest in this ice problem first arose.[8]

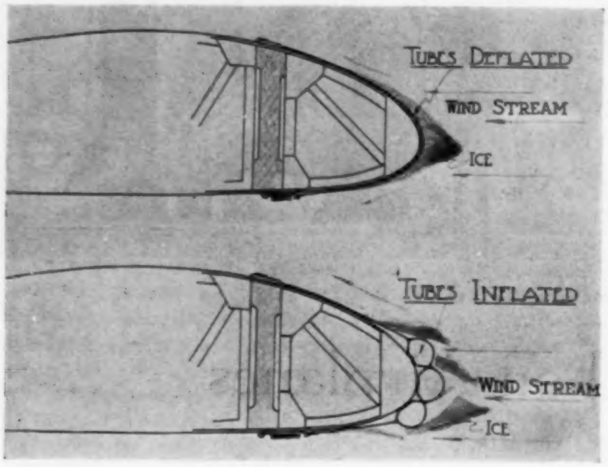

FIG. 2 GENERAL PLAN OF PNEUMATIC RUBBER OVERSHOE FOR ICE REMOVAL

However, the work of the author and Dr. Merit Scott, which was sponsored by the Daniel Guggenheim Fund for the Promotion of Aeronautics, Inc., and which was done through the cooperation of the Department of Physics at Cornell University in the Fall of 1929, has shown that even though low or nearly zero adhesion be obtained, the ice is not blown off, but because it shapes itself about the leading edges of airplane parts, movement of it is essential if it be removed. A discussion of this subject has already been published.[9] These studies proved conclusively in the laboratory that not only was a low adhesion surface necessary, but that some mechanical device was required through the operation of which the ice after formation could be removed.

The most practical of such devices proved to be a rubber overshoe attached to the leading edge of each of the exposed parts and capable of inflation by means of air pressure. The surface of the overshoe was formed of a thin sheet of vulcanized rubber into which was soaked a mixture of oils, the freezing points of which were so low that they would, under any practical conditions, be still liquid. Thus the rubber, which in itself possesses a low adhesion tension toward water, can be lubricated by such an oil mixture and the force of adhesion therefore kept still lower than shown by vulcanized rubber alone.

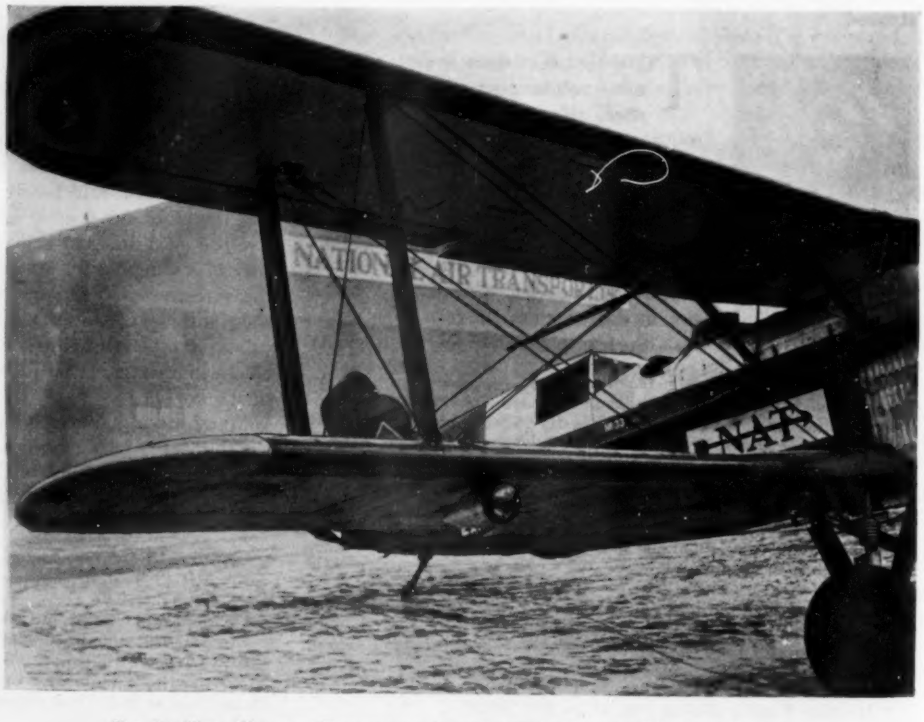

FIG. 3 NEAR VIEW OF PNEUMATIC OVERSHOES APPLIED TO WING OF PLANE

The first practical tests of this ice-removing overshoe were performed late in March and early in April, 1930, upon a plane of the National Air Transport, Inc., which was piloted by Mr. Wesley L. Smith, and indicated clearly the success and practicability of this pneumatic rubber-overshoe idea.

Since that time the B. F. Goodrich Rubber Company at Akron, Ohio, has been engaged actively in the development of these pneumatic ice-removing overshoes. For this purpose there was constructed at the factory of this company the largest refrigerated wind tunnel which has ever been made, the throat of which measures 18 in. by 36 in. This tunnel has permitted tests of sections of wings, struts, and wires in full size, although short in length. The wind velocity attainable is up to 85 miles per hour, and the temperature may be brought down to 0 deg. fahr.

Fig. 1 indicates schematically this refrigerated wind tunnel. The part to be tested is set up in position as shown, and precooled water is sprayed into the wind stream ahead of the leading edge of the part to be tested. Temperature, wind velocity, and other data are of course taken. The design of this wind tunnel was worked out through the cooperation of the engineers of the Langley Memorial Laboratory at Langley Field.

For the protection and removal of ice from wings, struts, radio masts, and other of the larger parts, the design of this pneumatic overshoe consists essentially of a layer of flexible fabric covered with rubber, in the leading edge of which are placed one, two, or three tubes composed of flexible fabric covered and lined with rubber. The general plan of it may be seen in Fig. 2. The principles involved are those of gaining strength and uniformity of inflation by means of flexible fabric, and air tightness on the inside of the tubes and contact with the atmosphere on the outside by the use of a proper rubber mixture.

The overshoe is made and vulcanized in the rubber factory

[9] Geer and Scott, N.A.C.A. Technical Note, no. 345 (1930).

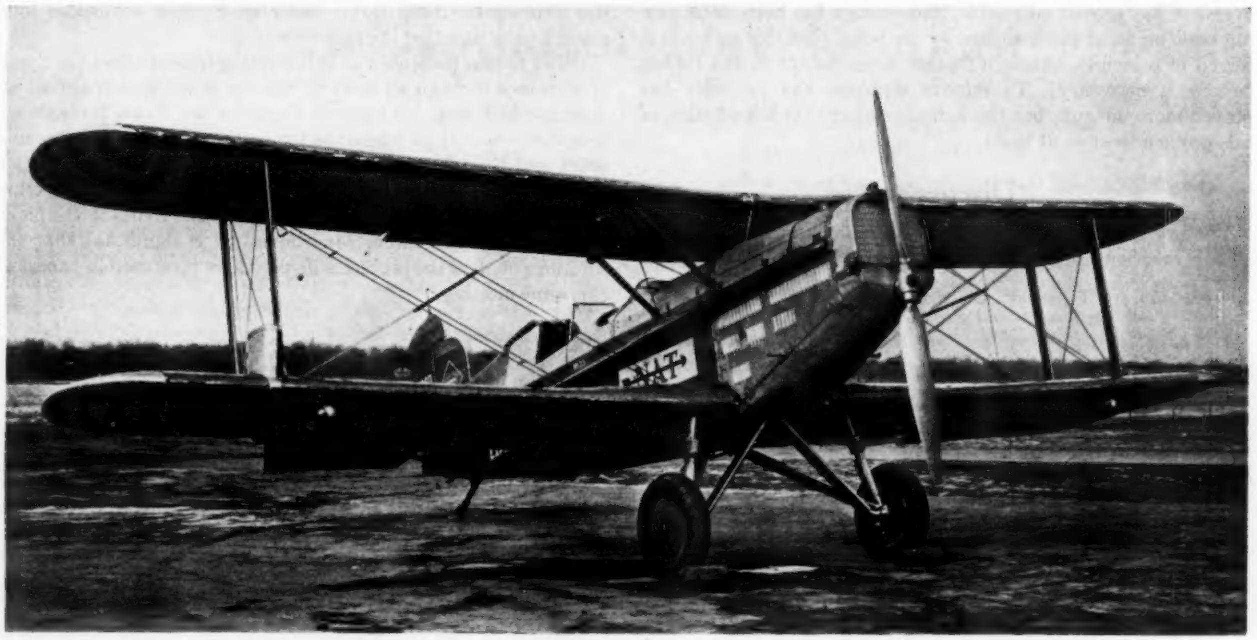

FIG. 4 FULL VIEW OF PLANE EQUIPPED WITH ICE-REMOVING DEVICE

before application to the plane. It is then attached to the leading edge as far back as the maximum diameter of wing or strut. Pressure tubes of small size are attached to the inflation tubes of the overshoe by means of nipples vulcanized in place. These tubes are placed inside the wings and are carried to a distribution valve in the fuselage.

Thus, as indicated in Fig. 2, this part upon the leading edge lies flat, with the tubes deflated, offering relatively little wind resistance, and a small change in curvature of the airplane part.

After the overshoe has been applied to the plane and attached by grommets or any other simple means, there is applied upon this outer rubber surface an oil mixture which soaks into the rubber and gives to it the properties of low adhesion toward ice.

This oil mixture is a combination which swells the rubber but little, and yet when the temperature is reduced to that of ice formation, develops upon its surface a thin lubricating film of oil which effectively lowers the adhesion of the ice. A near view of the pneumatic overshoes applied to the wings of a plane is shown in Fig. 3, and a full view of the plane in Fig. 4. These figures indicate how small these overshoes are relative to the wing surface of the plane.

On this particular plane installation the weight per foot of length of the wing overshoe was 0.526 lb., or a total of 36 lb. for the 68.5 ft. of covering. The wire overshoes, which are of a slightly different design, the details of which are not yet fully completed, would weigh less than 0.03 lb. per ft. The total weight involved to cover struts and wires is not given, because the construction of airplanes varies so greatly that a total-weight figure would be meaningless. It is, however, safe to say that ice may be removed by this device without seriously decreasing the useful load capacity of any given airplane.

In the operation of the plane it is necessary to provide an air pump, a capacity tank, and a rotary valve. These have been designed. The details need not be entered into because the scheme is a simple one of engineering in the field of handling air. However, if one assumes the mail plane of any type equipped with these overshoes, he would find tubes running from proper nipples attached to the overshoes to a rotary valve driven by an electric motor at a speed such that the tube in each overshoe when in use would be inflated and deflated three times per minute.

This rate has been found to be the most practical one after a long series of refrigerated wind-tunnel studies. In a completely equipped plane the pilot when running into an ice-forming area would need but to throw a switch to start his automatic rotating valve in operation and to open a valve connected with his air-storage tank. From then on the tubes will inflate and deflate at the rate of three times per minute and the ice be blown off before any of it has become thick enough to impede the maneuverability of the plane or to weight it down seriously. So far as the larger parts, such as the wings and struts, are concerned, the problem is solved and frequent practical tests have so proved.

However, the problem of wires and that of the propeller are far more difficult. The wires are so small, and the vibration of them when any body, either the overshoe or ice, is attached is so serious, that it has been a very difficult matter to find an article such that in itself the protecting device would not increase the vibration and yet be efficient enough to remove the ice as desired. Such a design has been made and has been tested enough to lead one to believe that it will be successful.

The propeller presents difficulties of even a more serious character because the ice, even if removed, is thrown off the propeller blades irregularly, and therefore unbalances it, leading to serious vibration of the plane. Several schemes have been tried with some success, but the work has not yet progressed far enough to warrant a statement that any one of them can be applied with certainty in actual practice.

Cooperation has been enjoyed with the laboratory of the National Advisory Committee for Aeronautics. In this laboratory tests of the effect of the overshoes on lift and drag have been made, and publications of the tests will doubtless be forthcoming.

To sum up, therefore: the removal of ice from airplanes has definitely been demonstrated in practical flying tests on full scale in so far as wings and struts are concerned by means of a pneumatic rubber overshoe applied to the leading edges of these parts. The removal of ice from wires has been studied on a 3-ft. scale in the refrigerated wind tunnel where a very small rubber overshoe has proved successful, and enough has been done at a full scale on an airplane to lead to the belief that this problem is solved in principle, although further development in the rubber factory is necessary. To remove ice from the propeller has proved more difficult, but the indications are that the solution of this problem is close at hand.

Discussion

WESLEY L. SMITH.[10] Since this paper has been written, complete protection from ice has been provided for a monoplane, and the airplane has been flown under ice-forming conditions long enough to be sure that the system is perfect.

Other papers presented at this meeting indicate that the flying of airplanes through all sorts of weather conditions is almost an accomplished fact. Whenever airplanes are flown through atmospheric conditions where the temperature is below the freezing point and the relative humidity is greater than 90 per cent, ice will form on the various parts of the airplane. Ice protection then becomes a part of the general problem of flying the airplane regardless of the weather conditions. It is significant that the solutions of all of the problems involved are presented in papers at this same meeting.

Wing Radiator Development

By G. A. LUBURG,[1] GARDEN CITY, N. Y.

This general paper on the subject of wing radiators contains a summary of experimental data of the Curtiss company and information of much original work. It should be of interest and help to airplane designers. The author explains apparently contradictory results by stating the comparatively few installations of this type and the usual accompanying secrecy. The use of wing radiators for general service is questionable, as they are expensive to build and easily subject to damage.

During 1920 the Curtiss Aeroplane and Motor Company built a Racer to compete for the Gordon Bennett Cup in France, and it was in connection with the development of this design that the idea of wing radiators originated. There was not sufficient time to develop the idea to an extent that the radiators could be relied upon for the race. Investigations continued, however, and an experimental radiator was installed in a Curtiss Oriole during 1921. The installation was not satisfactory due to defective construction, bad circulation, and leaks, and aside from this, the radiator itself was too small. Increased speed of the machine, however, indicated the advantage of the installation. A second radiator was made early in 1922 with better header construction and larger cooling area. This radiator was of sufficient size so that real test flights could be made. Results were so satisfactory and installation construction difficulties were so far overcome that wing radiators were included in the 1922 Curtiss Army Racer design. A Navy Racer a year before that had a top speed of 186 miles an hour when equipped with a Lamblin radiator was also fitted with wing radiators, with a speed increased to over 200 miles an hour. These wing radiators were all constructed of a flat sheet which lay directly on the wing cover and to which was soldered a corrugated sheet, these corrugations forming the water passages. Headers at the leading and trailing edges distributed the circulating water through the corrugated sheets.

Until 1928 the main construction details changed very little, although a number of installations were made by the Curtiss Company for the various Pulitzer-Schneider Cup Racers. All of them gave good performance, and some of the installations proved very rugged and reliable from a maintenance standpoint. Wing radiators were incorporated in the PW-8 Pursuit, a one-place type for the U. S. Army, and the service test of these machines indicated that wing radiators could be manufactured to give satisfactory service for general use.

For the 1926 Schneider Cup Race at Hampton Roads, the Italians sent over their first machine equipped with wing radiators. The author does not know the details of the construction of these radiators except that they were built up from separate flat tubes running fore and aft. The British machines that competed in the 1927 Races at Venice were equipped with wing radiators, the Supermarine having smooth skin radiators and the Glosters with a corrugated type, very much on the same style as the Curtiss type. The Mercury Racer built by Lieut. Alford J. Williams and his associates for the 1927 Schneider Cup Race had wing radiators constructed of flattened tubes. During test flights considerable trouble was experienced due to leaks and air locks.

In 1929 the Curtiss Company started an investigation of a separate-tube type radiator, and in 1930 built and installed a wing radiator of this design on the Marine Corps Racer flown by Captain Page.

Types and Construction

Fig. 1 shows a section of the Curtiss-design radiators of the corrugated type. The 0.005-in. thick brass for the corrugated sheet was 14 in. wide, so that after running this sheet through the corrugating rollers it became 9 in. wide. The lower flat sheet was also therefore made 9 in. wide and was tinned. The tops of the corrugations, which had to be soldered to this flat sheet, were tinned by a rolling process, and the unit was then sweated together by running through rollers that were heated to the proper temperature. It can easily be seen that this work required the utmost skill, as the sweating of these two sheets together had to be practically perfect. The rollers had to be exactly with the right temperature, and the speed at which the radiator section was fed through these rollers had to be governed to close limits. On racing installations, where maintenance was a secondary consideration, the radiator sections on the upper and lower surfaces of the wing were attached to single headers at the leading and trailing edges. Radiators of this type therefore had to be slid like an envelope over the wing panel. The ones designed for the PW-8 Army Pursuit were, however, constructed with separate header tanks for the radiators attaching to the lower and upper surfaces of the wing panel, so that these radiators were much more readily removable. The cooling system on this pursuit type was, moreover, fitted with a bypass valve by which the proportion of water going through the bypass as compared with that going through the radiator could be regulated, and therefore regulate the water temperature in the engine.

The new Curtiss-type separate-tube radiator as installed on the Page Racer is made up of individual tubes terminating at the leading and trailing edges in headers. A cross-section of these tubes is shown in Fig. 2. These tubes at intervals are sweated to brass tie strips, which are in turn attached to the surface of the wing. These radiators are probably more expensive to construct, but maintenance costs are very much lower than with the other type.

One type used on the Williams Racer consisted of tubes rolled flat to a dimension $^{3}/_{32}$ in. by $^{11}/_{32}$ in. This type naturally ap-

[1] Assistant Chief Engineer, Curtiss Aeroplane and Motor Company. The author was graduated from Central Manual Training High School, Philadelphia, Pa. He was graduated with B.S. in Mechanical Engineering from the University of Pennsylvania. He was junior engineer, gas distribution, with United Gas Improvement Company, Philadelphia, and then was in business for himself in layout and installation of factory equipment. He entered the employ of the Curtiss Company in March, 1918, as detail draftsman, and held successively the positions of checker, assistant engineer, structure's assistant, chief draftsman, project engineer, executive engineer, and assistant chief engineer.

For presentation at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931. All papers are subject to revision.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

proaches a smooth-skin condition with correspondingly reduced drag characteristics.

The smooth-skin types used by the Supermarine Company are built on the wing skeleton and help take the wing drag and wing torsion loads. Fig. 3 shows the design of this type. It should be noted that these radiators are made from sheet copper instead of brass. The material is approximately twice as thick and the weight is correspondingly increased. However, the heat dissipation through the copper radiator is very much higher than through the brass.

Heat Dissipation

The American radiators are all constructed of brass approximately 0.005 in. thick, which has a heat-transfer coefficient of 0.284 calorie per degree centigrade per second per square centimeter per centimeter thick. The British, according to reports, used copper and in some cases duralumin, which have heat transfer coefficients of 0.72 and 0.36, respectively. The copper is heavier than brass, but the number of square feet needed to transfer a given amount of heat will be less. Table 1 shows comparative data of British radiators (data taken from R. & M. Report No. 1311).

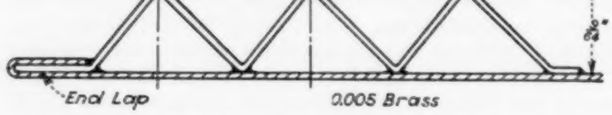

Fig. 1 Original Curtiss Section

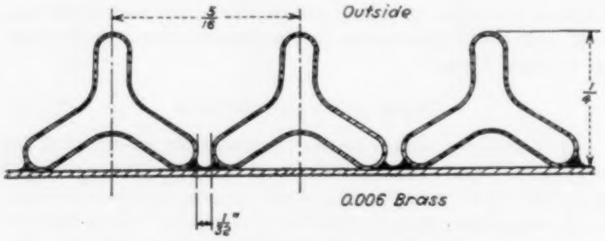

Fig. 2 Section of Tube Type

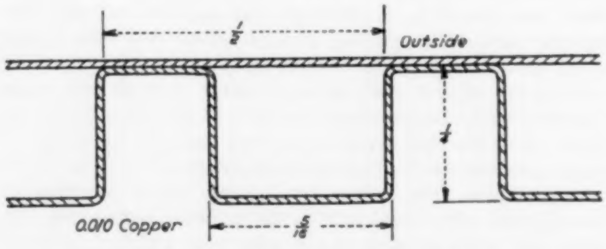

Fig. 3 Section of Supermarine Type

TABLE 1 COMPARISON OF BRITISH RADIATORS

	Drag per hp. at 90 m.p.h., in lb. per hp.	Lb. per sq. ft. cooling area	Heat dissipation at 90 m.p.h. per sq. ft. cooling area, in hp.[a]
Supermarine	0	1.70	0.91
Gloster	0.034	0.92	0.75
Average British Honeycomb	0.160	0.41	0.87

[a] 1 hp. = 42 B.t.u. per min.

Characteristics

For the heat dissipation per pound of drag the wing type is considerably more efficient than the best core type. The smooth outside skin used on the Supermarine is naturally the most efficient because of the complete absence of parasite drag, assuming that the power required to support the weight of each type of radiator in the air is approximately the same. In Table 1 the weights per square foot of cooling area of the wing radiators are based on the weight complete including water, whereas the weight of the honeycomb type is based on a section having no headers nor side walls nor water. The weight of the average American honeycomb for a 100 to 120 m.p.h. plane is between 0.50 and 0.60 lb. per sq. ft., which weight includes the complete radiator and filled with water, but exclusive of the supporting cradle. Fig. 4 shows a number of heat-dissipation curves of various types of radiators. All curves except curve 1 are calculated from actual flight tests and tunnel-test results. Curve 1 is standard up to 120 m.p.h. Above this velocity the curve was approximated from flight-test data on various high-speed honeycomb-radiator-equipped planes. In studying curves 1 and 2, it is found that at high speeds the corrugated type dissipates more heat than the honeycomb, which is probably due to increased wiping effect over the wing. Also the mass of air that flows through the honeycomb does not rise directly with the increase of the airplane speed.

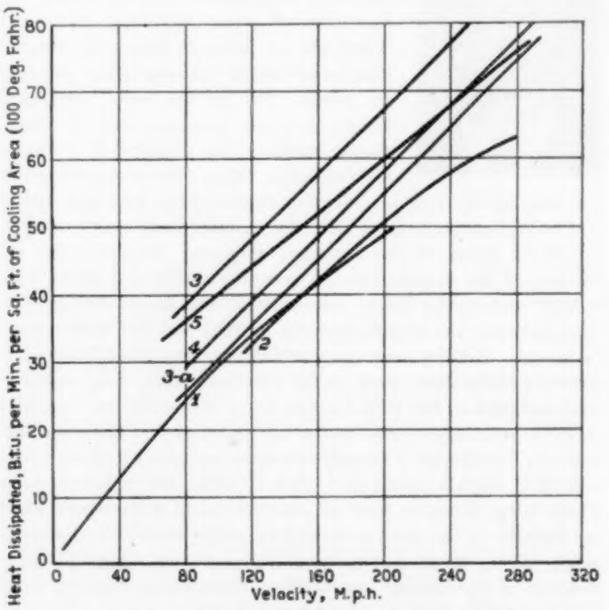

Fig. 4 Heat-Dissipation Curves of Various Radiator Types
(Curve 1, honeycomb; 2, Curtiss brass corrugated; 3, Curtiss tube type, 3-a, Curtiss tube type; 4, copper corrugated; 5, flat-plate type.)

Curve 3 represents the heat dissipated by the Page Racer, based on the area of the outside of the section shown in Fig. 2. However, the lower surface is also exposed to a considerable air flow due to the tubes being soldered to the attaching strips. This allows clearance under each tube for air to circulate. A correction for this additional area gives curve 3-a, which is close to what should be expected.

Curve 4 indicates how a corrugated type (Gloster) made of copper dissipates more heat per square foot than does the corresponding type made of brass. This seems reasonable in view of the fact that copper has a heat-transfer coefficient three times as great as brass.

Curve 5 represents the flat-plate Supermarine type. At high speeds the heat dissipation falls below that of the Gloster corrugated type shown in curve 4. This may be due to the sluggish moving boundary-air layer between the corrugations

reducing the efficiency of the radiator at slower speeds, while at high speed this boundary layer is kept cleared out, especially at the forward section of the wing, where most of the heat dissipation takes place. A report made by the Washington Navy Yard showed that the smooth-skin radiator dissipated about 32 per cent more than the old Curtiss corrugated type. Radiator cooling area per horsepower is higher for honeycomb than for wing radiators, showing the correspondingly higher heat-dissipation efficiency of the wing type.

Also the corrugated Gloster wing radiator has 44 per cent more cooling area per square foot of projected area than does the Supermarine type, but the added heat dissipation is only 19 per cent.

At high incidence the heat dissipation of the upper surface increases about 15 to 20 per cent, while that of the lower surface remains the same. The increase in the upper surface is due to more air turbulence as the angle of incidence increases.

Aluminum paint even over copper gives a slight increase in heat dissipated. Also a highly polished surface will radiate more heat, and, conversely, a dirty surface will greatly decrease the rate of heat dissipation.

Due to impact pressure and wiping effect, the section from the leading edge back 25 per cent of the chord dissipates five times the heat dissipated by the rest of the wing. These tests were made in England on a thin airfoil section. It is therefore safe to assume that on thick airfoils the effect will be very much more pronounced because of increased turbulence and wiping effect.

Table 1 gives a fairly good comparison of the relative drags of three types of English radiators. The Gloster corrugated radiator increases the drag of that part of the wing to which it is attached by 24 per cent. The Supermarine smooth-skin type therefore more than makes up the increased weight by the elimination of this increased drag.

On the Williams fin-tube type of wing radiator it was found that the drag of that part of the wing covered was doubled and that the lift was slightly reduced (N.A.C.A. Report 318). This type used by Williams was similar to the Curtiss type except that the fins on the Williams type were considerably higher.

Recent unofficial reports from the Army show that a plane having 73 sq. ft. total cove-radiator area had a speed of 160 m.p.h. The plane was converted to a type having a smooth-skin wing radiator of 60 sq. ft., and with the new installation the top speed became 165 m.p.h. This may be considered a very reasonable speed increase for a revamped ship. It should, however, be remembered that the largest gain in reduced drag does not necessarily come from the use of wing radiators but from the possible cleaner fuselage lines.

Another example of how a considerable speed increase was obtained by changing from the Lamblin type to the wing type is mentioned in the first paragraph of this paper. In this case the increase was 14 m.p.h., which is considerable for a higher speed ship. The English have found that at speeds over 300 m.p.h. a change from the corrugated-skin to the flat-skin type of wing radiator results in a gain in speed of $1^1/_2$ per cent.

Prestone is now being tried out as a cooling medium in place of water. Due to the much higher difference in temperature between the coolant and the air, as well as a larger proportion of the heat being dissipated through the exhaust, actual tests show that a Prestone radiator may have as low as 36 to 40 per cent cooling area as compared with an equivalent water-cooled installation. This decrease in size proportionately decreases parasite resistance due to the radiator. The advantages of the wing-type radiator are also correspondingly reduced. The Prestone-cooled wing radiators would have to be soldered with a special compound having a high melting point due to the high temperature in a Prestone system.

SUMMARY

Table 2 summarizes the general characteristics of various wing-radiator installations. Other general characteristics can be listed as follows:

1 The corrugated or tube wing radiator gives from 4 to 7 per cent speed increase at 200 m.p.h. over the honeycomb type.

2 The smooth skin gives further reduction of drag over the other wing types, but at an increase in weight.

3 Corrugated and tube types have been built as light as the honeycomb type.

4 The use of aluminum paint or even the polishing of the radiator increases the rate of heat radiation.

5 The leading-edge part of the present types dissipates approximately 80 per cent of the heat.

6 The upper and lower surfaces dissipate the same quantity of heat at low angles of attack; at high angles the upper surface increases its rate of heat dissipation.

7 The weight, installed and filled with water, runs from 0.33 to 0.53 lb. per hp.

8 The number of square feet of cooling surface per horsepower is approximately 0.51 at 200 m.p.h. and 0.44 at 250 m.p.h. for the tube type, and 0.36 at 300 m.p.h. for the smooth-skin type.

CONCLUSION

This paper intends to correlate and summarize such data as are available on wing-radiator design and construction. Due to the comparatively few installations that have been made and the secrecy that usually accompanies these installations, the data are rather meager, and in many cases are not based upon the same assumption or conditions. The results, therefore, to a certain extent, contradict each other. In new designs it is best to use data that have been obtained from an installation of the same type as well as judgment from past experience.

The use of wing radiators for general service is questionable. They are very expensive to build, and due to the thin material of which they are made and their exposed location, they are subject to damage. The use of Prestone reduces the radiator efficiency to about one-third of the water-cooled type, so that the advantage of gain in speed from a wing radiator over the core-type installation is cut to a very small amount. In this case, its use will probably be confined to planes of very high speed.

FIG. 1 LOCKHEED "VEGA" SIX-PASSENGER SINGLE-ENGINE PLANE

Supercharging the Airplane Engine and Increasing Speed With Altitude

BY ROBERT J. NEBESAR,[1] DETROIT, MICH.

On longer distances a high cruising speed is a necessity. As the speed increases with the cube root of the horsepower, high-speed transportation would not be economical. Flying at higher altitudes with supercharged engines would greatly increase the efficiency. A simple mathematical equation for close estimation of the increased speed in altitude is developed, and the merits of the size of an efficient plane are discussed.

THE problem of high-speed transportation by airplane has many important factors. The desired speed depends primarily on the given distance and on the cost, that is, the efficiency of such transportation. For short distances a surplus of speed would not be justified at a higher cost; for long distances, where the questions of comfort and higher safety of daylight travel enter into the problem, a higher cruising speed is a necessity.

In this paper the author proposes to analyze the best available means of increasing speed and to obtain a criterion of efficiency which, as will be demonstrated, even for greater speeds can be kept reasonably high.

The following nomenclature is used:

NOMENCLATURE

b = span of wings, ft.
$C_{D\text{ind.}}$ = coefficient of induced drag
$C_{D\text{prof.}}$ = coefficient of profile drag
$C_{D\text{par.}}$ = $C_{D\text{prof.}} + C_{D\text{struc.}}$ = coefficient of total parasite drag in the polar diagram (recalculated on unit area of wings)
C_L = coefficient of lift
$\varphi = \dfrac{C_{D\text{par.}}}{C_{D\text{prof.}}}$ = ratio of total parasite drag to profile drag
h = a certain altitude, ft.
$\lambda = b^2/S$ = aspect ratio of wing
L_B = power loading, lb. per hp.
L_w = wing loading, lb. per sq. ft.
ρ_0 = standard density of air at sea level
ρ_h = density of air at altitude h
$T_{HP\text{av.}}$ = thrust horsepower available
$T_{HP\text{req.}}$ = thrust horsepower required
S = wing area, sq. ft.
V_0 = speed at sea level, miles per hour
V_h = speed at altitude h, miles per hour
W = gross weight of airplane, lb.

I—THE ENGINE AND ITS EFFICIENCY IN THE AIRPLANE

One of the main factors to be considered in flying is weight. The weight of an airplane consists of four parts:

1 Weight of the *structure and equipment* of the plane, that is, wings, fuselage, landing gear, tail surfaces, flying controls, flying

instruments, seats, electrical installations, gasoline, and oil tanks.

2 Weight of the *power plant*, including engine mount, engine controls, engine instruments, propeller with hub, starter, gasoline and oil installations, and water radiator, water and its installation in the case of water-cooled engines.

3 *Useful load*, which includes pilots and attendants, gasoline, and oil.

4 *Pay load*, that is, passengers, baggage, mail, etc., which is often included in the useful load.

The size and type of engine determines the weight of the power plant and also a part of the useful load—that is, the weight of gasoline and oil—which weight varies directly with the specific consumption of the particular type of engine. The difference in weight of tankage will be considered negligible.

Therefore, from the viewpoint of weight, two engines will be considered equivalent if they will enable us to obtain the horsepower per pound of combined weight of power plant and fuel for the same number of hours of flying.

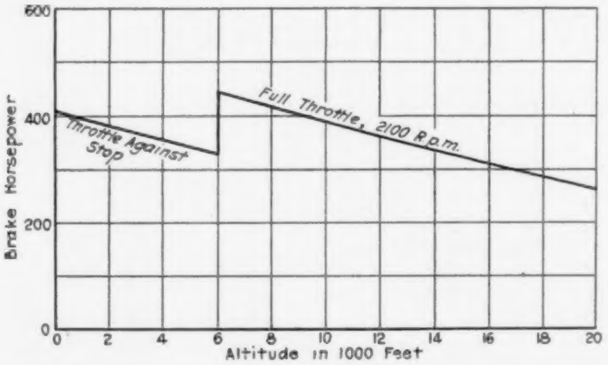

FIG. 2 POWER AT ALTITUDES—PRATT & WHITNEY "WASP" SERIES SC ENGINE
(Compression ratio, 5.25:1; impeller gear ratio, 10:1.)

From the standpoint of speed, flying range, and transport capacity, this would be much more complicated, and no definite relation could be determined. The frontal area of the power plant, its adaptability for efficient cowling, would have to be considered. Also, the speed of the engine would be of great importance due to propeller efficiency.

The best way of comparing two different engines would be to test them out on a given plane, e.g., a six-passenger single-engined machine having a pay load of about 1100 lb. and a range of 700 miles. Let us therefore compare two identical planes of a well-known aerodynamically highly efficient type —the Lockheed Vega (Fig. 1)—one equipped with a 420-hp. engine and the other with a 300-hp. See Table 1.

In order to have comparative results let us bring up the 300-hp. plane to the same gross weight as the 420-hp. one, the saving in weight resulting from decreased horsepower being taken care of in increased pay load.

We see then that the pay load of the 420-hp. plane would be 24.5 per cent of the gross load, and that of the 300-hp. plane, 33.3 per cent of the gross, that is, an increase of 36 per cent. But the cruising speed of the 300-hp. plane would decrease 12.5 per cent and all its flying qualities would be very unfavorably affected. There would be a decrease of 59 per cent in the rate of climb combined with a 40 per cent increase in the take-off distance. Even in bringing the pay load down to the value of the 420-hp. plane (as shown in the third line of Table 1), the flying qualities would not be much improved: climb would be still 42 per cent lower, and take-off distance 27 per cent longer, while crusing speed would remain at its low value.

Now let us see what would happen if we went in the other direction, namely, increase the horsepower.

The higher horsepower would increase the speed and improve the flying qualities of the plane to an unnecessary extent, but the pay load would decrease. In order to keep the pay load at the same percentage of gross weight, we should have to employ a larger-sized plane—a problem which will be considered later.

For the case in question it will be seen that the combination of wing and power assumed is the most desirable. A landing speed of 62 m.p.h. for a plane with all-around good control at low speeds is within reasonable limits.

Flying at altitude with a standard engine would decrease the speed and also the cruising range, owing to the lower efficiency of such an engine at altitude. This will be shown in the next section. However, there is a decided advantage in altitude flying with a supercharged engine.

The weight of a supercharged engine delivering a constant horsepower at a certain altitude would not be practically increased, and the specific fuel consumption would not be much

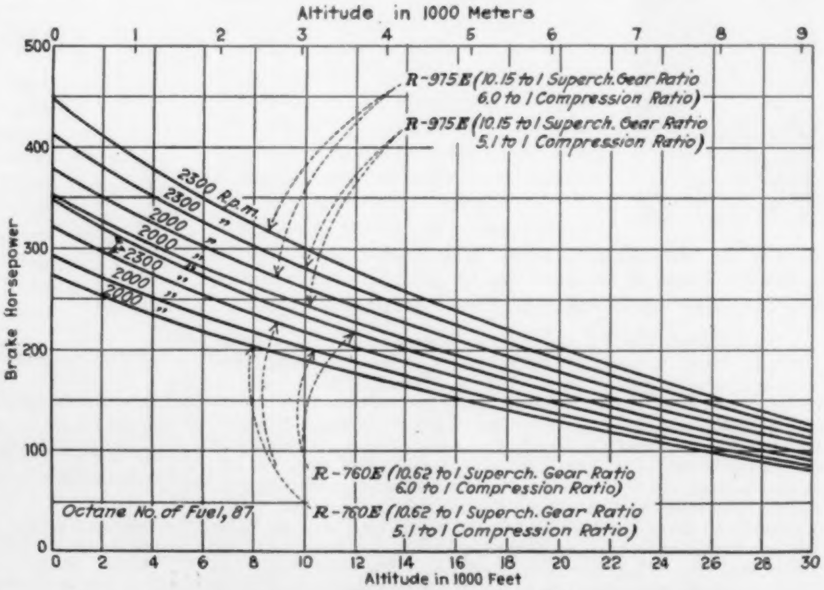

FIG. 3 ESTIMATED POWER AT ALTITUDE—WRIGHT "WHIRLWIND" ENGINES

higher, because of the higher compression ratio and therefore the greater thermodynamic efficiency of such an engine.

As the speed of the plane would be increased and the combined power-plant and fuel weight per horsepower would be constant, the range of the plane would increase with the speed for the same pay load; and as the good flying qualities, landing speed, take-off, and climb would be maintained, we should have a more efficient, more desirable airplane.

Fig. 2 shows the performance at altitude of a Pratt & Whitney "Wasp" Series SC engine, which has a 5.25:1 compression ratio, and a 10:1 impeller gear ratio, and develops 450 hp. at 6000 ft. altitude.

Fig. 3 shows the altitude performance of Wright "Whirlwind" J-6 engines and Fig. 4 that of English "Jupiter" engines.

The Diesel engine would seem to offer many advantages for altitude flying. As it has a high compression ratio and excess of air and oxygen, the power at altitude decreases slower than with the gasoline engine. This has been verified by different flight tests, where the top speed increased to a maximum value at an altitude of 8000 ft. Further, the lower specific fuel consumption will of course extend the cruising range.

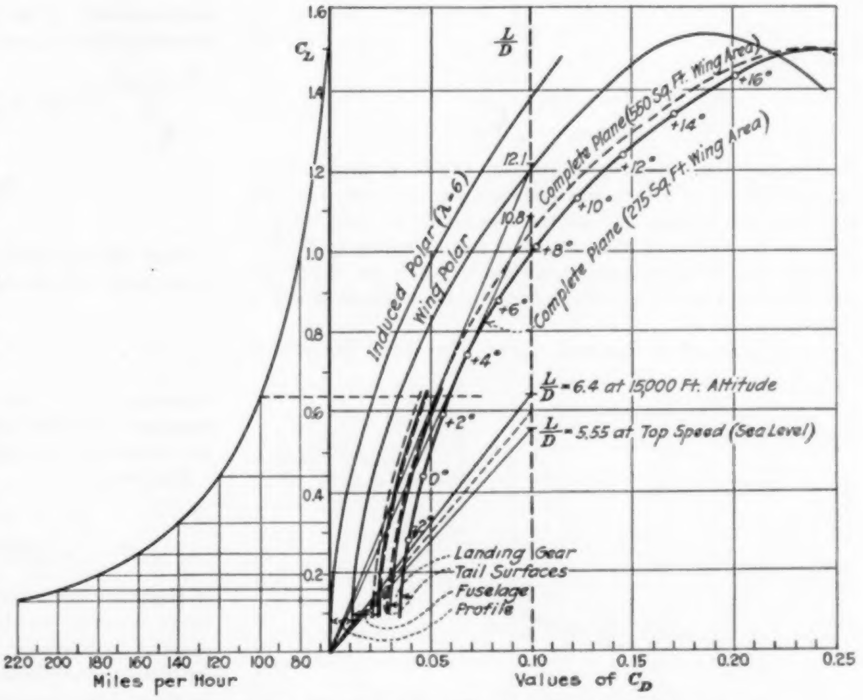

FIG. 6 POLAR CURVES OF LOCKHEED "VEGA" HIGH-WING MONOPLANE

The power at altitude of a 225-hp. Packard Diesel engine is given in Fig. 5.

II—SPEED AT ALTITUDE

Before developing the mathematical equation for high speed at altitude, let us consider the problem for a certain plane, the polar curve of which has been established from the test results as shown in Fig. 6.

The maximum lift coefficient (C_L = 1.5) and wing loading (16.35 lb. per sq. ft.) determine the stalling speed of 65 m.p.h. Due to the ground effect, the landing speed is few miles lower. To any lift coefficient there corresponds a certain speed at sea level—shown by means of the curve at the left in Fig. 6. The efficiency of flying at any speed, or any angle, can be determined by projecting that point corresponding to the desired speed, or angle of attack, on the polar curve from zero point on the vertical line through C_D = 0.10, where we find the value of L/D.

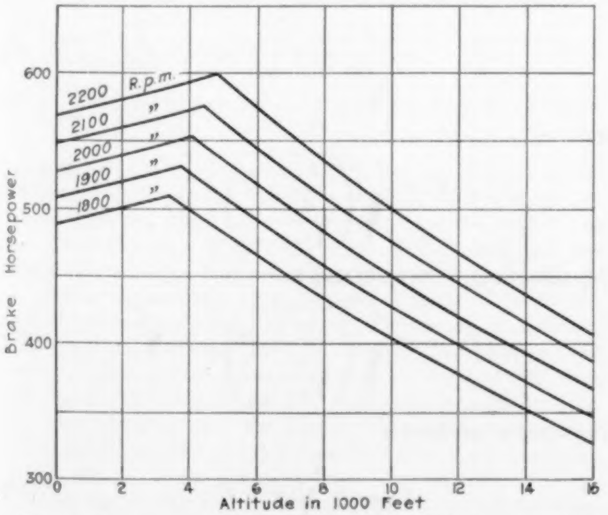

FIG. 4 POWER AT ALTITUDE—"JUPITER" XFAM AND XFAB ENGINES

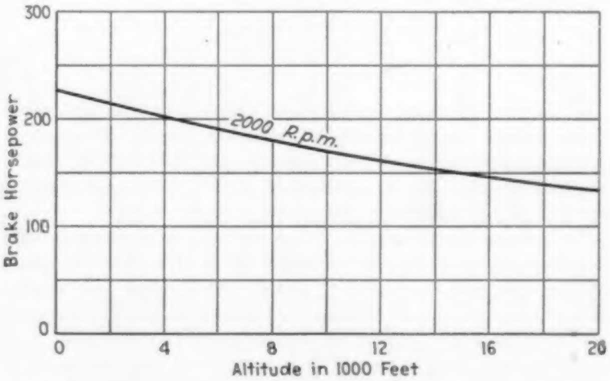

FIG. 5 POWER AT ALTITUDE—225-HP. PACKARD DIESEL ENGINE

The efficiency, as determined by the L/D ratio, depends very much on the wing loading, and therefore on speed. For planes with low wing loading and with large wing area, a higher value of L/D max. could be reached, but the speed would be much lower. For increasing speed the ratio L/D would decrease.

In the present case the maximum L/D is 10.8, and is reached at an angle of attack of +3 deg. for a speed of 95 m.p.h. For the high speed of 179 m.p.h., corresponding to an angle of —3 deg., the value of L/D is only 5.55.

Let us now transform our polar curve into the regular required thrust-horsepower curve, as shown in Fig. 7, and see what happens at altitude. To any point on the required thrust-horsepower curve at sea level would correspond a point in altitude where the speed, as well as the thrust horsepower required, would increase in the ratio of the square root of the air densities:

$$\frac{V_h}{V_0} = \sqrt{\frac{\rho_0}{\rho_h}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots [1]$$

$$\frac{T_{HP\ \text{req.}\ h}}{T_{HP\ \text{req.}\ 0}} = \sqrt{\frac{\rho_0}{\rho_h}} \quad\ldots\ldots\ldots\ldots\ldots\ldots [2]$$

If we neglect the variation in slipstream effects on wing and tail, the given angle of attack will maintain its L/D ratio and will shift on a line passing through the zero point; and the value of L/D can be read on a horizontal line corresponding to $W/375$. Plotting the thrust-horsepower-available curve we check the high speed of 179 m.p.h. corresponding to the angle of attack of —3 deg.

For the case of a standard engine, the thrust horsepower available at constant speed would decrease in the ratio given in the empirical formula:

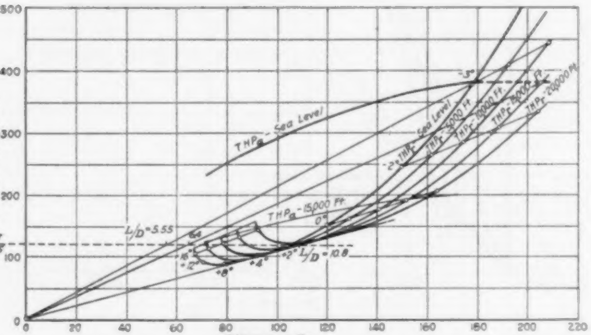

FIG. 7 THRUST-HORSEPOWER CURVES OF LOCKHEED "VEGA" HIGH-WING MONOPLANE

$$\frac{T_{HP\ ah}}{T_{HP\ a0}} = \left(\frac{\rho_h}{\rho_0}\right)^{1.35} \quad\ldots\ldots\ldots\ldots\ldots\ldots [3]$$

In order to visualize the decrease of speed at altitudes, some of the altitude curves have been plotted in Fig. 7. These show that the speed decreases very rapidly and the angle of attack increases rapidly. For an altitude of 15,000 ft. the high speed is only 152 m.p.h., and the angle of attack about 0 deg.

For a supercharged engine, if we neglect the increase in efficiency of the propeller due to higher value of V/ND, the speed will increase and the angle of attack will increase but slowly. Nevertheless a better L/D value for higher speed will be reached. For an altitude of 15,000 ft. the speed would be 206 m.p.h., L/D would increase in same ratio, from 5.55 to 6.4, and the angle of attack would increase to about —2$^1/_2$ deg.

If we replot the change in the angle of attack on the polar diagram, Fig. 6, a mathematical expression for the increase in speed at altitudes may be developed.

Since the equation for the thrust horsepower required for steady horizontal flight at sea level is:

$$T_{HP\text{req.}\,0} = \frac{1}{375 \times \pi \times 0.002558} \times S \times \left(\frac{W}{S}\right)^2 \times \frac{S}{b^2} \times \frac{1}{V_0} + \frac{0.002558}{375} \times S \times C_{D\text{par.}} \times V_0^3 \ldots\ldots [4]$$

for top-speed flight the thrust horsepower required at that speed must equal the maximum thrust horsepower available.

As stated in Equation [2], the thrust horsepower required for a given angle of attack increases at altitude as the square root of the air density. Then, since at an altitude h (density ρh) the thrust horsepower required equals the maximum thrust horsepower available at sea level, the corresponding thrust horsepower at sea level for a given angle of attack would be:

$$\frac{T_{HP\text{av.max.}}}{\sqrt{\frac{\rho_0}{\rho_h}}} = \frac{1}{375 \times \pi \times 0.002558} \times S \times \left(\frac{W}{S}\right)^2 \times \frac{S}{b^2} \times \frac{1}{V_0} + \frac{0.002558}{375} \times S \times C_{D\text{par.}} \times V_0^3 \ldots\ldots [5]$$

From this equation we can determine the corresponding speed at sea level, and the top speed at the altitude h will be

$$V_h = V_0 \times \sqrt{\frac{\rho_0}{\rho_h}} \quad\ldots\ldots\ldots\ldots\ldots\ldots [6]$$

Equation [5] is of the fourth degree and to solve it for speed V would be somewhat difficult, but if we analyze its components we can obtain very simple results.

The portion

$$\frac{1}{375 \times 0.002558 \times \pi} \times S \times \left(\frac{W}{S}\right)^2 \times \frac{S}{b^2} \times \frac{1}{V_0}$$

of Equation [5] is the induced thrust horsepower required and varies inversely as the speed. For usual wing loadings W/S is about 16 lb. per sq. ft. and the aspect ratio S/b^2 about 6, and for high-speed, well-designed planes its value at top speed would be about 5 to 10 per cent of the total thrust horsepower required. Its variation with speed with the supercharged engines up to 30,000-ft. altitudes is small, as may be seen from the polar curve.

The portion

$$\frac{0.002558}{375} \times S \times C_{D\ \text{par}} \times V_0^3$$

of Equation [5] is the parasite thrust horsepower required. It depends primarily on the aerodynamical fineness of the design, the value $C_{D\text{par.}} = \varphi \times C_{D\text{prof.}}$, being measured in terms of the profile drag coefficient. For the range of speeds considered, this portion of the drag can be assumed constant, that is, $C_{D\text{par.}}$ is parallel to $C_{D\text{ind.}}$ and increases as the cube of the speed.

Neglecting the variation of the induced thrust horsepower required for a range of speeds up to 30,000 ft. altitude, as previously stated, we can, for a given plane, by substituting the constants A, B, and C, transform Equation [5] as follows:

$$\frac{A}{\sqrt{\frac{\rho_0}{\rho_h}}} = B + C \times V_0^3 \quad\ldots\ldots\ldots\ldots [7]$$

and

$$V_0 = \sqrt[3]{\left(\frac{A}{\sqrt{\frac{\rho_0}{\rho_h}}} - B\right) \times \frac{1}{C}} \quad\ldots\ldots\ldots\ldots [8]$$

Top speed at altitude h will then be

$$V_{h\max.} = \sqrt[3]{\left(\frac{A}{\sqrt{\frac{\rho_0}{\rho_h}}} - B\right)\frac{1}{C}} \times \sqrt{\frac{\rho_0}{\rho_h}} \quad\ldots\ldots\ldots [9]$$

Top speed at sea level is

$$V_{0\max.} = \sqrt[3]{(A - B)\,\frac{1}{C}} \quad\ldots\ldots\ldots\ldots [10]$$

and if we omit the constant B, whose influence on top speed at

TABLE 2 EFFECT OF INCREASING SIZE OF PLANE

sea level is approximately the same as at altitude, we obtain a simple equation

$$V_{h\max.} = V_{0\max.} \sqrt{\frac{1}{\sqrt{\frac{\rho_0}{\rho_h}}}} \times \sqrt{\frac{\rho_0}{\rho_h}} = V_{0\max.} \times \sqrt[3]{\frac{\rho_0}{\rho_h}} \quad \ldots\ldots [11]$$

or the speed at altitude increases as the cube root of the air-density ratio.

For the altitude of 30,000 ft. the difference between the speed obtained with this simplified method and the theoretical value calculated for a given case will be little over 2 per cent, and the increase of speed will be only 36 per cent instead of 39 per cent as given by Equation [11].

Curves showing the increase of top speed at different altitudes are given in Fig. 8.

III—EFFECT OF SIZE OF PLANE

The size of the plane is of primary importance in obtaining high speed and flight efficiency.

In Fig. 6 there is shown the polar curve of a six-passenger plane with 275 sq. ft. wing area. The wing loading is 16.35 lb. per sq. ft. and the power loading 10.7 lb. per hp. The maximum L/D is 10.8, and for a top speed of 179 m.p.h. L/D = 5.55.

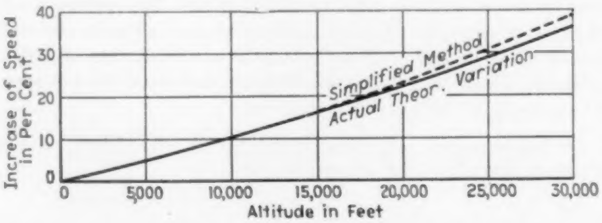

FIG. 8 INCREASE IN TOP SPEED AT ALTITUDE DUE TO CONSTANT POWER

From different flight and wind-tunnel tests the author has determined the drag of different parts of the plane and has plotted the corresponding values in the polar diagram, Fig. 6, and in the thrust-horsepower diagram, Fig. 9. Due to the angle of incidence of wing and to the interference, it has been found that the drag coefficients for fuselage, tail surfaces, and especially landing gear decrease as the low angle of attack is approached. The wing-profile drag-coefficient variation is taken from data obtained with the Langley Memorial Aeronautical Laboratory high-density wind tunnel (N.A.C.A. Tech. Note No. 367, Fig. 6).

The values of drag and thrust horsepower required for these different items at 100 m.p.h. speed are tabulated in the left half of Table 2.

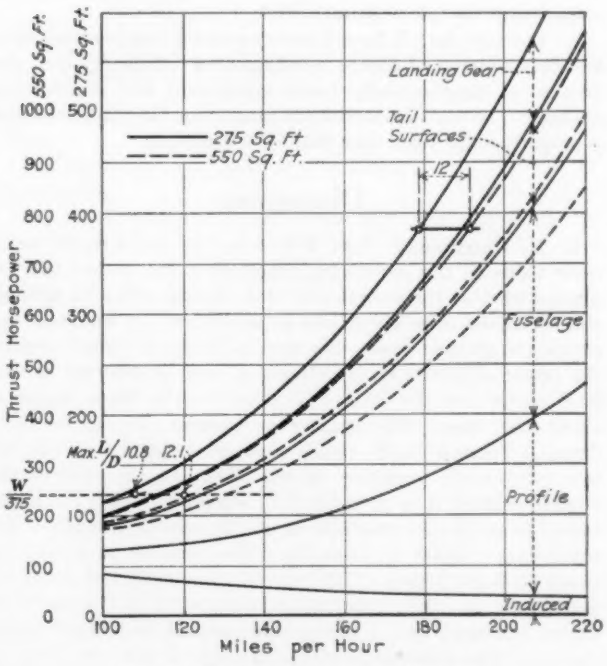

FIG. 9 THRUST-HORSEPOWER CURVES

The efficiencies of the different parts of the plane are compared with the efficiency of the wing on the basis of the ratio of the drag of each part to the profile drag, expressed as a percentage. φ = 3.046, and L/D at 100 m.p.h. = 10.7.

Let us now consider a larger plane—twice the size—of similar design. The wing and power loading will be kept the same, so that the landing speed, take-off, and climb will not be changed.

The drag and thrust horsepower required at 100 m.p.h. for this plane of 550 sq. ft. wing surface are given in the right half of Table 2. We can accordingly visualize how the corresponding parasite drags decrease in their ratio to the wing drag.

The fuselage drag coefficient is only 77.6 per cent of that of the smaller plane; the tail surfaces drag coefficient, 70.6 per cent, and the landing-gear drag coefficient, 71.8 per cent.

The ratio of total parasite drag to wing profile drag, or φ, is decreased to 2.526, and L/D at 100 m.p.h. is increased to 12.

Corresponding values are plotted in the polar diagram, Fig. 6, and shown by broken lines.

The thrust-horsepower curves are shown by broken lines in Fig. 9 to half-scale, so that the induced and profile thrust-horsepower curves for 275 and 550 sq. ft. wing are identical. We can check up an increase of 12 m.p.h. in speed, with increased efficiency. *L/D* at high speed will be = 6, as compared with 5.55 for the 275-sq. ft. plane.

Flying at altitudes would still improve the efficiency, and the speed would increase quite considerably. At 20,000 ft. altitude the top speed of 233 m.p.h. could be easily attained.

Apart from the aerodynamical advantage obtained, the improvements will be as follows:

1 Weight saving; a more efficient and lighter structure could be built for a larger unit.

2 More comfort for passengers could be provided because of a larger and roomier fuselage.

3 Better inherent stability could be obtained, because of the easier problem of weight distribution and the increased damping moment of a larger airplane. It has been shown by Professor Klemin that the disturbing moment increases with the cube of the dimensions of the airplane, while the damping moment increases with the fourth power.

4 The airplane will have a lower operating cost per passenger, not only because of higher aerodynamical efficiency, but also because of proportionally lower investment and depreciation charges. The cost of material and production for a large machine is proportionally lower than that for a small one.

Discussion

H. K. Cummings.[2] Figs. 2 to 5 in the paper would be of more value to the power-plant engineer if the author had explained whether the variation of brake horsepower with altitude was estimated from flight data or determined by means of approximate altitude tests. For each of the four Wright engines the power at 20,000 ft. is between 45 and 48 per cent of sea-level power and the rate of decrease for the Wasp engine is about the same. The engines in question are considerably "ground boosted" and require a superior quality of fuel for safe full-throttle operation at sea level. In the case of the Jupiter engines it is probable that sea-level pressure is maintained in the intake manifold up to the critical altitude of the supercharger (3300 to 4800 ft.). The decrease in power between 6500 and 16,000 ft. (28 per cent) is slightly less than that determined at the Bureau of Standards for a Curtiss D-12 engine equipped with a low-altitude geared centrifugal supercharger. The decrease in power of only 40 per cent between sea level and 20,000 ft. shown by the Packard Diesel engine is indeed noteworthy, being about two-thirds that experienced by conventional aircraft engines.

The supercharged engine which will deliver a specified horsepower at a particular altitude may weigh much less than the unsupercharged engine required to deliver equal power at the same altitude, but the engine equipped with a high-altitude geared centrifugal supercharger will not compare as favorably with the unsupercharged engine at low altitudes, on account of the power required to drive the supercharger. Although the built-in centrifugal supercharger is much used at low altitudes, the turbo-centrifugal supercharger and the Roots-type supercharger are better adapted to the problem of maintaining approximately sea-level power up to considerable altitudes. If the author contemplates engines supercharged up to 30,000 ft., as is implied in Section 2, the use of a compressor of several stages as proposed recently by Schey[3] might be considered.

With reference to advantages 1 and 4 mentioned at the end of the paper, it will probably be found necessary to supercharge the cabin of a passenger transport operating at high altitudes.

Author's Closure

The author wishes to thank Mr. Cummings for his comparison of given altitude curves with the Bureau of Standard's experiences. The altitude performances of the engines, as shown in Figs. 2 to 4, are determined by means of approximate altitude tests, keeping constant r.p.m., and the author purposely gave these three different types of operating them:

Fig. 2, where the throttle would be only partly open until the altitude of safe full-throttle operation is reached.

Fig. 3, where the boosted sea-level output is permissible (throttle fully open), provided a fuel of 87 octane value is used.

Fig. 4, where the safe intake-manifold pressure is maintained, and the throttle gradually opened up to the critical altitude.

It is believed that up to the altitude of 20,000 ft., passenger flying could be organized on existing airways, the engines having built-in centrifugal superchargers and no special equipment or supercharging of the cabin. The increase on the cruising speed would be quite noteworthy, considering that the engines would then, with wide-open throttle, deliver at that altitude the same power as at present cruising speeds at sea level. At 20,000-ft. altitude the cruising speed would be higher than the top speed at sea level, as we have it nowadays.

AER-54-7

Study on Airplane Weight Complex

By A. A. GASSNER,[1] HASBROUCK HEIGHTS, N. J.

By deciding on the type of engine and the overall dimensions of an airplane, the weight becomes quite well fixed. To obtain good take-off and climb characteristics the gross weight per horsepower should be kept low. Such items as engines, starters, propellers, generators, wheels, tires, and instruments have a weight which cannot be altered by the airplane designer, so his problem is quite difficult. In this paper the author groups the various equipment and parts of an airplane into three classes: (1) Those with weights outside the designer's direct influence, (2) those with weights over which the designer has limited influence, and (3) those with weights which can be controlled by the designer. Design data are also given for three Fokker airplanes. These are the Super-Universal, the F-10-A, and the F-32.

ONE OF THE essentials of airplane design is the treating of the weight problem. To design a plane around a given engine with a minimum of dead weight and a maximum of useful load, at the same time fulfilling demands for strength of all structural and control parts, is a problem. The finished airplane should, of course, exceed in performance all ships of the same class previously built by the same concern, and must at least equal contemporary competitive designs.

Commercial planes can be classified into three groups: (1) Mailplanes carrying only the pilot and mail or express matter, (2) training and sport planes of the open-cockpit type, and (3) passenger-transport planes of the cabin type. In this paper only the latter type will be considered in detail, although the basic principles are of course alike for all kinds of airplanes.

In treating scientific or technical problems one is most always inclined to generalize. However, one should, as far as possible, accumulate a large number of particular instances before attempting a generalization, and then attempt to discover the reason that underlies that particular collection of similar instances.

In the field of airplane design most designers are very free in giving information as to wing areas, control-surface areas, number and horsepower of engines, and such facts. With but a single exception, C. Dornier, the author has never seen statements given out by any designer on detailed weights of their ships. Magazines and sales literature contain data on the weight of empty planes, but as a rule this data means little, as information as to what equipment and furnishings are included in this weight empty is lacking.

As the author has available only the data on his own previously constructed ships, and has, unfortunately, to generalize on a rather limited number of particular cases, it is hoped that the question brought up here will have a stimulating influence in persuading other airplane manufacturers to publish their experiences with this problem.

The automobile industry is in a different position as to such trade secrets. There are none existing. Every concern buys and tries out models of the other manufacturers and the results prove profitable to every one. Unfortunately the financial question prohibits the same methods for the airplane industry, and the airplane engineer is not able to check up on his competitors to the same degree as is the automobile engineer.

Three items influence airplane weight: (1) The dimensioning and appointments of the fuselage or cabin necessary for the comfort of the passengers; (2) the demands on fuel and oil capacity of the tanks, and on cooling and operative facilities as made when the engine type and the cruising range are given; and (3) the necessary structural safety requirements. An endeavor will be made to show that the weight of a plane is predetermined to a very large degree when the engine type and the overall dimensions of the plane are chosen, and that great care has to be taken in this respect. This fact explains why new ships of designers having long experience most always prove to be successful, and that a ship specially designed around a given engine is most always better in general performance than a ship primarily designed for a different type of engine and later equipped with a more powerful motor.

It is essential to choose the right kind of material and design details for all parts of the ship. Today, one cannot say that all-metal construction is superior for the one type and the composite design with steel-tube fuselage is better for the other. Ease of production and adaptability to changes have a great influence on this selection. It can, however, be said that one special type of design of tanks, engine mounts, floors, etc., is basically superior to another.

To the airline operator the plane is merely another and new form of transportation vehicle. He manufactures and sells transportation, and the fundamental principles of all manufacturing business have to be taken care of. He can sell his transportation only when the public derives a material benefit by buying it in preference to older methods, and if the saving in time, which is the one advantage of airplane traveling, is not derived by a disregard of comfort and safety. Comfort is a rather indefinite term, but the traveling public seems to have accepted the facilities as offered by the railroads in Pullman cars as satisfactory. People want more than necessities, they demand luxuries.

The airline operator expects, therefore, that his planes are comparable to busses and railroad Pullman cars so far as the interior equipment and arrangement are concerned. Large windows which afford unobstructed view, good heating and ventilating facilities, and large, comfortably upholstered chairs and ample leg room and sufficient aisle space are needed. The

---

[1] Chief Engineer, Fokker Aircraft Corp. of America. Mr. Gassner was born on Sept. 19, 1893, in Vienna, Austria. He studied at the High School, Vienna, and at the Technical University, Vienna, in mechanical engineering and shipbuilding, graduating in 1913. His professional experience includes the following: 1913–1915, designing engineer, Jacob Lohner Airplane Works, Vienna; 1915–1917, chief designer, Austro-Aviatik Airplane Works, Vienna, where he designed the Aviatik observation and bombing planes; 1917–1919, chief engineer, Vienna Aircraft Works, where he designed the WKF pursuit and observation planes; 1919–1923, part-owner and general manager of Moeve Motorboat Works, Vienna; 1923–1924, deisgning engineer, International Motor Corporation, New York; 1924–1926, project engineer, Atlantic Aircraft Corporation; from 1927 in his present position.

Presented at a meeting of the Metropolitan Section, New York, N. Y., Nov. 18, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

larger type planes have to be equipped with lavatories, pantries, folding tables, thermos bottles for drinking water, ice boxes, and other equipment of this nature.

The designer or manufacturer of the commercial transport plane has to solve a difficult problem. He must provide all this luxurious equipment which the modern traveler demands, and still keep the weight of the plane as low as possible to ensure good performance, a problem which does not exist to any such extent in other branches of manufacturing of transportation vehicles.

The designer has less freedom in handling this weight problem than one might first suppose. Of course, all purchasers, be they private individuals, business corporations, or operators of commercial airlines, consider the disposable load which can be carried by the plane as one of its most useful characteristics.

Weight empty plus disposable load makes the gross weight of the ship. The author's experience shows that the gross weight of a modern commercial plane as used in this country should be between 10 and 15 times the rated horsepower for multi-engined ships, and between 13 and 18 times the rated engine horsepower for single-engined ships. The gross weight for the same total horsepower must be lower for multi-engined ships as this class has to be able to continue level flight with full load if one engine ceases to function.

To obtain good performance, especially good take-off and climb characteristics, the lower factor of the ones given should be used. As the gross weight has to be kept within rather narrow limits, it is necessary to reduce the weight empty of the plane if one wishes to increase the disposable load.

There are a number of items on each plane which have a prefixed weight which cannot be influenced by the designer of the airplane. This group consists of engines, starters, propellers, generators, wheels, tires, instruments, etc.

The type and horsepower of the engine are in most cases given before the first sketches of the plane are made. Sometimes a different design of engine is substituted for the old one during the manufacturing of the type, but in both cases the airplane designer has very little choice, as the engine selection depends on a number of factors, as for instance, price, horsepower, method of cooling, service facilities, and reputation of the engine-manufacturing company.

Selection of the engine circumscribes the gross-weight range of the airplane, and determines the type and thereby the weight of starter, wheels and tires, propellers, engine instruments, ignition switches, etc. In most of the cases the purchaser of the plane gives specifications as to the electrical equipment to be used. This means that one must consider the weight of generator, batteries, electric-light equipment, and electric inertia starters with cables and switches as fixed, and cannot be influenced by airplane designers. The Department of Commerce regulations provide that all commercial planes must be equipped with safety belts for passengers, and with first-aid kits and hand fire extinguishers, the weights of this equipment also being fixed.

In a second group are items on which the designer has a limited influence as far as weight is concerned, because he has but a limited choice of material and has to consider very definite requirements made by the sales department or by the purchaser of the ship. This second group consists of fuel and oil tanks, fuel and oil pipe lines, fuselage and nacelle cowlings, exhaust system, cabin and cockpit floors, cabin windows, pilots' and passenger seats, cabin interior walls and doors, upholstery, baggage racks, toilet equipment, cabin sound insulation, cabin floor carpet or linoleum, electric-light installation, and engine controls.

The third group consists of weights of items on which the designer has direct influence. These are all structural parts, such as wings, fuselage, tail surfaces, landing-gear structure, nacelle structure (outboard engine mount), and flying control group.

In Tables 1 to 4 these weights and their percentage of weight empty are given for three entirely different types of ships—the Fokker Super-Universal, the Fokker F-10-A, and the Fokker F-32. All these ships are well known in this country and their specifications are given in Table 5. Although these ships are so entirely different from each other in engines, loads carried, size, wing, and power loading, it is surprising how closely the

percentages of weight empty of groups A, B, and C come. The average percentage of weight empty is 35.4 per cent for group A, 20 per cent for group B, and 44.6 per cent for group C.

The fact that about 55 per cent of the weight empty of any landplane of the commercial cabin type is either entirely outside of the plane designer's influence or can be influenced only to a very limited degree, is also indicated by a comparison of ships built by different manufacturers around the same engines for the same general purpose, but of different structural design.

As already mentioned, the weights of empty planes as published do not always contain a list of items of equipment included in this weight, nevertheless the variation between these figures is small.

Operators of air lines and most private purchasers have in mind a fixed program as to where the ship is to be used. The distance between refueling fields plus a generous margin for delays due to weather conditions is specified as the range at cruising speed. If the engine has been pre-selected, as is usually the case, it is necessary to divide the required range by the cruising speed which has been roughly estimated, and one obtains thereby the duration of flight without refueling at cruising speed and engine revolutions of about 85 per cent of maximum design revolutions.

The power and fuel-consumption curves of the engine give the fuel consumption in gallons per hour, and as the duration of flight without refueling in hours is known, one can easily calculate the required tank capacity. Fuel tanks have a weight of 0.75 to 0.95 lb. per gal. capacity if constructed of brass, and a weight of 0.45 and 0.55 lb. per gal. capacity if made of aluminum or aluminum-alloy sheet.

There are left to the designer but two possibilities of influencing the fuel-tank weight: One is to increase the cruising speed, and with a given distance between refueling, thereby reduce the amount of fuel which has to be carried at take-off. The second possibility is to use lighter material for the tank construction. Most ships built during the last few years are, however, using aluminum tanks of either riveted or welded construction, and further weight reduction in this type is not very probable on account of serviceability and maintenance problems.

More promising is the way of increasing cruising speed. The average range to be flown without refueling is about 500 miles. If the ship has a cruising speed of 120 miles and is equipped with a single Wasp engine running at about 1600 r.p.m., the fuel consumption is 19 gal. per hr., the duration of flight is 4.16 hr., and the necessary fuel capacity therefore 79 gal. If the tank is of aluminum with a weight of 0.5 lb. per gal. capacity, the tank weighs 40 lb.

When the cruising speed is increased by 10 per cent to 132 m.p.h., the duration becomes 3.79 hr., the fuel required is 72 gal., and the tank weight is 36 lb. In this particular case an increase of cruising speed of 10 per cent means, therefore, a saving on tank weight of 10 per cent.

The fuel-tank weight is, however, only between 2 and 4 per cent of the weight empty as has been found for a great number of transport planes, and a saving of 10 per cent of the tank weight is comparatively negligible by itself, as it would mean only a saving of 0.2 to 0.4 per cent of the weight empty. However, these possibilities of small individual savings repeat themselves many times during the designing of new planes, and are well to be remembered as they may total up to 5 or 8 per cent of the weight empty.

Increase of cruising speed by 10 per cent from 120 to 132 m.p.h. reduces the amount of fuel to be carried at take-off for a range of 500 miles from 79 gal. to 72 gal. This means a weight reduction of 7 × 6 = 42 lb. for the fuel and 4 lb. for the fuel tanks.

The total saving of 46 lb. can be either carried as pay-load or the wing can be reduced in area. For the single Wasp-engined ship which is considered here, a wing loading of around 13 lb. per sq. ft. would be appropriate. The wing area could therefore be reduced by about 3 sq. ft., and if the wing weight is 1.8 lb. per sq. ft. another 5.4 lb. is saved.

For this example the weight empty has been reduced by the 4 lb. as calculated for the fuel tank and 5.4 lb. for the wing, i.e., a total of 9.4 lb. The useful load has been reduced by 42 lb. of fuel, and the gross weight thereby by 51.4 lb. This single Wasp ship would have a gross weight of about 5000 lb., and by all the careful consideration and the assumption of an increase of cruising speed of 120 m.p.h. by a full 10 per cent, only 1 per cent of the gross weight of the ship was saved.

The oil tanks cannot be made smaller by decreasing the fuel-tank capacity, because of the heating up of oil and because of the reserve capacity necessary. Tanks of a capacity of less than 3 gal. for each 100 b.hp. of the engine cannot be installed. The only way to save weight in oil-tank construction is by the use of aluminum or aluminum-alloy tanks instead of brass or terne-plate tanks which have been previously used.

The fuel and oil lines again are more or less determined by the choice of the engine, i.e., at least as far as their inside diameter is concerned. Copper pipes are used for fuel lines, as aluminum in the required small diameters is too easily damaged and more apt to crystallize. Oil lines, however, are made of aluminum tube in most of the larger ships. With the size of the pipe lines are also given the size and weight of all pipe fittings and connections as well as of the fuel cocks, strainers, drains, etc.

The only possibility for the designer to save weight is therefore by decreasing the length of the pipe lines. For the oil lines this can be done by placing the tank close to the engine. The fuel tanks are now carried in the wing in most of the ships of the class under discussion, and the distance to the carburetor is determined by a number of other considerations, as for instance, weight distribution and balance, and cannot be changed for the sake of saving a few feet of pipe. The weight of the fuel and oil pipe lines is determined to 70 per cent or more by the choice of the engine, and only the remaining 30 per cent or less can be influenced by the designer.

Cowling for air-cooled engines is determined by cooperation between engine and plane manufacturer, and in many cases the difficulty is to keep the engine warm enough, contrary to the common conception. Weight of cowling, which is of course always made of aluminum or aluminum-alloy sheet, is depending therefore to a very large percentage on size and power of the engines. The same is true for the exhaust system, with the additional requirement of means of silencing, which is necessary for the comfort of pilot and passengers. On some engines the exhaust system has to be made so that exhaust gases can be used for heating up the fuel mixture or so that air, preheated by exhaust, can be supplied to the carburetor. Weights of such devices should be actually added to the engine weight, as it is most always impossible to operate the engine without them.

Closely connected with the exhaust problem is the cabin-heating question, as practically all planes are now heated by fresh air which passes over the hot exhaust pipes or mufflers. Cabin size and shape have, of course, great influence on design and size of the cabin heater, and efficient heating, with ventilation, is one of the many cases where consideration of passenger comfort requires additional or increased devices, and therefore weight increase.

Cabin floor space is determined by the number of passengers carried. For each passenger a floor space of at least $4^{1}/_{2}$ sq. ft. area is required, and the larger multi-engined ships provide 6 to 7 sq. ft. These figures include the floor space under chairs and benches, but not floors in pilot's cockpit, entrance compartments, toilets, galleys, and baggage compartments. This requirement of floor space and the necessary strength requirements are determining the floor weights to a large degree.

Large cabin windows must be provided for the passengers' comfort, and window panes and frames must be sufficiently strong to resist the air pressures. The use of non-shatterable glass is advisable on account of its safety value. It has, however, the disadvantage of weight increase.

The weight of window per passenger decreases with the increase in size of the plane, as it becomes necessary to arrange three or four seats side by side and two passengers use one window.

Cabin interiors, with walls, doors, bulkheads, upholstery, sound-proofing, baggage racks, chairs, cushions, and a number of minor items, have to be designed for passenger comfort, and become a rather intricate engineering problem with increase of size of the ship. Many pounds can be saved or wasted on these items, but the demands of operators and sales departments are justly concentrated on satisfying the traveling public.

There remains therefore only the group of structural parts on which the designer's influence on weights is not limited, and this group makes approximately 45 per cent of the weight empty. If the designer is able to save as much as 10 per cent of the weight of this group, he will be saving only $4^{1}/_{2}$ per cent of the weight empty or around $2^{1}/_{2}$ per cent of the gross weight. A lightening of the structural parts by 10 per cent can only be accomplished by using the most efficient design, and the best available materials.

From all this it can be seen that only close cooperation and understanding between all parties concerned, and closest control of weights of all parts of the ship will have the desired effect of reducing the weight of the empty plane. A logical procedure in starting a layout of a new type of ship would therefore be to determine first the weights as definitely given by choosing the engine and accessories, and by determining weights of the group upon which the designer has limited influence. During this stage, careful study is necessary to make sure that all the items of equipment and furnishing are really absolutely essential, and that none of them could be spared in the particular design. Every effort has to be made to keep the size of the ship, for a given motor, as small as possible, and as commensurate to the comfort and safety of passengers and crew.

Discussion

T. P. Wright.[2] The writer is in entire agreement with the author on the importance of weight control in airplane development. It is one of the items existing in airplane design which is different from those found in other branches of engineering as regards importance and, therefore, one which is rather novel in nature, and on which there are no precedents to work.

Weight charts have been prepared similar to those appearing in the paper, but applicable to widely varying types; namely, the Condor, an 18-passenger transport; the Carrier Pigeon, a 2000-lb. payload mailplane; and the Fledgling, a 2800-lb. training plane. (See Tables 6 to 10.) It is interesting to note that the average percentages of weight empty given in the paper for the three groups listed compare as follows, giving a very close check:

	Fokker	Curtiss
Group A	35.4	35.1
Group B	20.0	21.8
Group C	44.6	43.0

The author states that his experience indicates that the gross weight of a modern commercial plane should be between 10 and 15 times the rated horsepower for multi-engined ships and 13 and 18 times for single-engined ships. On the Condor, this ratio becomes 14.9, on the Carrier Pigeon 12.7, and for the Fledgling 11.9, which do not follow the statement above. The author shows that a 10 per cent increase in cruising speed gains only 1 per cent saving in weight. Assuming that the 10 per cent increase in cruising speed is obtained by greater r.p.m. of the engine, should not the fuel consumption per hour also increase?

Fuel capacity, max. (gal.)	444	175	40

In conclusion, the most important and significant fact brought out by this discussion is that the designer of an airplane has a very narrow margin within which he is able to exercise his ability of efficient design from the weight standpoint. This limited margin averages 28.5 per cent of the gross weight of the three types chosen for the discussion. The matter of weight control is of extreme importance in airplane design, and the paper is of interest to all aeronautical engineers.

C. T. Porter.[3] The paper is extremely well expressed and very timely. Although the material presented is well known to the experienced designer, nevertheless a careful study of the weight ratios as given should do a great deal to discourage the enthusiasts who hope by revolutionary methods of construction to make impossible savings in weight, and to get great increases in performance.

It seems to the writer that inasmuch as so much of the weight of an airplane is outside the control of the designer, the real saving is to come from better aerodynamic design, which, as the author shows, will have immediate effect on the weight of fuel carried per passenger mile. It would seem that he might have elaborated a little more on the saving in weight through reduction of power required per passenger with increased aerodynamic performance, as this seems to be the direction in which all development should point. Weight tables and general

Lessiter C. Milburn.[4] There is one point on which the writer would like to comment, namely, that the company with which the writer is connected has been building service-type vibration-tested, riveted aluminum-alloy gasoline tanks in capacities varying from 50 to 350 gal. with unit weights of about 0.32 lb. per gal. as compared to the minimum figure of 0.45 which the author mentions. This represents a direct saving of 0.1 lb. per gal. or 50 lb. on an airplane of 500-gal. capacity.

Altitude Laboratory Tests of Aircraft Engines[1]

By H. K. CUMMINGS[2] and E. A. GARLOCK,[3] WASHINGTON, D. C.

This paper gives a concise description of the altitude laboratory and its operation, followed by a discussion of available reports on altitude laboratory testing at the Bureau of Standards during the past 13 years and a summary of conclusions drawn as to engine performance under altitude conditions. Experimental data are presented on a modern 12-cylinder aircraft engine to illustrate (1) the effect of pressure and temperature on power and (2) some theoretical and practical advantages from supercharging. Additional problems to be studied with the present equipment and the need of an altitude laboratory for testing air-cooled aircraft engines are mentioned. Approximate altitude performance data on engines of the latter type are already being obtained by the Navy Department.

THE power delivered by an internal-combustion engine operating a mile above sea level is reduced about 20 per cent by the decrease in air density, while the loss in power at an elevation of two miles is at least 30 per cent. Consequently, the designer of aircraft power plants is vitally concerned with the effects of altitude on engine power and performance. Complete information on this subject cannot be obtained from flight tests, for the change in air density affects the air resistance and the propeller efficiency, as well as the performance of the power plant.

H. K. Cummings

E. A. Garlock

Early in the World War, tests of the Liberty engine and of centrifugal superchargers were made on Pike's Peak, although the equipment which could be transported to the altitude of 14,000 ft. permitted only crude tests. The Bureau of Standards, therefore, in cooperation with the National Advisory Committee for Aeronautics, undertook in 1917 the design and construction of an altitude laboratory (1)[4] where complete tests of aircraft-engine performance could be made under the precise conditions of temperature and pressure which prevail at various high altitudes.

The Altitude Laboratory

This laboratory was the first of its kind in the world, although a similar laboratory has since been built in France, and altitude laboratories are contemplated or under construction in Italy and Japan. The original testing plant (2) has been modified from time to time to provide increased capacity, better control of test conditions, and improved safety (30) in operation. The present altitude laboratory (36) comprises an altitude chamber, air-conditioning apparatus, a battery of exhaust pumps, and power-absorbing equipment, together with apparatus for metering the amounts of air, fuel, oil, and water supplied to the engine and means for measuring engine temperatures and pressures.

Referring to Figs. 1 and 2, the altitude chamber is a room about 15 ft. long, 7 ft. wide, and 7 ft. high inside, with walls of reinforced concrete capable of withstanding an external pressure of 1 ton per sq. ft. This room contains refrigerating coils and the stand on which engines are mounted. Opposite the engine stand are doors opening outward into safety tunnels which lead to the outside of the building. When the chamber is exhausted for an altitude test, the doors are held tightly closed against rubber gaskets by the differential pressure, but should an explosion occur within the chamber, they are free to open, relieving the pressure without damage to the chamber. No one is permitted in the tunnels when a test is in progress.

In the insulated air-cooling box above the altitude chamber, the carburetor air is passed successively over four banks of refrigerating coils which cool it to a low temperature and remove most of its moisture as frost. The air then enters a chamber of large cross-section where any entrained snow tends to settle out, due to the slower speed. Heating grids for final temperature adjustment are next encountered by the cold, dry air. The insulated pipe from the air-cooling box to the altitude chamber contains a 6-in. throttling valve, with a 3-in. valve in parallel. The latter is used for final adjustment of the carburetor air pressure. The air flow is measured by means of a calibrated venturi in the pipe line between the throttling valves and the carburetor. The refrigerating plant includes a positive-displacement booster pump which takes ammonia vapor from the coils at an absolute pressure of 5 lb. per sq. in. and delivers it at atmospheric pressure to the two 25-ton ammonia compressors. This equipment makes it possible to supply engines using up to 1000 cu. ft. of air per minute with practically dry air at temperatures down to —40 deg. cent.

The two direct-driven water-sealed vacuum pumps shown in Fig. 1 are used to remove the engine exhaust gases. The engine exhausts into a special water-jacketed manifold, and a water spray is injected to cool the gases. The quantity of water used and its rise in temperature serve to measure the heat dissipated in the exhaust. By suitably controlling the pump suction a pressure corresponding to the desired altitude is maintained at the exhaust ports. Two smaller vacuum pumps in an adjacent building are connected to the altitude laboratory by means of a 10-in. main. One of these pumps is usually sufficient to reduce the pressure of the air in the altitude chamber to the desired figure. The minimum pressure which can be maintained at the exhaust ports corresponds to an altitude of about 30,000

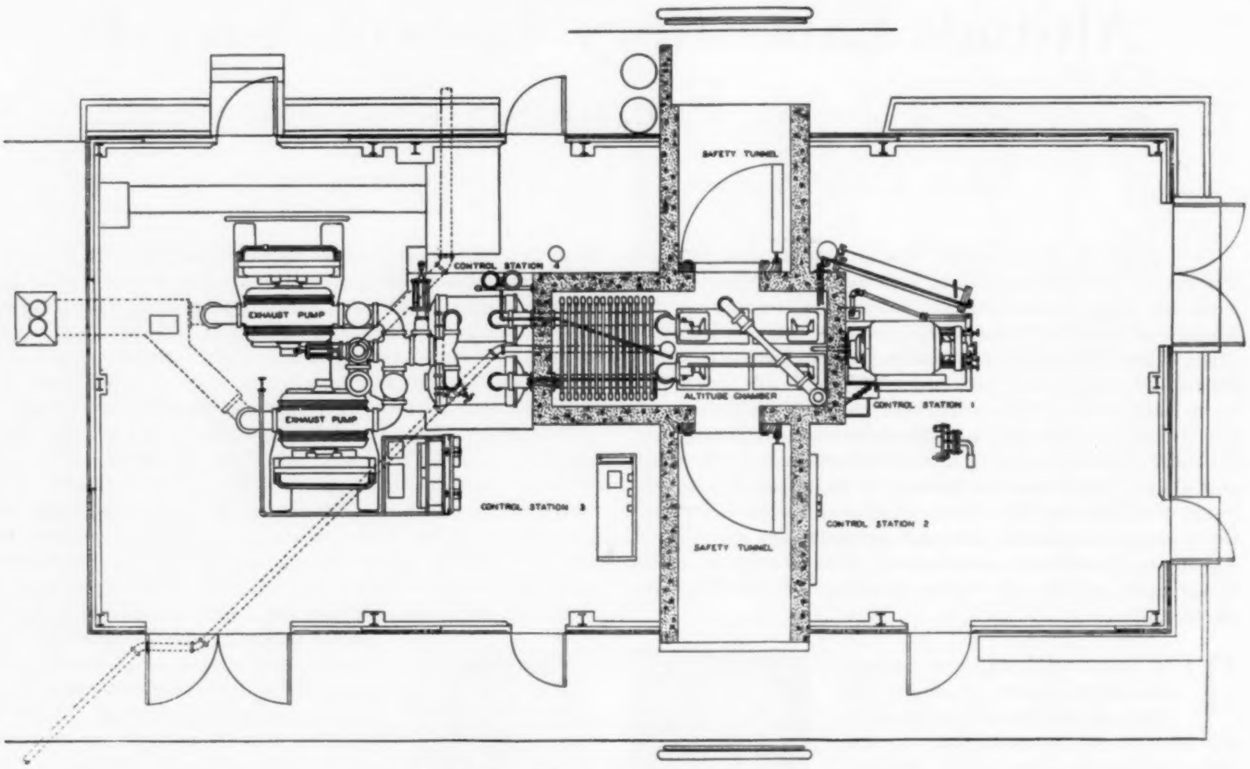

FIG. 1 PLAN VIEW OF ALTITUDE LABORATORY

ft., but the air pressure at the carburetor and that surrounding the engine can be held at a lower value if desired.

At the first control station are located the usual engine controls and instruments. The combined electric dynamometer and water brake, coupled to the engine by means of a shaft carried through the altitude chamber wall, is capable of absorbing at least 700 hp. The temperatures of jacket water and engine oil are regulated by circulating them through tanks which are maintained at constant temperature by admitting steam or cold water as required. From the inlet and outlet jacket-water temperatures and the quantity of water circulated, the heat dissipated in the jacket water is computed.

At the second control station are barometers and manometers for reading absolute pressures and pressure differences. The engine exhaust and chamber pressures are adjusted by hydraulically operated valves and the carburetor air pressure by valves controlled by hand wheels. The venturis used to measure carburetor air, jacket water, and exhaust water are read here.

All recorded temperatures are obtained at the third control station, using thermocouples connected to a potentiometer through selector switches. From this station the heating grids which determine the temperature of the carburetor air are controlled.

Fuel consumption is determined at the fourth control station by timing the flow from a calibrated measuring tank. These tanks are filled by air pressure from fuel drums kept outside the building. During an altitude test the pressure on the fuel in the measuring tank supplying the engine is adjusted with respect to the air pressure at the carburetor entrance.

To insure simultaneous observations, annunciators and signal lights are installed at the pressure, temperature, and fuel stations. The operators also can communicate by telephone without leaving their posts. The staff consists of a test engineer assisted by an airplane-engine mechanic and three observers.

Reports on Altitude Tests

The tests conducted in the altitude laboratory during the past 13 years have been of three general kinds: (*a*) Performance tests of a particular engine under specified conditions, such as those laid down by the Army (9) in 1920. (*b*) Comparative tests of a given engine under various conditions or with various compression ratios. (*c*) Tests for the purpose of comparing fuels, lubricants, carburetors, methods of carburetor control, induction systems, and various gear-driven superchargers.

Tests of the first kind were made for the Army or the Navy on many representative engines, and the results obtained on the following engines have been released for publication: Liberty 12 (13), 300-hp. Hispano-Suiza (14), 300-hp. Maybach (20), and 185-hp. B.M.W. (21). Tests of the second kind were made specifically on Liberty, Hispano-Suiza, Packard, and Curtiss engines, but much data obtained on other tests with these engines are also available for use. The first two reports issued in printed form considered (*a*) compression ratio, pressure, and temperature (3) and (*b*) heat losses, friction, and engine speed, (4) and were based on tests of the 150-hp. and 180-hp. Hispano-Suiza engines. A second analysis by Gage (16) considered tests of the 300-hp. Hispano-Suiza and Liberty 12 engines. The effect of temperature (24), compression ratio (25), and friction (31) were later considered individually by Sparrow, who also presented a general discussion of aviation-engine performance (29) before the Franklin Institute in 1925. Tests of the third kind are represented by six reports on fuels or carburetion: two in 1918 (5, 6), two in 1920 (10, 11), one in 1924 (23), and one in 1925 (28).

In connection with many of the reports cited, it should be pointed out that the precise relationship between altitude, pressure, temperature, and density known as the standard atmosphere (27, 33) was not used in the altitude laboratory prior to 1924. The actual relation used is shown graphically in most reports.

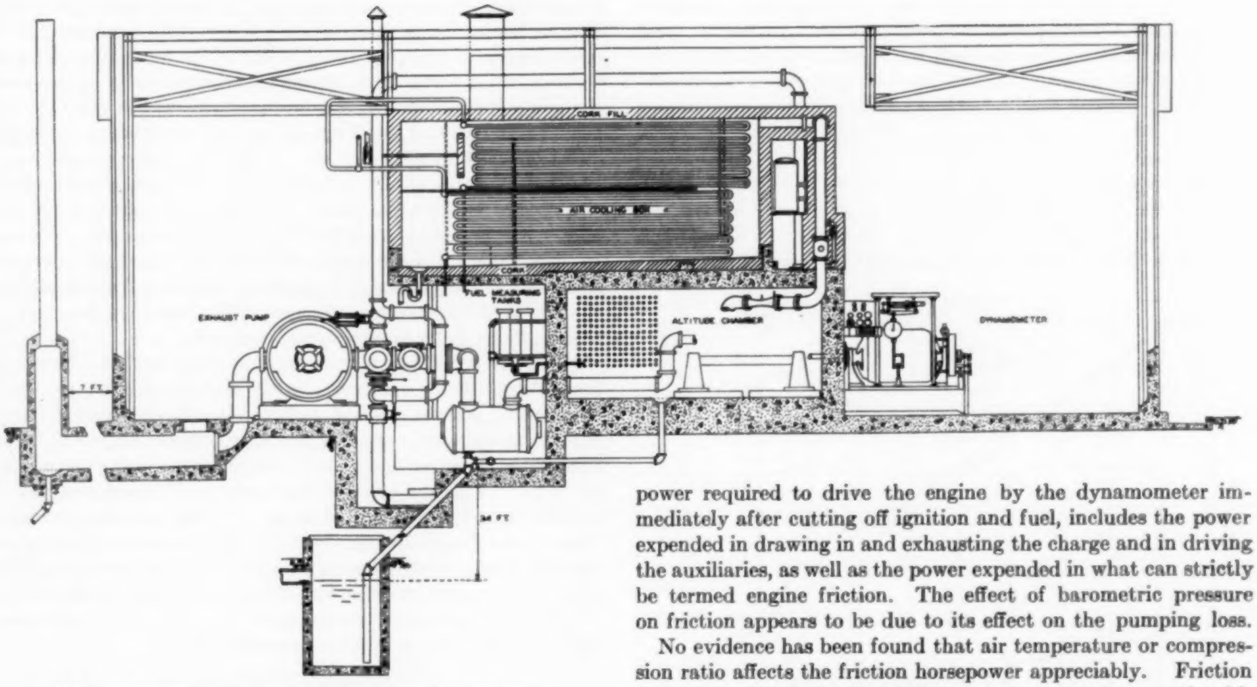

Fig. 2 Sectional Elevation, Altitude Laboratory

In some cases the change of altitude or air density means only a change of pressure.

Engine Performance at Altitude

Indicated Horsepower. The altitude laboratory tests appear to be most satisfactorily compared on the basis of indicated horsepower, defined as the sum of brake horsepower and friction horsepower. The difficulty of obtaining satisfactory indicator cards of high-speed engine performance at sea level is well known, and while the balanced diaphragm indicator (15) developed at the Bureau of Standards makes it possible to obtain indicator cards at any altitude, the variations in pressure shown by the shaded areas in Fig. 3 make such cards only qualitative. These particular cards were obtained on a 300-hp. Hispano-Suiza engine operated at 1800 r.p.m. and have been discussed in *Automotive Industries* (22).

The indicated horsepower of water-cooled aircraft engines appears to vary directly as the pressure and inversely approximately as the square root of the absolute temperature. A priori, the indicated horsepower should depend on the weight of charge received by the engine per cycle. Hence the volumetric efficiency, defined as the ratio between the volume of charge received per cycle measured at the temperature and pressure existing at the carburetor entrance and the piston displacement, must vary approximately as the square root of the absolute temperature, because the density of the air supplied to the carburetor varies inversely as the absolute temperature. It should be remarked at this point that the foregoing discussion applies only to comparisons of power at the same engine speed and fuel-air ratio. The effect of increasing compression ratio (i.e., expansion ratio) is to increase the indicated thermal efficiency approximately in proportion to the air-cycle efficiency, provided the character of the fuel is such that neither detonation nor preignition occurs at either compression ratio (28). The increase in thermal efficiency is accompanied by a decrease in the relative heat losses to the water jacket and in the exhaust.

Friction Horsepower. Friction horsepower, measured by the power required to drive the engine by the dynamometer immediately after cutting off ignition and fuel, includes the power expended in drawing in and exhausting the charge and in driving the auxiliaries, as well as the power expended in what can strictly be termed engine friction. The effect of barometric pressure on friction appears to be due to its effect on the pumping loss.

No evidence has been found that air temperature or compression ratio affects the friction horsepower appreciably. Friction decreases with increasing jacket-water temperature and with decrease in barometric pressure. For all engines tested, the average decrease in friction mean effective pressure (f.m.e.p.) was found to be 0.1 lb. per sq. in. for 1 cm. of mercury decrease in barometric pressure. In the normal operating range, the f.m.e.p. increases with engine speed, but in most instances the percentage increase is less than the percentage increase in speed. The increase in friction resulting from a decrease in throttle opening is also due to change in pumping loss. For a group of representative engines, the change in f.m.e.p. accompanying a change in manifold suction of 1 in. of mercury was found to range from 0.2 lb. per sq. in. at an engine speed of 1200 r.p.m. to 0.4 lb. at 1800 r.p.m. The estimated value at 2200 r.p.m. is 0.5.

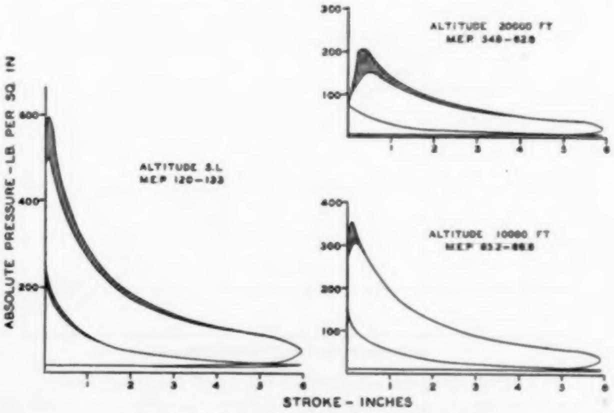

Fig. 3 Specimen Indicator Cards

(These cards were obtained during the altitude test of an eight-cylinder, water-cooled V-type engine having a 5.51-in. bore, 5.91-in. stroke, and a compression ratio of 5.6 to 1. The speed during this test was 1800 r.p.m.)

Brake Horsepower. From the foregoing discussion, it is evident that, while brake horsepower is a function of barometric pressure and air temperature and is not uniquely defined by specifying the air density, the brake horsepower should not be assumed to vary inversely as the absolute temperature or as the square root of the absolute temperature. When it is not practicable to make an altitude test, the mechanical efficiency may be determined at sea level and its variation with altitude estimated (29) or the empirical formula given in the early report on the "Effect of Temperature on Power" (3) and quoted in various textbooks may be used.

Fuel-Air Ratio. It is the practice of the Bureau of Standards to obtain the maximum power value in any engine test from a mixture-ratio run rather than to rely upon the correctness of a single carburetor adjustment for maximum power. This has given a large amount of data from which to estimate the effect of various factors on the fuel-air ratios giving maximum power and maximum economy. The following conclusions were stated by Sparrow (23): (*a*) With gasoline as a fuel, maximum power is obtained with fuel-air mixtures of from 0.07 to 0.08 lb. of fuel per pound of air; (*b*) maximum power is obtained with approximately the same ratio over the range of pressures and temperatures encountered in flight; (*c*) nearly minimum specific fuel consumption is secured by decreasing the fuel content of the charge until the power is 95 per cent of its maximum value. These conclusions are not affected by differences in engine speed or compression ratio, but faulty distribution to the various cylinders is likely to result in the use of unnecessarily rich mixtures.

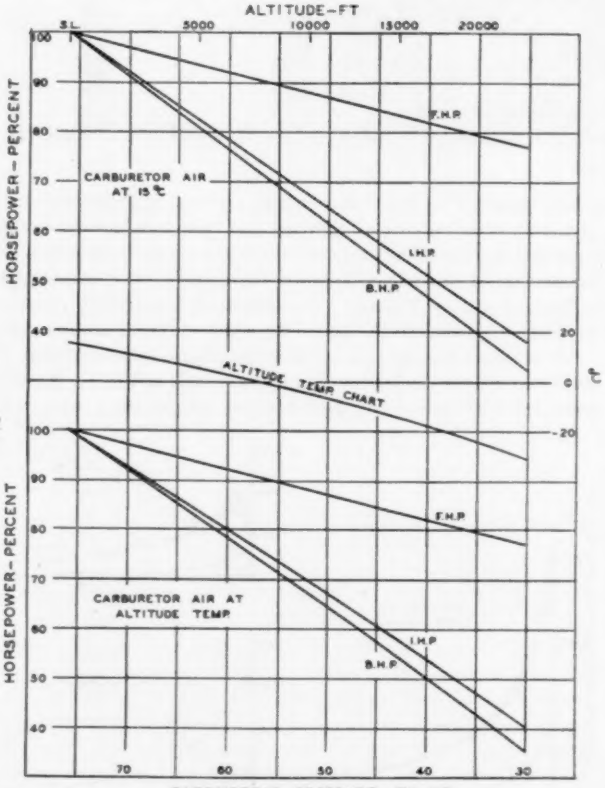

FIG. 4 CHANGE OF ENGINE POWER WITH ALTITUDE

(Showing the effect of pressure alone and the combined effect of pressure and temperature on indicated, friction, and brake horsepower. These curves are based on altitude tests of a modern twelve-cylinder, water-cooled, V-type engine having a 4.5-in. bore, 6-in. stroke, and a compression ratio of 5.3 to 1. The speed during this test was 2000 r.p.m.)

Air Humidity. Recent tests in the altitude laboratory have showed that indicated horsepower is decreased by air humidity at altitude in the ratio of the absolute humidity to the barometric pressure. Humidity not only decreases power, but changes the effective mixture ratio and the optimum spark advance. The correction of engine tests for humidity is discussed in a recent research paper by Brooks (35). The maximum effect of humidity under standard atmosphere conditions is to decrease the power 1.7 per cent at sea level, 0.7 per cent at 5000 ft., 0.4 per cent at 10,000 ft., and 0.2 per cent at 15,000 ft. so that the direct effect of humidity of the air used in altitude tests is not important above 10,000 ft. However, a more serious effect of moisture in the air is observed when air of high relative humidity is supplied to the carburetor at temperatures at or below 10 deg. cent. Erratic performance and a marked decrease in power are likely to result from the formation and accumulation of snow in the carburetor. Similar difficulties may be encountered in flight under some circumstances (18).

Vapor Lock. Vapor lock is another flight hazard which was first identified in connection with altitude laboratory tests. When using volatile gasoline under high altitude pressure conditions at temperatures above 0 deg. cent., erratic engine performance was experienced and traced to interruption of the fuel supply by vapor. This difficulty is now quite well recognized and is familiar to many operators of motor vehicles as well as to pilots. Fuel-system design frequently limits the volatility of the gasoline which may safely be used, especially in warm weather. This boiling of the gasoline in the fuel lines would be less likely to occur at altitude if provision were made to have the fuel in the main tank promptly reach altitude temperature.

EXPERIMENTAL DATA

Below are presented hitherto unpublished results of tests on a well-known 12-cylinder water-cooled aircraft engine having a $4^1/_2$-in. bore and a 6-in. stroke. The compression ratio was 5.3 and the operating speed 2000 r.p.m. in all tests.

Effects of Pressure and Temperature on Power. In the upper part of Fig. 4 is shown the relative change in horsepower with barometric pressure or altitude when the carburetor-air temperature is held constant. Under these conditions the variation of indicated, friction, and brake horsepower with barometric pressure is linear and the decrease in indicated horsepower is almost directly proportional to the change in pressure (at B = 39 cm. Hg, the indicated horsepower is reduced to one-half its sea-level value).

In the lower part of Fig. 4 is shown the relative change in horsepower with barometric pressure when the carburetor-air temperature varies according to the standard atmosphere. Since friction horsepower does not vary with air temperature, this curve is unchanged. In both cases the friction horsepower has 79.5 per cent of its sea-level value at 20,000 ft. Both the indicated- and brake-horsepower lines are now slightly convex upward. At 20,000 ft. the indicated horsepower is reduced to 47.5 per cent of its value at sea level and the brake horsepower to 43 per cent, as against 44.5 per cent and 39.7 per cent, respectively, at 15 deg. cent. carburetor-air temperature.

The effect on indicated horsepower of varying carburetor-air temperature at constant barometric pressure is illustrated in Fig. 5. Sparrow's discussion of the temperature correction (24) was based on 1600 measurements lying chiefly between —20 and +40 deg. cent. Here the range from —38 to 100 deg cent. is covered, and only the lowest point departs as much as 2 per cent from the curve which represents the inverse square-root relation. Gardiner and Schey (32) reported tests of a Liberty 12 engine over the range from 7 to 82 deg. cent. in which the variation of indicated power was approximately linear and intermediate between the inverse square-root relation and the inverse first-power relation. On the contrary, a test of the same engine at the Bureau of Standards in 1926 showed agreement with the inverse square-root relation within 2 per cent from 15 to 106 deg. cent.

Supercharging. A brief paper on the "Value of Supercharging" (3) by Dickinson and Anderson (originally issued as Aeronautic Power Plants Report No. 9) presents a family of curves showing the relative change with altitude in the normal sea-level brake horsepower of an engine when the air pressure at the carburetor entrance is maintained constant as exhaust pressure is reduced. These curves were obtained to show what gain in horsepower may reasonably be expected through supercharging and were used by Kemble (12) in calculating performance curves for an aircraft engine equipped with a centrifugal supercharger. A reexamination of the data on which the curves were based suggested that they might be redrawn as straight lines, giving a chart similar to Fig. 6, which was obtained with the 12-cylinder engine already mentioned, operated at a speed of 2000 r.p.m. with the carburetor air at 15 deg. cent.

Lines *A-B* and *A-C* in Fig. 7 are taken from Fig. 6 and represent respectively, the relative brake horsepower of the unsupercharged engine at various altitudes and the gross brake horsepower of the same engine with sea-level pressure maintained at the carburetor entrance at all altitudes. Line 1–1–1 shows the net brake horsepower when the engine is supercharged by means of a gear-driven Roots-type supercharger having a rated altitude of 7500 ft. Line 2–2–2 shows the net brake horsepower when the engine is supercharged by means of a gear-driven centrifugal supercharger installed between the carburetors and the engine. Line 3–3–3 is a calculated curve taken from Fig. 11 in Chenoweth's paper (34) on "Supercharged Engine Performance" and shows the performance that is to be expected of the engine when it is equipped with a centrifugal supercharger of this rating.

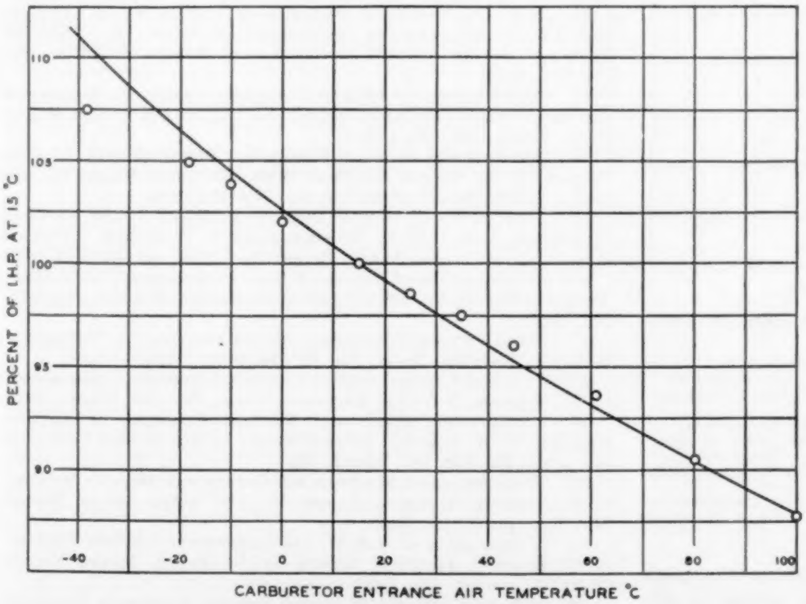

FIG. 5 CHANGE OF INDICATED HORSEPOWER WITH TEMPERATURE

(Full line represents change of horsepower inversely proportional to the square root of the absolute temperature, based on a standard temperature of 15°C. Circles indicate experimental values. For engine specifications, see Fig. 4. Speed, 2000 r.p.m.)

Supercharging has been a major problem in the altitude laboratory for several years past, and reports covering this work in detail are being prepared for publication by the National Advisory Committee for Aeronautics, at whose request this investigation was originally undertaken.

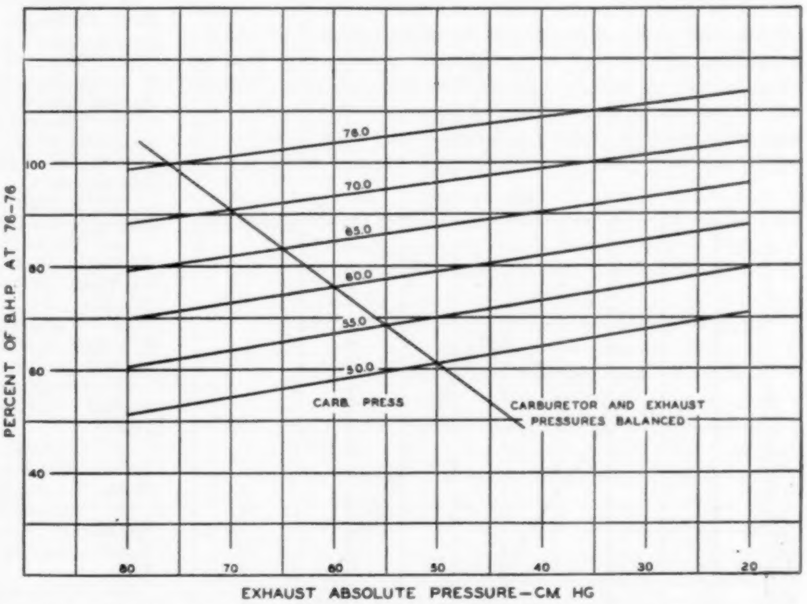

FIG. 6 CHANGE OF BRAKE HORSEPOWER WITH EXHAUST ABSOLUTE PRESSURE

(Referred to condition where both carburetor entrance and exhaust pressures are 76 cm. Hg. One line is for equal carburetor entrance and exhaust pressures, while the remaining lines are for various constant carburetor entrance pressures. Carburetor air temperature, 15° C. For engine specifications, see Fig. 4. Speed, 2000 r.p.m.)

ALTITUDE LABORATORY PROGRAM

A further research program of altitude testing is now being formulated. This will probably include, in addition to work on supercharging, a study of the performance characteristics of modern aviation fuels and tests of engines cooled by liquids other than water to determine the relative efficiency of high cylinder-wall temperatures. Work is in progress to ascertain the reasons for the wide variations in explosion pressure from cycle to cycle obtained with the balanced diaphragm indicator. When means of obtaining more satisfactory indicator cards have been developed, the study of pressures and temperatures in aircraft engines will be extended to include altitude conditions.

Beyond the immediate program for the present altitude laboratory, consideration is being given to the design of a laboratory in which modern air-cooled engines can be tested under altitude conditions. The provision of means for adequately cooling such engines with air at reduced pressure offers a problem surpassing in difficulty any involved in the design of a laboratory for testing water-cooled engines.

However, it is believed that altitude tests of air-cooled engines will be of sufficient value to justify the cost of such equipment.

Approximate Altitude Testing

As pointed out by DuBois (26) in 1924, approximate altitude performance data can be obtained without an altitude chamber if facilities are available (*a*) for conditioning the carburetor air as regards temperature, pressure, and humidity and (*b*) for maintaining the desired low pressure at the exhaust ports of the engine. In making such tests of unsupercharged engines, care must be taken to prevent leaks into the air horn and carburetor, as these will render the air measurements inaccurate. Air-bleeds to the carburetor must be inclosed and connected to the air horn. In regular altitude tests of supercharged engines, when the air surrounding the engine is at low pressure, any leakage takes place from the induction system outward, reducing volumetric efficiency. Thus an approximate altitude test of a supercharged engine may give results which are high owing to the absence of such leakage.

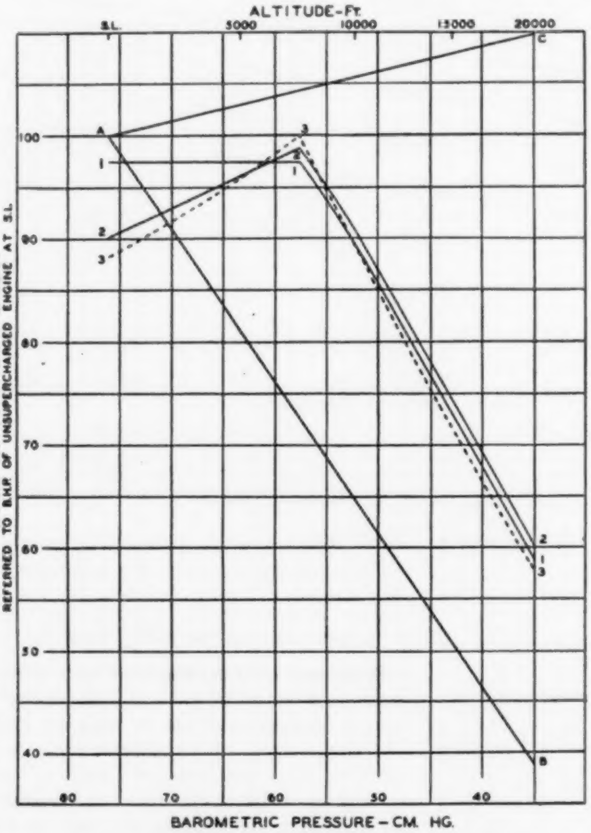

FIG. 7 CHANGE OF BRAKE HORSEPOWER WITH BAROMETRIC PRESSURE

Referred to normal power of unsupercharged engine at sea level.

Curve	Conditions of test	Air temperature
A–B	Altitude test, no supercharging	15° C. (at carb.)
A–C	Sea-level pressure independently maintained at carburetor entrance	15° C. (at carb.)
1–1–1	Gear-driven Roots-type supercharger in advance of carburetors	Alt. temp. at supercharger entr.
2–2–2	Gear-driven centrifugal supercharger between carburetors and engine	Alt. temp. at carb. entr.

Curve 3-3-3 shows relative brake horsepower calculated by Chenoweth for the engine with geared-driven centrifugal supercharger. For engine specifications see Fig. 4. Speed, 2000 r.p.m.

The Navy Department has installed equipment for making approximate altitude tests at the Aeronautical Engine Laboratory in Philadelphia and has made such tests on several air-cooled aircraft engines. In these tests the carburetor air was not conditioned as to temperature and humidity. The Army Air Corps is understood to be designing equipment for the same purpose at Wright Field. Data thus obtained will be of undoubted value although somewhat approximate.

Discussion

Sanford A. Moss.[5] As the authors point out, existing data indicate that variation of engine power depends upon the square root of absolute temperature, instead of according to the law which would be naturally expected, variation with the first power of the absolute temperature. However, this law possibly applies primarily only in a region where the pressure and temperature are about the atmospheric values. Is it known that the same law holds when the pressure is above atmospheric, as in the case of modern engines with supercharging or ground boosting at sea level or when a supercharger is used to restore sea-level pressure at altitude, in which case the temperature is nearly the adiabatic value corresponding to the pressure ratio, and much above the usual atmospheric value? Perhaps some additional testing work would be required in these regions. The authors mention a possible reason why variation is with the square root of the absolute temperature, instead of with the absolute temperature, as being a matter of volumetric efficiency. Why should the volumetric efficiency be affected by the temperature?

P. M. Sartell.[6] The authors make the statement that the Aeronautical Engine Laboratory at the Naval Aircraft Factory, Philadelphia, Pa., does not condition the carburetor air as to temperature and humidity. The writer feels that the authors have been misinformed. As to temperature of the carburetor air, it is cooled to —60 deg. fahr. in the air refrigerator and then heated to the desired value by means of electrical heaters. Regulation is kept to within ±2 deg. fahr. of the desired temperature.

As to humidity, the air is dry due to its previous cooling to —60 deg. fahr. In a conversation with Mr. Cummings it was found that the Bureau of Standards also uses dry air.

Donald L. Bower.[7] The writer has never seen any figures on the effect of supercharging on the fuel rate and thermal efficiency of aircraft engines, and would therefore like to ask the authors for these figures on engine performance, both at sea level and at high altitudes, giving a comparison of these quantities with engine operating supercharging and non-supercharging.

Authors' Closure

The second question asked by Dr. Moss is discussed briefly by Sparrow in references (24) and (29). If the intake valve acted as a simple orifice, the velocity of flow would vary as the square root of the absolute temperature. The problem is complicated by cooling or heating of the charge in the induction system and cylinder during the intake stroke, but there is adequate experimental evidence that volumetric efficiency as defined in this paper varies with the square root of the absolute temperature, at least in the case of unsupercharged, water-cooled engines. The indicated horsepower curves in Fig. 4 and the experimental points in Fig. 5 show that the inverse square-root temperature correction is not limited to sea-level conditions nor to a narrow range of air temperatures. The correction should be directly applicable to cases where the air pressure and temperature at the carburetor entrance have been raised above atmospheric values by means of a supercharger. As Dr. Moss suggests, additional tests are required to determine the effect on power of pressure and temperature changes at the carburetor entrance when there is a supercharger between the carburetor and the engine cylinders. Studies also should be made to ascertain the effect of atmospheric conditions when the carburetor is replaced by fuel-injection apparatus.

In reply to Mr. Sartell, the particular reports of approximate altitude tests at the Aeronautical Engine Laboratory available when this paper was written specified only control of carburetor and exhaust pressures. We are glad to learn that the Navy now uses dry air and controls its temperature within ±2 deg. fahr.

In regard to the thermal efficiency and specific fuel consumption of aircraft engines, Mr. Bower will find reports of engine tests listed in the bibliography which show the effect of altitude on these quantities in the absence of supercharging. In general, indicated thermal efficiency and specific fuel consumption in pounds per indicated horsepower-hour change little with altitude. Brake thermal efficiency tends to decrease and fuel consumption in pounds per brake horsepower-hour tends to increase with altitude, owing to the decrease in mechanical efficiency. We have no data available comparing the thermal efficiency and economy of supercharged and unsupercharged engines, but a report is in preparation which will compare the performance of an unsupercharged water-cooled engine (for specifications see Fig. 4) with the performance of similar engines equipped, respectively, with Roots-type and centrifugal-type superchargers. Increasing compression ratio, as pointed out in the paper, increases the indicated thermal efficiency, but increasing compression by supercharging without a corresponding increase in expansion ratio reduces the indicated thermal efficiency. In the case of single-cylinder engine tests the variation in mechanical efficiency may be such as to give little or no decrease in brake thermal efficiency due to supercharging. Thus recent tests at the Langley Memorial Aeronautical Laboratory on the N.A.C.A. universal test engine at various compression ratios and at "boosts" up to 10 in. of mercury showed a marked improvement due to increasing the compression ratio and also a very slight improvement in fuel economy when boosted.

It is believed that a brief description of the new Isotta Fraschini altitude laboratory will be of interest. During 1931 a laboratory for the testing of air-cooled aircraft engines under altitude conditions was completed at Milan, Italy. The altitude chamber consists of a double, closed-throat wind tunnel in the form of a vertical figure eight. Air at the desired temperature and pressure is drawn over the engine by means of an eight- or ten-blade propeller, and is subsequently cooled by passage over ammonia coils. It is reported that pressures and temperatures corresponding to altitudes up to 7 km. (23,000 ft.) can be maintained and that the cooling-air velocity at the engine is about 90 m.p.h. The power of the engine is absorbed by means of a water brake located outside of the altitude chamber. The publication of a full description of this laboratory, with test data on air-cooled engines, will be awaited with great interest.

Sonic Altimeter for Aircraft

By CHESTER W. RICE,[1] SCHENECTADY, N. Y.

The author describes the development of an aircraft altimeter which works on the sound-echo principle now commonly employed for depth finding at sea. The problem was to devise means and equipment to send a powerful sound from the airplane and receive the echo back from the ground through the intense masking sounds produced by the engine and propeller. It is believed that the use of the sonic altimeter and sonic boundary markers will make fog flying reasonably safe.

IT IS presumed that all are familiar with the excellent results that are obtained with the sound-echo method of depth finding used on shipboard; so much so that many doubtless have thought of making an aircraft altimeter on the same principle. Most of these, however, have rejected the idea when they stopped to think about the large amount of engine noise through which they would have to listen. Roughly, the problem is to hear a distant echo in the noise of a hundred boiler factories, where to be understood one has to shout into the other fellow's ear.

Before proceeding to the experimental work, it will be well to review some of the fundamentals of ear-response, the masking effect of noise, and the sound output from various familiar sources. In Fig. 1 there are given a family of curves[2] showing the sound-pressure, frequency characteristics of the average ear. The lower boundary of the area represents the threshold of audibility at the particular frequency. The upper boundary is the threshold of feeling. The intermediate lines give the values of the sound pressures, which are 10, 100, 1000, etc. times the threshold values. The author has added to the ordinate scale (which gives the sound pressure at the ear in dynes per square centimeter or bars) the approximate value of the sound pressure corresponding to familiar places, such as a quiet office, department store, etc. This helps to place the magnitude of various sound pressures.

From Fig. 1 it is seen that the average threshold for hearing is approximately 0.0006 dyne per sq. cm., between 1000 and 4000 cycles, and that the ear is relatively much more sensitive to sound pressures in this region than for low frequencies, where a much larger sound pressure is required to reach the threshold. The threshold of feeling is reached at sound pressures of the order of 3000 dynes per sq. cm.

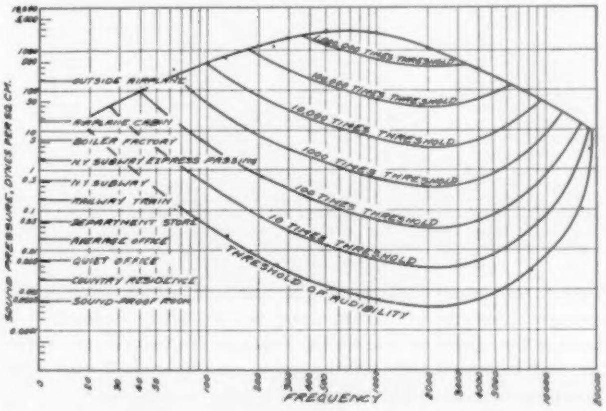

Fig. 1 Sound-Pressure Frequency Characteristics of Normal Ear

TABLE 1 AMOUNT OF NOISE IN TYPICAL PLACES AND APPROXIMATE MASKING EFFECT ON AVERAGE AND LOUD SPEECH

Typical place	Amount of threshold shift for average speech, in decibels	Ratio of sound intensity to the threshold intensity	Ratio of sound pressure to the threshold sound pressure	R.M.S.[a] sound pressure, dynes per sq. cm.	Maximum distance for hearing average speech, ft.	Maximum distance for hearing when speaking as loudly as possible, ft.
Soundproof booth	0	1	1	0.0006	1000	10,000
Country residence	10	10	3.17	0.0019	316	3,160
Quiet office	20	10^2	10	0.006	100	1,000
Average office	30	10^3	31.7	0.019	31.6	316
Department store	40	10^4	100	0.06	10	100
Railway train	50	10^5	317	0.19	3.16	31.6

5 gives the sound pressure in the different places, assuming an average threshold of 0.0006 dyne per sq. cm. Column 6 indicates the distance at which average conversational speech can just be heard through the noise, and column 7 the corresponding distance when talking as loudly as possible.

In Table 2 there is given the sound output in watts for various familiar sources, together with the corresponding sound pressure in dynes per square centimeter at 3 ft. from the source. The sound pressure is calculated from the relation

$$P_{\text{r.m.s.}} = \sqrt{\frac{415\,W \times 10^{6}}{4\pi R^{2}}} \text{ dynes per sq. cm.} \ldots\ldots [1]$$

where W equals sound radiated in watts and R is the distance from the source in centimeters. It will be noted from the equation that it has been assumed that the radiation is to take place equally in all directions through a spherical surface. When sound is radiated near the surface of the ground and the listener is at a considerable distance, a more correct assumption is that the sound is radiated through a hemisphere which corresponds to multiplying the sound pressure obtained from Equation [1] by $\sqrt{2}$. Since the values given in Table 2 are merely to indicate orders of magnitude, the spherical assumption has been used throughout for the sake of simplicity. It is seen from Table 2 that familiar sounds range from 10^{-9} watts, for a very soft whisper, to 1000 watts, for whistles and foghorns.

EARLY EXPERIMENTS

During the summer of 1929, while spending week-ends at camp on Honnedaga Lake, in the Adirondacks, New York State, the author decided to find out whether it was not possible to get through the airplane noise with the aid of a directive transmitter and receiver, when supplemented with an acoustic filter.

A $1\frac{1}{2}$-hp. outboard-motor boat was used in place of an airplane, and the echoes from the shore represented the ground. Some idea of the noise made by the outboard-motor boat is obtained from the fact that a person seated 4 ft. from the driver had to speak very loudly to be understood. If reference is made to Table 1, it will be noted that this corresponds roughly to a sound pressure of one or two bars.

Preliminary experiments, in which the audibilities of firecrackers of various sizes and whistles of different pitches were compared indicated that a small mouth-blown high-pitched whistle (3600 cycles) was much more readily distinguished through the engine noise than either firecrackers or any of the low-pitched whistles.

Considerable improvement was obtained by using a large megaphone (12 in. diameter to 2 in. diameter in 30 in.), both on sending and receiving, as shown by tests in which a member of the author's family blew the whistle on the dock while the author ran the motor boat out and back. The results were as follows:

1 Unaided ear—whistle drowned by engine noise at approximately 120 ft.

2 Megaphone held loosely to ear—whistle drowned at 500 ft.

3 Unaided ear on boat, with whistle blown into megaphone at dock—whistle drowned by engine noise at 480 ft.

These rough experiments show that a megaphone, used either as transmitter or receiver, will give approximately four times the range. Echo experiments at a spot on the lake called "Rocky Point" gave distinct echoes up to approximately 225 ft., both with the megaphone placed to the ear or by blowing the small whistle into the megaphone and listening with the unaided ear. The echoes at Rocky Point were obtained from a group of large flat-faced rocks rising almost perpendicularly from the water, approximately 30 ft. high by 60 ft. long. The fact that echoes were obtained up to 225 ft., which is approximately half the distance at which the whistle was drowned out by the engine noise in the previous test, shows that the reflection was approximately specular. Similar echo experiments made along the wooded shores gave good echoes up to 150 to 200 ft.

Some tests were made with a pair of stethoscope earpieces attached to the small end of the megaphone by a small cone. When this connection was made tightly, the value of the megaphone was practically destroyed due to the masking effect of the low-pitched horn resonance. By leaking or venting the junction between the small end of the megaphone and the small cone, the resonance was eliminated, and good results were obtained.

These experiments led to the belief that a Stewart high-pass acoustic filter[4] would be ideal for this job. Subsequent trials with acoustic high-pass filters which had a calculated cut-off around 2300 to 2500 cycles gave excellent results and practically eliminated the low-pitched noises.

Early in the progress of this work it became evident that the high-pass filters should be enclosed to prevent the entrance of sound and the disturbing effect of wind blowing over the holes. This was accomplished by enclosing them in a soundproof damped cylindrical box.

Multiple-unit broadside-directive devices, of the type proposed by Wilson, Zeleny, and Mason,[5] showed fine directive properties, but the one constructed by the author, which is shown in Fig. 2, was weak in intensity due to the crudity of the elements and high attenuation in the long lengths of small-diameter rubber tubing.

[5] *Physical Review*, vol. 15, p. 178, 1920. See also Rayleigh Sci. Papers, vol. 5, p. 129, and Max Mason, U. S. patent 1,422,876, filed June, 1919.

Some preliminary tests using the binaural effect as a level indicator for aircraft showed considerable promise. Two large megaphones, spaced from 2 to 6 ft. apart, as shown in Fig. 3, were used in these experiments. High-pass filters were connected at the small end between the megaphones and the stethoscopes. With this arrangement sharp echoes were obtained from Rocky Point at from 150 to 225 ft., as well as a good sense of direction. By swinging the megaphones to locate the direction of the echo wave front and by comparing this with the angle of the boat, it could be determined whether the boat was parallel or at an angle to the shore. The ability to swing the megaphones helped greatly in finding the position. If, instead, the boat had to be turned, the time element reduced the effect of the observation; thus a compensator[6] or scheme for turning the pick-up device seems desirable for the application of the echo method to a sonic vertical keeper.

METHODS OF MEASURING ECHO TIME

Fig. 4 shows the set-up. The phonograph with a small projection on the turntable operated the small balanced air valve, which blew the whistle once each revolution. An air tank supplied from one of the engine cylinders through a check valve served as the source of compressed air. Two methods were tried with this apparatus, as follows:

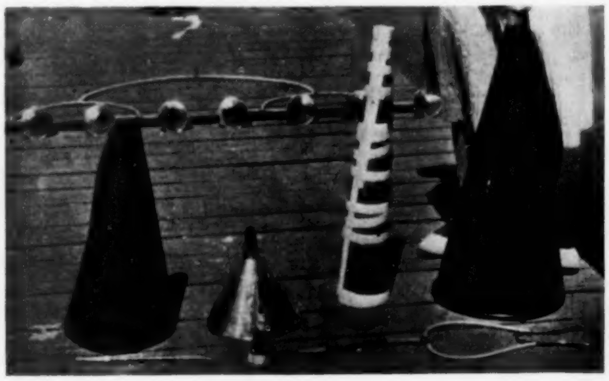

FIG. 2 PICK-UP DEVICES USED IN EARLY EXPERIMENTAL WORK

First, the position of the pointer on the turntable was estimated at the time the echo was received, by moving the finger around the periphery until the position of the finger and pointer coincided when the echo was heard. Tests with this method indicated an error of approximately 5 per cent in estimating distances from 80 to 500 ft.

The second method consisted in using the sound box of the phonograph to introduce a click into the listening system by making mechanical contact with the pointer. Here the procedure is to move the sound box around until the echo and the click appear to be simultaneous. A few trials with this method made it appear more difficult to operate than the visual one. The trouble seemed to be that there were too many things for the mind to coordinate easily. Besides the original source of sound, there is an echo and then a click.

COMPARISON OF AIRPLANE AND MOTOR-BOAT NOISES

Dr. A. R. Stevenson, Jr., and the author made the following tests at the Schenectady Airport, using his Stinson, Jr., plane, which is powered with a 165-hp. J-6 Wright engine.

The plane was held and the engine was run at full throttle, 1700 r.p.m. With the unaided ear the small mouth-blown whistle could be distinctly heard when sounded at 30 ft. perpendicular to the plane. When using the 12-in. diameter 30-in. long megaphone, fitted with high-pass filter and stethoscope earpieces, the limit was approximately 50 ft. The need of the high-pass filter when using a megaphone in the vicinity of an airplane was amply evident from these tests, for the sound was painfully loud if the stethoscopes were put in the ears without the high-pass filter.

In the motor-boat tests cited, the limit using the megaphone was approximately 500 ft. In other words, there is a ratio of 10 to 1 in the distance at which the whistle is just audible. This corresponds to a 10-to-1 ratio in sound pressures; and since the power output is proportional to the square of the sound pressure, there results 100 to 1 as the ratio of airplane to motor-boat noise. It is interesting to note that the powers of the two engines stand approximately in the same ratio.

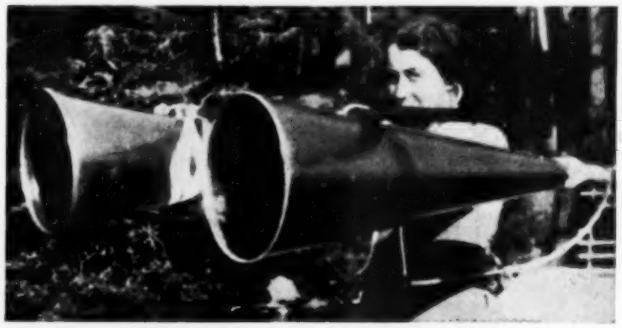

FIG. 3 EARLY EXPERIMENTS IN USE OF BINAURAL EFFECT

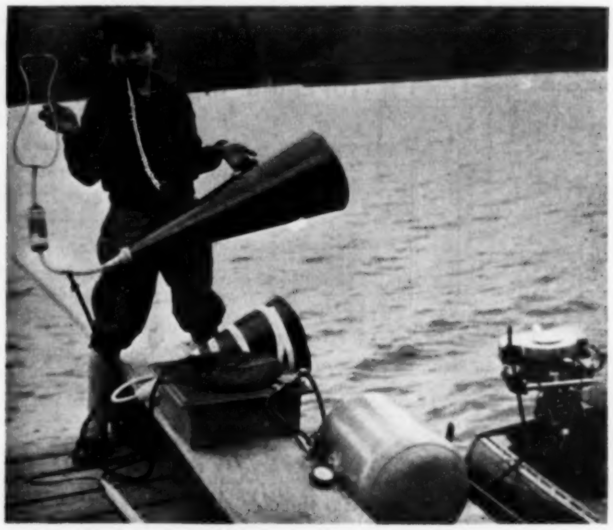

FIG. 4 EARLY SONIC ALTIMETER, WITH ECHO-TIMING DEVICE

While at Honnedaga Lake the motor boat was run away from the dock until it was estimated that it sounded about as loud as an airplane would when flying overhead at the normal height of 3000 ft., and in this way it was found that the motor boat needed to be about 300 ft. distant. This again gave a 10-to-1 ratio in distance for the same sound pressure, which corresponds to a 100-to-1 ratio in noise power. Reference to the data of Table 1 shows that these estimates were not far from the mark.

It was concluded from these tests that if a sound source could be made which would give roughly 50 times the sound pressure of the small mouth-blown whistle, a successful sonic altimeter could be made. Since a pressure of about 1 lb. per sq. in. is exerted when blowing the small whistle, it seemed reasonable to assume that a suitable whistle designed for a pressure of 50 to 100 lb. per sq. in. would meet the need.

---

Experiments With Various Sound Sources

Some time later Dr. Stevenson and Messrs. J. H. Clough and J. S. Apperson joined the author in making further listening tests and in comparing the effectiveness of different types of sound sources.

TABLE 3 DISTANCES AT WHICH SOUNDS COULD BE RECOGNIZED

Early Motor-Boat Tests			
Small mouth-blown whistle	120	480	4:0

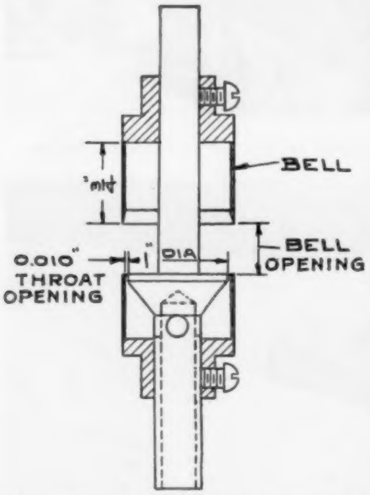

Fig. 5 Experimental 1-In. 3000-Cycle Whistle

In the meantime the small whistle shown in Fig. 5 had been built. It had a bell $^{3}/_{4}$ in. long by 1 in. in diameter and was supported on a $^{3}/_{8}$-in. diameter central rod. The annular opening for the air jet was 10 mils, and the distance between the annulus and the lower edge of the bell was found to give the best output at approximately $^{1}/_{2}$ in. The air pressure available at the whistle was approximately 50 lb. per sq. in. gage.

The distances at which the various sounds could just be distinctly recognized are summarized in Table 3. For these ground tests the author sat in the open doorway of the airplane cabin and listened while the various sound sources receded at right-angles to the plane.

That the ratios of distances heard with the megaphone plus the high-pass filter to those with the ear alone are worse for the airplane-engine experiments than with the motor boat is probably due to the fact that the acoustic filter was improperly shielded for the high-intensity airplane sounds. Better shielding was used in the later work.

At the conclusion of the ground tests, Messrs. Stevenson and Clough flew over the airport and listened to the whistle which was blown from the ground. The first time over, both heard the whistle loudly at 225 ft. The second time, they came over at 500 ft., and the whistle was distinctly heard by Mr. Clough, but not by Dr. Stevenson. Mr. Clough was leaning out of the cabin window.

Under these conditions the plane was making approximately 60 miles per hour, which corresponds to an engine speed somewhat above that necessary to sustain it.

Preliminary Calculations on the Probable Heights to Which Echoes May Be Received in an Airplane

The sound-pressure tests which are described in Appendix 1 show that the 1-in. 3000-cycle whistle, when operating at 50 lb. per sq. in. gage, produces a mean spherical sound pressure of 783 dynes per sq. cm. at 3 ft. For radiation into a hemisphere, assuming that the presence of the ground does not affect the power output of the source, multiply the mean spherical sound pressure by $\sqrt{2}$ and obtain 1100 dynes per sq. cm. at 3 ft. The sound pressure at 500 ft., which Mr. Clough could just distinguish through the engine noise, is therefore,

$$P_{500} = 1100 \times \frac{3}{500} = 6.6 \text{ dynes per sq. cm} \ldots\ldots [2]$$

Tests given in Appendix 2 on the transmission characteristics of the horn and the high-pass filter show that the system gives approximately a threefold sound-pressure amplification at 3000 cycles and that there will be approximately a tenfold reduction in the low-frequency masking sounds from the engine.

The sound-pressure curve for the 1-in. whistle in the 12-in. by 30-in. megaphone, given in Appendix 1, shows that the mean sound pressure over the 12-in. opening of the horn is approximately 4400 dynes per sq. cm. Therefore, by putting the horn on the whistle, there is obtained four times the sound pressure at 3 ft. from the source. These findings may be summarized as follows:

1 Airplane in flight (60 miles per hour), with ear alone, the 1-in. whistle could be heard at 500 ft. Sound pressure at ear 6.6 bars.

2 If receiving megaphone and high-pass filter were installed on plane, there would be obtained approximately three times this distance, or 1500 ft.

3 With the horn added to the whistle, the distance should be multiplied by approximately four, giving 6000 ft.

4 If specular reflection is assumed at the ground, one should divide this height by two and obtain as the limiting altitude 3000 ft. Obviously the assumption of specular reflection is seldom realized when one considers that the wave length of the 3000-cycle note is approximately 4 in. A slight roughness of this order of magnitude will cause the sound to be diffusely reflected. In the case of trees and shrubbery this effect will be still further enhanced by a relatively poor coefficient of reflection.

In Appendix 3 it is shown that the intensity ratio of specular to diffuse reflection is given by

$$\frac{I^1_R}{I_R} = \frac{1}{4K \tan^2 \alpha} \ldots\ldots\ldots\ldots [3]$$

where K is the coefficient of reflection and α the semi-angle of the conical beam sent out by the whistle in the megaphone. For $K = 1$ and $\alpha = 10$ deg.; $I^1_R/I_R = 8$. This corresponds to a sound-pressure ratio of 2.8 to 1. If $K = 0.5$, the intensity ratio becomes approximately 16 to 1 and the pressure ratio 4 to 1. For $K = 0.25$, the intensity ratio becomes 32.8 to 1 and the pressure ratio 5.75 to 1.

5 Assuming diffuse reflection with a reflection coefficient near to unity, divide the height obtained under the assumption of specular reflection by approximately three and obtain as the limiting altitude 1000 ft.

These results convinced the author that a practical sonic altimeter for airplanes was possible.

First Flight Tests

Mr. Ray Stearns, engineer of this company's Aeronautics and Marine Department, became interested in the project and provided further facilities to try out the sonic altimeter by actual flight tests. Arrangements were made with Mr. V. A. Rickard, manager of the Schenectady Airport, to equip his Stinson-Detroiter six-place cabin plane, which was powered with a 225-hp. J-5 Wright engine, with suitable equipment.

The 1-in. whistle was installed in a 12-in. by 30-in. megaphone just back of the baggage compartment. This brings the center line of the whistle approximately 17 ft. from the propeller. A motor-operated whistle valve and air-storage tank were installed in the baggage compartment. The storage tank was supplied with CO_2 gas from a high-pressure tank, through a reducing valve.

A pair of listening megaphones were installed approximately 6 ft. back of the whistle megaphone. The distance between the centers of the listening megaphones across the ship was approximately 18-in. Tubing 1 in. in diameter, with rubber-hose connections, properly insulated from the fuselage by felt attachments, was brought forward from the listening megaphones to the pilot's seat in the front of the cabin, a distance of approximately 16 ft. Various sizes of acoustic high-pass filters and other frequency selective devices were then inserted between the 1-in. speaking tube and the stethoscopes in the listener's ears. The object of the two receiving megaphones was to permit experiments with the binaural effect and allow changes to be made in one listening line while keeping the other fixed for comparison purposes. Intensity controls were introduced in the 1-in. listening line by having clamps which would close off a 1-ft. section of 1-in. felt-lined hose, to form a gradual restriction and subsequent expansion. The object of the intensity control was to vary the total intensity of signal and noise over a wide range in as nearly as possible a non-frequency selective manner.

In order to measure the time interval between the outgoing signal and the echo, a timer was arranged in front of the listener, driven from the motor-operated whistle valve through a flexible shaft. With this arrangement a short blast of the whistle went out every time the pointer passed zero on the scale. The motor speed was adjusted to send out a blast approximately every 2 seconds. At this speed the pointer on the dial makes one revolution in 2 seconds. Taking the velocity of sound as 1000 ft. per sec., as a round figure, the time interval between outgoing signal and echo for an altitude of 1000 ft. is 2 seconds; for 500 ft., 1 second; for 50 ft., $^{1}/_{10}$ second; and for 5 ft., $^{1}/_{100}$ second.

The height of the plane above the ground is then obtained by noting the approximate position of the pointer, as it moves around the dial, when the echo is heard. The numbers on the dial are marked so as to correspond directly with the height above the ground in feet.

It will be noted that the time intervals for moderate heights are not excessively short, and experience shows that with a little practice the altitude can be estimated within ± 5 per cent. If the aviator is flying toward a mountain, the rising ground is indicated by a reduction in the echo time interval. With a little practice the pilot also can estimate quite accurately his height without using the dial.

It is important to select a suitable frequency for the whistle, and 3000 cycles has been selected as an appropriate value. At this frequency one cycle has a duration of $^{1}/_{3000}$ of a second; and in order that the blast shall have a musical character, which is important, to allow of differentiating it from the extraneous engine noises, it is necessary that the blast have a duration of the order of 10 to 30 cycles. This means that with 3000 cycles as the frequency, a blast of 30 cycles lasts $^{1}/_{100}$ of a second, which corresponds to an altitude of 5 ft. above the ground.

If 300 cycles is used, 1 cycle equals $^{1}/_{300}$ of a second, and 30 cycles equals $^{1}/_{10}$ of a second, which corresponds to 50 ft. in altitude. It is evident from this comparison that a low frequency of 300 cycles is not favorable for altitude work.

It also is well known that the masking effect of a low-frequency sound is very much greater for a sound of similar pitch than it is for a sound having a much higher pitch.

Another reason for selecting the high frequency is that the depth of penetration into woods will be less with high frequency than with a low frequency. In other words, by using a high frequency, a distinct echo is received from the tops of trees, which would not be the case with a low frequency. Here the inverse fourth-power law of scattering comes to the rescue.

On the high-frequency side it is preferable not to go above 4000 cycles because the ear begins to fall off in sensitivity in this vicinity and also the turbulence around the plane and in the atmosphere will probably become more troublesome by scattering the sound and reducing the intensity of the echo.

Still another object in keeping the frequency between 2000 and 4000 cycles is to allow the acoustic filter to differentiate easily the sound of the signal from the low-frequency noises produced by the engine and the propeller. The engine and propeller noises probably have their maximum intensity between 100 and 300 cycles.

A further advantage of high frequency is that the wave length is small, and one can make highly directive devices of reasonable dimensions.

The foregoing reasons for using a high-frequency sound source may be summarized as follows:

1 Many cycles available in a short blast.

2 Reduced masking effect from low-frequency engine noise.

3 Improved scattering.

4 Maximum ear sensitivity.

5 Wide separation between engine and signal frequencies permits effective filtering or tuning.

6 Directive transmitters and receivers of moderate size.

Conclusions From Early Flight Tests

A great many variations were made in the test equipment during the early flight experiments, a few of which are listed as follows:

1 Variation of height at which echoes could be heard for different positions of the whistle in the sending megaphone.

2 Tipping the megaphone forward, backward, and sidewise.

3 Duration of the whistle blast.

4 Effect of covering listening megaphones with thin fabric.

5 Varying the intensity of signal with the intensity-control clamps.

6 Leaking the listening megaphones at the small end with various sized holes, to reduce the low-frequency response.

7 Various types of acoustic tuning devices at the receiving end of the speaking tube.

8 Effect of climb and bank on received echoes, using both horns connected binaurally and monaurally to the stethoscope earpieces.

9 Some preliminary work on electrical pick-up devices.

10 Observations on height at which echoes can be heard over various types of terrain, such as woods, shrubbery, unkempt fields, airport ground, Mohawk River, ice on Ballston Lake, 6 in. of rather hard snow, bare trees and trees with leaves, ravines, and hillsides.

11 Tests on still days, windy days, and bumpy days.

Any one who has tried to do experimental work in an airplane will realize the difficulties encountered in obtaining anything but qualitative results. Better facilities and a great many more hours available for flight would be required to obtain reliable answers to the various questions raised in the tests outlined. It therefore seems desirable at this time to record only what might be termed the overall results, as follows:

1 With engine running at cruising speed, reliable echoes were obtained over all types of terrain at 800 ft. and below.

2 With engine throttled for gliding flight, 1600 ft. and below.

3 The echo is lost at 800 ft. when bank or climb angle reached approximately 30 deg.

4 Echoes at 800 ft. were clearer and sharper over flat ground, water, and ice than over trees and fields.

5 When flying over mountainous country, the rise or fall of the ground is easily detected by the time interval between the outgoing and the received signal, as measured by the pointer on the altitude indicator or as judged by the ear alone.

6 When flying parallel to a steep hillside, the echo was noticeably long and drawn out by reflection from the varying distances.

7 When coming into a landing, the approach of the ground was very evident due to the closing in of the time interval between signal and echo, and when the plane reached approximately 5 or 10 ft. from the ground, the outgoing signal and echo blended into a continuous reverberation. This provided a definite notification point which it was felt would allow the pilot to make successful blind landings.

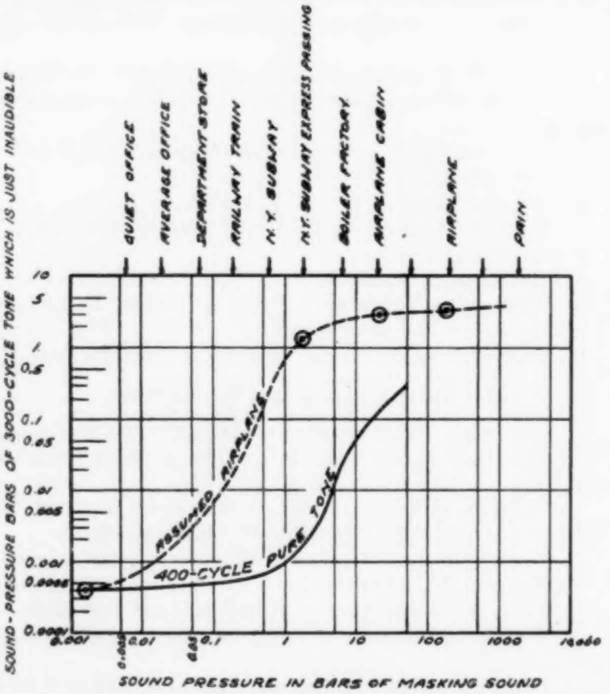

FIG. 6 PURE-TONE AND ASSUMED AIRPLANE-MASKING CURVES

During these early tests the author was ably assisted by Messrs. A. H. Brown, Jr., A. L. Ruiz, and H. L. Bojer, who were assigned to the work from time to time.

After the project was well under way, Mr. H. V. Marvin assigned Mr. A. J. Muchow to the work. He took full charge of the subsequent construction and installation of apparatus for the Douglas plane, as well as making sound measurements and calculations.

REVIEW OF EARLY CALCULATIONS IN LIGHT OF SUBSEQUENT FLIGHT TESTS AND DEDUCTION OF AIRPLANE-MASKING CURVE

It is interesting to note that the altitudes for satisfactory echoes predicted from the early motor-boat and airport-ground tests were confirmed by the subsequent flight tests in the Stinson-Detroiter.

In Fig. 6 there is shown in the full curve the masking effect of a 400-cycle pure tone on a 3000-cycle signal for different sound pressures of the 400-cycle masking tone. This curve is obtained from the values given by Fletcher[7] on the assumption of a threshold of 0.0016 bar for the 400-cycle tone and 0.00042 bar for the 3000-cycle tone. The curve shows that moderate values of the 400-cycle sound pressure produce very little interference with the reception of a 3000-cycle tone. As the sound pressure of the masking tone increases above approximately one bar, the masking effect on the 3000-cycle tone increases very rapidly. For loud sounds—that is, after passing 10 bars—the masking curve shows a tendency to flatten out again. The flattening out of masking curves at high sound pressures is more evident from some of Fletcher's other curves where the masking tone is nearer the frequency of the signal.

The upper dotted curve is a hypothetical masking curve which has been drawn to represent the masking effect of airplane noise on the reception of a 3000-cycle signal. The general shape and position of this curve have been deduced from the sonic altimeter experiments. For example, starting on the assumption that the airplane noise at the mouth of the pick-up megaphone is roughly 190 bars, the flight tests show that the necessary sound pressure received at the ear must be approximately six bars to have the signal distinctly heard above the engine noise. If this value of sound pressure is divided by 2, there is obtained three bars as the first point on the hypothetical masking curve. This assumes that a ratio of 2 to 1 in sound pressure is sufficient to make the signal audible.

The fact that the 10-to-1 reduction in sound pressure for the low frequencies, which is produced by the filter, does not appreciably affect the calculation of the height at which echoes may be heard, indicates that the masking curve is flat in this region. The ordinate for the second point, which goes with the 19-bar noise, has therefore been taken only slightly below the ordinate for the 190-bar noise.

If it is assumed that throttling the engine for gliding reduces the engine-sound pressure to approximately $^1/_{100}$ its normal value, there is obtained 1.9 bars as the masking-sound pressure when gliding. Under these conditions the flight observations give roughly twice the height for good echoes, and therefore approximately 1.5 bars have been taken as the ordinate on the masking curve. From there down there has merely been drawn a smooth curve similar in form to the full-line pure-tone masking curve.

If the imaginary masking curve is correct, it indicates that small reductions in airplane noise or improvements in the low-frequency characteristics of the pick-up system will add very little to the heights at which one can receive satisfactory echoes. On the other hand, any improvement in the efficiency of the 3000-cycle pick-up or 3000-cycle sound source will add almost directly to the echo altitudes. The fact that the echo heights obtained on the 225-hp. Stinson were practically the same as those obtained with the installation on the 450-hp. Douglas plane, as well as the listening tests in Dr. Stevenson's plane, which was powered with a 165-hp. engine, tends to confirm the foregoing conclusions.

ARMY TESTS

At this point of the development it was felt that the experiments had demonstrated the feasibility of the sonic altimeter and that the next step would be to induce somebody to make a trial installation and thereby determine the actual merit of the sonic altimeter as applied to practical aviation.

Messrs. Ray Stearms, A. H. French, C. E. Clark, and J. Bosway took the matter up with the Army officials. Shortly thereafter Major Hugh Mitchell and Lieut. Albert F. Hegenberger came to Schenectady and tried out the crude equipment which had been installed on the Stinson-Detroiter.

---

[7] Fletcher, "Speech and Hearing," p. 117.

Blind-landing projects come under Lieutenant Hegenberger at Wright Field. Shortly after the aforementioned trip, arrangements were made to equip Lieutenant Hegenberger's two-passenger, open-cockpit Douglas plane, which is powered with a Pratt & Whitney 450-hp. Wasp engine, with the sonic altimeter.

It was felt that for this trial installation the simplest and most rugged arrangement should be selected as determined from the tests on Mr. Rickard's Stinson-Detroiter. The installation is shown diagrammatically in Fig. 7, with the principal dimensions.

In this case the air supply for the whistle was obtained by bleeding one of the engine cylinders through a suitably designed cooler and check valve. The need of a cooler in front of the check valve was suggested by Mr. H. I. Becker, after much difficulty had been experienced in trying to make hot check valves work. The author is also indebted to Messrs. R. W. Ayers and C. L. Heisler for valuable suggestions regarding the check-valve design.

In place of the mechanically driven timer used on the Stinson, there was substituted a spring-driven timer in which a contact-operated solenoid released the pointer electrically each time the motor-operated whistle valve sent out a blast. Under these conditions the altitude, as indicated by the timer, is independent of the speed of the motor which drives the whistle valve. The sending megaphone and air-storage tank were mounted in the front compartment of the Douglas plane, as shown in Fig. 8. Here the check valve and cooler may be clearly seen. Fig. 9 is a close-up, looking into this compartment from the other side of the plane.

FIG. 7 DIAGRAM OF SONIC ALTIMETER INSTALLATION

A single receiving megaphone was mounted in the tail of the ship, approximately 18 ft. from the sending megaphone. Aluminum tubing of 1 in. diameter, with suitable breaks, connected by rubber tubing, to reduce the sound transmission, and flexible attachments to the structure of the plane were provided to bring the sound from the megaphone to a point between the two seats. Here a reducing cone was provided to make an impedance fit between the 1-in. speaking tube and the $^5/_{16}$-in. diameter high-pass filter and stethoscopic earpieces.

Preliminary flight tests with this equipment showed that the outgoing signal was about equal to the echo at 600 ft. altitude, which is not loud enough to give a natural echo effect. It was difficult to judge heights without looking at the timer, and the effects on coming in to land were not nearly as pleasing as they had been in the Stinson. Accordingly there was installed a 1-in. speaking tube to convey an additional signal from the whistle megaphone to the listening line. The sound was inserted into the listening system ahead of the acoustic high-pass filter, after passing through a reducing cone and intensity-control valve. The listener can adjust the intensity of the outgoing signal blast to give the best psychological effect both in flight and for landing. It was found that a single adjustment was satisfactory for both conditions.

The sonic altimeter has been in practically continuous use without showing any important mechanical or acoustical defects since its installation. The average of results by several listeners indicates the following:

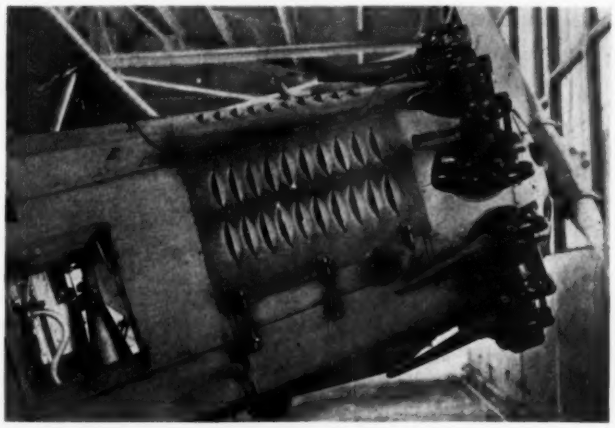

FIG. 8 INSTALLATION OF SONIC ALTIMETER ON ARMY PLANE

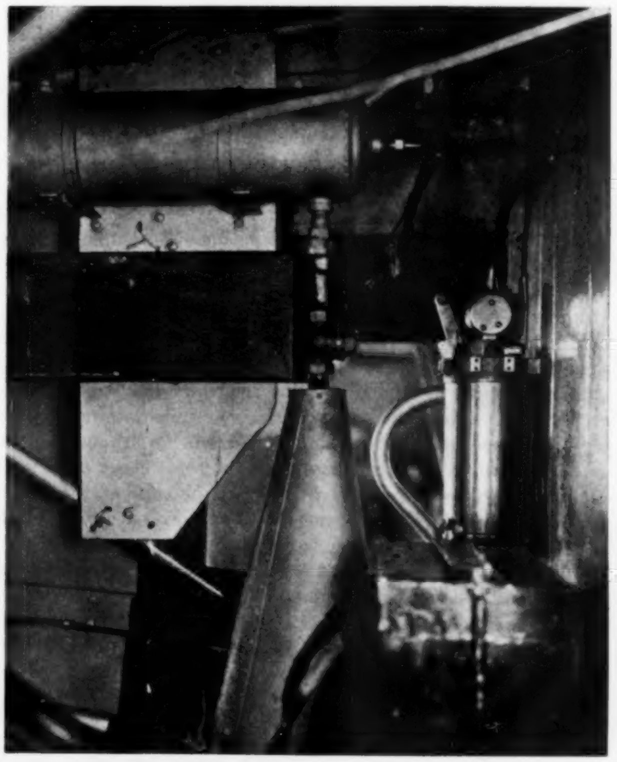

FIG. 9 TRANSMITTING EQUIPMENT FOR SONIC ALTIMETER INSTALLED ON ARMY AIRPLANE

1 Engine running at cruising speed, reliable echoes at 800 ft. and below.

2 Engine idling for a glide, reliable echoes at 1400 ft. and below.

Numerous blind landings have been made by Lieutenant

Hegenberger, in which he finds he can make use of the blending of outgoing signal and echo in the vicinity of 5 ft. as a point from which to pull back the stick and allow the plane to settle to the ground.

The total weight of the apparatus as installed is approximately 45 lb. In this connection it should be understood that no special stress has been put on reducing either the weight or the volume of the apparatus to a minimum.

USES OF THE SONIC ALTIMETER AND SONIC BOUNDARY MARKERS

In conclusion, it may be interesting to review in a general way how the sonic altimeter and other aeronautical devices may be employed to make fog flying safe.

If an aviator is flying cross-country and is caught in a fog, it is highly desirable to have a means that will allow him to determine approximately his height above ground. In the first place, the aviator wishes to know that he is at a safe height to clear buildings, transmission-line towers, mountains, etc., and may proceed without danger of collision. Supposing that he is bound for the Schenectady Airport. He can steer the plane by compass or use his directive radio receiver to keep him headed for radio station WGY at Schenectady. The sonic altimeter keeps him at a safe height from the ground if he wishes to fly low. If he wishes to fly high, he may come down to 1000 ft. or so from the ground and check his barometric altimeter with the sonic, as proposed by Dr. E. F. W. Alexanderson, and then climb again to a high altitude.

When he reaches the vicinity of Schenectady, he is supposed to pick up some sort of short-wave radio or other type of airport marker located at the Schenectady Airport. This will bring him in proximity to the landing field. In addition to the radio or other beacon which locates the field, it is generally conceded that it will be desirable to have some sort of field-boundary or runway marking. Several schemes using ultra-short-wave radio, sound, or light have been proposed. It is felt that at present the most simple and rugged means of accomplishing this result would be to mark the field by sending up properly located and coded beams of sound. The present work on the sonic altimeter has shown that relatively cheap and rugged apparatus can be used to send up sound beams which may be picked up at approximately 3000 to 6000 ft.

After locating the extent of the field and his position with respect to it by some of the methods outlined, the pilot will cut his engine and start gliding down. As he approaches the ground the times between signal and echo come closer and closer together. At approximately 5 ft. from the ground the signal and echo blend in a reverberation. The pilot then pulls back the stick and allows the plane to settle to the field.

A great advantage of the sonic altimeter is that it puts the ear to work and relieves the eye to watch the various instruments and obtain the first glimpse of the ground in making a fog landing. Judging from observation there are few fogs where it will not be possible to see the ground before actually setting the plane down.

There are other cases where an aviator may wish to attempt a fog landing on an airport or field which is not provided with radio beacons or other landing aids. In this case he must be able to feel his way down through the fog until he is able to see the ground. With the sonic altimeter he can safely approach the ground without danger of collision, and if he finds he is in one of those exceptionally heavy fogs where vision is impossible at a few hundred feet, his only alternative is to fly on and look for an opening in the fog in some other direction. If, after feeling his way down to 200 ft. in some other locality, he is able to pick up the ground by sight, as is usually the case, he may then fly at this altitude and use his sight to pick out a suitable landing place.

Since fog is the exception rather than the rule, the sonic altimeter or any other type of altimeter will be used relatively seldom. It is therefore essential that the device be light, simple to operate, and cheap and reliable; otherwise it would not pay to carry the apparatus for the infrequent times when it is needed.

ACKNOWLEDGMENTS

It is desired to acknowledge the great assistance rendered by Mr. Ray Stearns' enthusiastic support throughout the progress of the work.

The author also is greatly indebted for the fine cooperation obtained from Mr. V. A. Rickard of the Schenectady Airport.

Special mention also should be made of the able assistance which Mr. A. J. Muchow gave to all phases of the development.

Lieutenant Albert F. Hegenberger's wide personal experience and skill as a flyer, combined with his enthusiasm and vision, were essential factors in the success of the enterprise.

The hearty cooperation obtained from Capt. H. M. McClelland and others of the Army staff at Washington and Wright Field was also a large factor in the success of the project.

If space permitted, the author would like to cite a long list of General Electric men, besides those mentioned in the text, whose special knowledge was freely given to assist in overcoming many difficult phases of the development.

Appendix No. 1

CHARACTERISTICS OF SOME SOUND SOURCES

A STUDY of the sound output and efficiency of various sound sources constituted an important part of the sonic altimeter development. A summary of the most interesting results are collected in Table 4. The efficiencies in Table 4 are the ratios of sound output of the source to the power available from the adiabatic expansion of the air. It will be noticed that a corrected value of sound output for the diaphone (foghorn) is given. In the original article[8] the expression for the sound output is given as:

TABLE 4 CHARACTERISTICS OF SOME SOUND SOURCES

Sound source	Frequency, cycles per sec.	Air pressure, lb. per sq. in. gage	Air flow, cu. ft. per min.	Mean spherical sound pressure at 3-ft. bars	Sound output, watts	Efficiency, per cent
1-in. whistle, 1/2-in. bell	3600	50	37	461	52	2.4
1-in. whistle, 3/4-in. bell	3000	50	37	783	152	7.0
1-in. whistle, 1-in. bell	2000	50	37	610	92	4.3
2-in. whistle, 0.010-in. throat	3000	81	107	1185	346	4.6
2-in. whistle, 0.010-in. throat	3000	50	69	946	221	5.4
2-in. whistle, 0.020-in. throat	3000	72	192	1600	630	4.8

[a] King.
[b] Corrected.
[c] This point is one taken from test No. 1 in L. V. King's article and represents average condition.
[d] Should be considered as an estimate only because of difficulty in determining distribution of sound pressure.

---

[8] L. V. King, Phil. Trans. of Roy. Soc., series A, vol. 218, p. 224, 1919.

$$\text{Sound output} = MC_v\Delta T \quad \text{[4]}$$

where
M = mass of air consumed per second
ΔT = temperature drop through diaphone
C_v = specific heat of air at constant volume
C_p = specific heat of air at constant pressure

The correction consists in replacing C_v by C_p, so that

$$\text{Sound output} = MC_p\Delta T \quad \text{[5]}$$

The need for this correction was pointed out by Mr. W. L. Knaus, who has assisted greatly by making all of the calculations for this Appendix.

In the original article the expression for efficiency is correct, as the same error was made in deriving the expression for available energy, and therefore the quotient of sound output and available energy, which is the efficiency, remains unchanged.

Table 4 shows that the sirens, at least those which the author built, consumed a large quantity of air and gave a relatively poor sound output. The 1-in. whistle with the $^3/_4$-in. bell gave the highest efficiency of any of the whistles, consumed a moderate amount of air, and gave a good sound output. The Allan Cunningham horn (size 3) shows a remarkably high efficiency and large sound output for a very moderate air consumption.

It would be interesting to try to build a practical high-frequency horn on this principle. Briefly, the horn consists of a flat diaphragm which is pressed against the small end of a short flaring horn. The clamping ring which supports the diaphragm is joined to the horn an inch or so from the small end, in such a way as to form a closed annular chamber. The air from the high-pressure line is fed into this annular chamber through a small constriction. The action is presumably somewhat as follows:

The air pressure builds up in the annular space and then escapes into the horn by forcing the diaphragm back off the closed small end. When the contents of the chamber are emptied, the diaphragm closes the small end of the horn, and the pressure builds up again in the annular chamber through the constriction.

WHISTLE DIRECTIVE CURVES

Fig. 10 gives the polar sound-pressure curve of the 1-in. 3000-cycle whistle at 3 ft. from the throat, for an air pressure of 50 lb. per sq. inch gage. The measurements were taken in a soundproof room 17 ft. by 8 ft. by $9^1/_2$ ft. high, using a condenser microphone and suitable amplifier. The experimental points are given by circles, and a smooth curve was drawn through the points for the purpose of obtaining the mean spherical sound pressure. Obviously more points are required to justify the smooth curve, but this would call for more money than was available. At 3000 cycles the sound pressures as indicated by the condenser microphone were divided by three to correct for pressure doubling and cavity resonance, as described in Appendix 2.

In what follows, the mean spherical sound pressure of a source is taken to be that which, if exerted uniformly over the surface of a sphere, would result in the same power output as the actual source when radiating through the surface of the same sphere. The following method of calculation applies only to those types of sources which have a distribution that may be represented by a figure of revolution. All that is necessary, then, is a polar distribution curve taken in a plane through the axis of symmetry.

Referring to Fig. 10, consider the sound output through a zone such as zone 3.

If r = radius of sphere and h = height of zone, the area of the zone is $2\pi rh$.

The mean sound pressure P_3 over the zone is taken to be that along a radius such as r_3. The power radiated through the zone is

$$W_3 = 2\pi rh\left(\frac{P_3^2}{425}\right) \times 10^{-6} \text{ watts} \quad \text{[6]}$$

If the sphere is divided into n equal zones, the expression for the total power is given by the following summation:

$$W = \sum_{K=1}^{K=n} W_K = \sum_{K=1}^{K=n}\left[2\pi r \times \frac{2r}{n}\left(\frac{P_K^2}{425}\right) \times 10^{-6}\right]$$

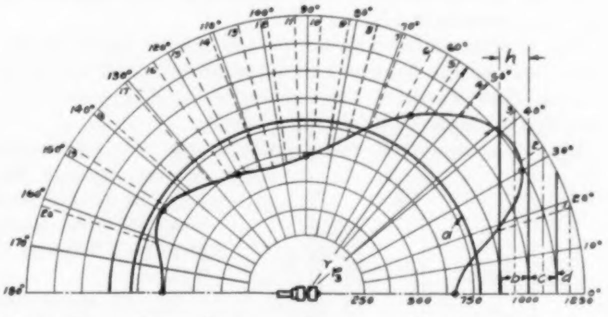

FIG. 10 POLAR SOUND-PRESSURE CURVE AT 3 FT. FROM THROAT OF WHISTLE

(1-in. whistle, 3000 cycles, $^{15}/_{32}$-in. bell opening, 0.01-in. throat, 50 lb. per sq. in. gage pressure. a, mean spherical sound pressure, 783 bars, bars at 3 ft. from source; d, zone 1; c, zone 2; b, zone 3.)

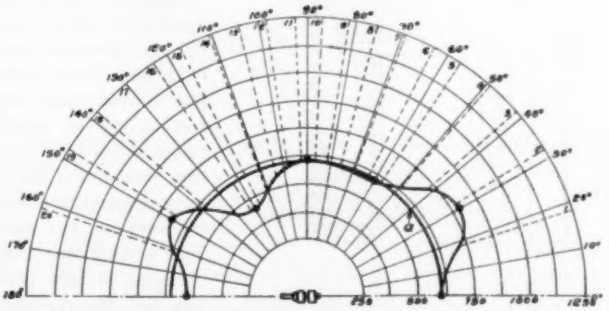

FIG. 11 POLAR SOUND-PRESSURE CURVE AT 3 FT. FROM THROAT OF WHISTLE

(1-in. whistle, 2000 cycles, $^{15}/_{16}$-in. bell opening, 0.01-in. throat, 50 lb. per sq. in. gage pressure. a, mean spherical sound pressure, 610 bars, bars at 3 ft. from source.)

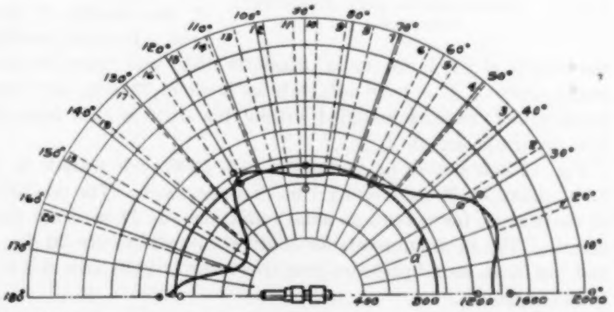

FIG. 12 POLAR SOUND-PRESSURE CURVE AT 3 FT. FROM THROAT OF WHISTLE

(2-in. whistle, 3000 cycles, $^{15}/_{32}$-in. bell opening, 0.01-in. throat, 50 lb. per sq. in. gage pressure. a, mean spherical sound pressure, 946 bars, bars at 3 ft. from source.)

$$= \frac{\Sigma P_K^2}{n} \times \frac{10^{-6}}{425} \times 4\pi r^2 \text{ watts} \quad \text{[7]}$$

From this it is seen that the first term, $\frac{\Sigma P_K^2}{n}$, is the square of the mean spherical sound pressure P_m, or

$$P_m = \sqrt{\frac{\Sigma P_K^2}{n}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

In Fig. 10 n has been taken as 20. It is evident from the foregoing that a simple average of uniformly spaced readings will not give a correct result.

The present calculation is similar to that of obtaining the mean spherical candlepower of a light source, and is explained in almost any illumination text.[9]

In Fig. 10 the calculated mean spherical sound pressure is 783 bars at a distance of 3 ft.

Fig. 11 gives similar data for the 1-in. whistle with 1-in. bell, which lowered the frequency to approximately 2000 cycles per second. The calculated mean spherical sound pressure is 610 bars at 3 ft., as shown by the heavy circle.

Fig. 12 gives corresponding data for the 2-in., 3000-cycle whistle shown in Fig. 13. The calculated mean spherical sound pressure is 946 bars at 3 ft.

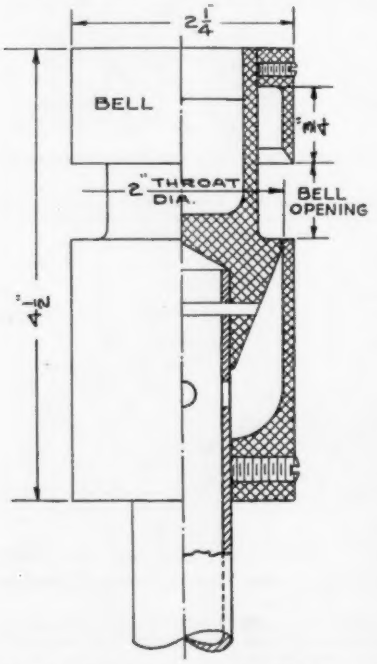

Fig. 13 Experimental 2-In. 3000-Cycle Whistle

Fig. 14 shows the effect on the sound-pressure distribution obtained by putting the 1-in. 3000-cycle whistle in a 12 in. diameter by 14 in. long by 1 in. diameter conical horn. The whistle was moved back and forth along the axis of the cone until the position was found which gave maximum sound pressure on the axis. The whistle was then clamped in this position for the directive curve readings. It will be noted that the microphone was held at 3 ft. from the center of the mouth of the horn. In other words, the mouth of the horn (12 in. diameter disk) was taken as the sound source. This horn subtends an angle of 43 deg., and the mean sound pressure included within this angle is 1290 bars at 3 ft. from the mouth.

Fig. 15 is a similar curve for the 1-in. 3000-cycle whistle in a 12 in. diam. by 30 in. long by 1 in. diameter horn. The position of the whistle for maximum axial radiation was 21 in. from the mouth. The horn subtends an angle of approximately 20 deg., and the mean sound pressure over this angle is 4400 bars at 3 ft. from the mouth.

Effect of Horn on Power Output of Whistle, and Calculated Concentration Factors

The concentrating efficiencies of the horns are brought out in the following comparisons:

(1) The ratio of sound pressure and power density which would exist with a fixed amount of power distributed over a sphere and over the solid angle subtended by the horn.

A_s = area of sphere
A_h = area subtended by horn angle
W_s = power density over the sphere
W_h = power density over the area subtended by the horn angle
P_s = sound pressure over sphere
P_h = sound pressure over the area subtended by the horn angle

Since the amounts of power distributed over the sphere and over the area subtended by the horn are the same, $W_sA_s = W_hA_h$.

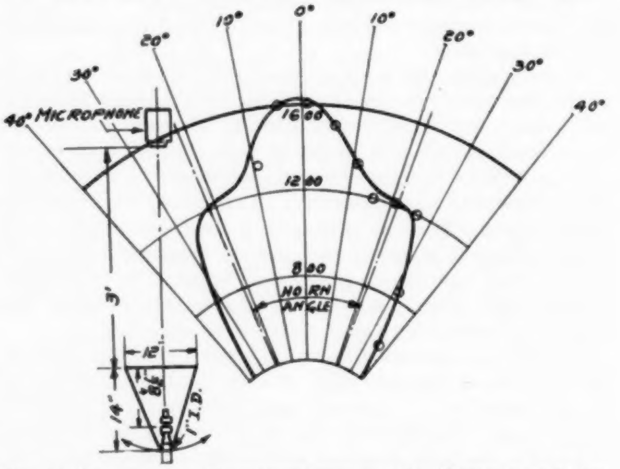

Fig. 14 Directional Characteristic of 1-In. Whistle in 14-In. Horn

(1-in. whistle, $^1/_2$-in. bell opening, 50 lb. per sq. in. gage pressure, mean sound pressure 1290 bars; bars at 3 ft. from source.)

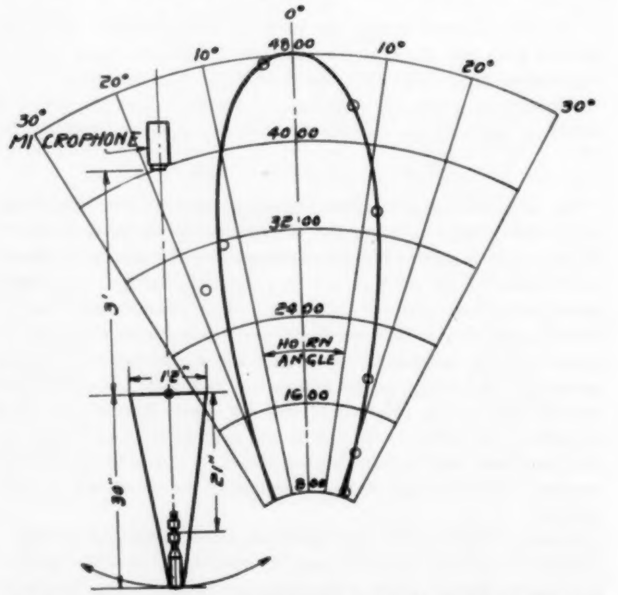

Fig. 15 Directional Characteristic of 1-In. Whistle in 30-In. Horn

(1-in. whistle, $^1/_2$-in. bell opening, 50 lb. per sq. in. gage pressure, mean sound pressure 4400 bars; bars at 3 ft. from source.)

$$\frac{W_h}{W_s} = \frac{A_s}{A_h} = \frac{\text{(watts per sq. cm. in solid angle of horn)}}{\text{(watts per sq. cm. in } 4\pi \text{ steradians)}} \ldots [9]$$

The ratio A_s/A_h can be easily found. Referring to Fig. 16, which is a section through the center of the sphere,

---

[9] "A Text Book of Illumination," William Kunerth, pp. 68–77, or "Illuminating Engineering," Cady and Dates.

$$\frac{A_s}{A_h} = \frac{4\pi r^2}{2\pi r h} = \frac{2}{1 - \cos\left(\dfrac{\alpha}{2}\right)} \ldots\ldots\ldots\ldots [10]$$

For the long horn, $\alpha = 20.8$ deg.

$$\frac{W_h}{W_s} = 122 \ldots\ldots\ldots\ldots [11]$$

The ratio of sound pressures is:

$$\frac{P_h}{P_s} = \sqrt{\frac{W_h}{W_s}} = 11 \ldots\ldots\ldots\ldots [12]$$

For the short horn, $\alpha = 42.8$ deg.

$$\frac{W_h}{W_s} = 29 \text{ and } \frac{P_h}{P_s} = 5.4 \ldots\ldots\ldots\ldots [13]$$

(2) The ratio of sound pressure and power density, actually measured, for the 1-in. 3000-cycle whistle operating in and out of the horns. For the long horn, $P_h = 4400$ bars at 3 ft., so that

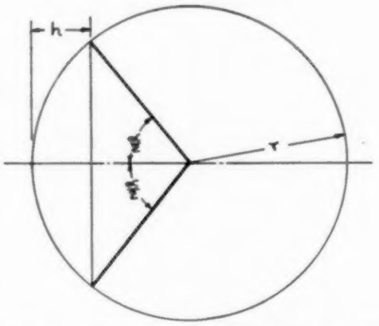

FIG. 16 SECTION SHOWING SPHERICAL ANGLE OF HORN

$$\frac{P_h}{P_s} = \frac{4400}{783} = 5.6 \ldots\ldots\ldots\ldots [14]$$

$$\frac{W_h}{W_s} = \frac{\text{(watts per sq. cm. observed for whistle in horn)}}{\text{(watts per sq. cm. observed with whistle in the open)}}$$

$$= \left(\frac{P_h}{P_s}\right)^2 = 31.5 \ldots\ldots [15]$$

For the small horn, $P_h = 1290$ bars at 3 ft.

$$\frac{P_h}{P_s} = \frac{1290}{783} = 1.65 \ldots\ldots\ldots\ldots [16]$$

$$\frac{W_h}{W_s} = (1.65)^2 = 2.7 \ldots\ldots\ldots\ldots [17]$$

(3) It was found by calculation from the polar distribution curve, Figs. 14 and 15, that the amount of power radiated was greatly reduced by placing the whistle in the horn. In the following, the ratio of sound pressures and power densities is found on the assumption that the whistle maintained the *same* output in and out of the horn.

In the case of the long horn it was found that the total output was 86 watts. With the whistle in the open, the total output was 152 watts. Therefore, if the outputs were equal, the ratio of W_h/W_s would not be that found in (2), but

$$\frac{W_h}{W_s} = \frac{\text{(watts per sq. cm. which would be obtained in cone if horn did not reduce output)}}{\text{(watts per sq. cm. with whistle in open)}}$$

$$= 31.5 \times \frac{152}{86} = 55.7 \ldots\ldots\ldots\ldots [18]$$

$$\frac{P_h}{P_s} = \sqrt{55.7} = 7.5 \ldots\ldots\ldots\ldots [19]$$

With the whistle in the short horn, the measured output was 29 watts. Equalizing, as in the foregoing, there is obtained:

$$\frac{W_h}{W_s} = 2.70 \times \frac{152}{29} = 14.2$$

$$\frac{P_h}{P_s} = \sqrt{14.2} = 3.8 \ldots\ldots\ldots\ldots [20]$$

A comparison of the power-density ratios found in (3) with those found in (1) gives a measure of the horn concentration. This may be called the "concentration efficiency."

For the long horn, this ratio is:

$$\frac{\left(\dfrac{W_h}{W_s}\right)_{(3)}}{\left(\dfrac{W_h}{W_s}\right)_{(1)}} = \frac{55.7}{122} = 45 \text{ per cent} \ldots\ldots\ldots [21]$$

For the short horn, this ratio is:

$$\frac{\left(\dfrac{W_h}{W_s}\right)_{(3)}}{\left(\dfrac{W_h}{W_s}\right)_{(1)}} = \frac{14.2}{29.0} = 49 \text{ per cent} \ldots\ldots\ldots [22]$$

The subscripts refer to the method of computing the power-density ratio.

MEASURED AND CALCULATED AIR FLOWS

The circles in Fig. 17 give the observed air flows for the 1-in. whistle and the 2-in. whistle with 0.01-in. throats. The smooth curves drawn through the points indicate calculated values obtained from the following familiar equations for adiabatic flow:[10]

$$W = A\sqrt{2g\,\frac{r}{r-1}\,\frac{P_1}{V_1}\left[\left(\frac{P_2}{P_1}\right)^{\frac{2}{r}} - \left(\frac{P_2}{P_1}\right)^{\frac{r+1}{r}}\right]} \text{ lb. per sec.} \ldots [23]$$

where

W = rate of discharge
A = area of throat in square feet
g = acceleration of gravity in feet per second^2
$r = \dfrac{\text{specific heat of the gas at constant pressure}}{\text{specific heat of the gas at constant volume}}$
= 1.40 for air
P_1 = tank pressure in lb. per sq. ft. abs.
V_1 = specific volume of air in tank in cu. ft. per lb.
P_3 = pressure outside of orifice in lb. per sq. ft. abs.
P_2 = pressure in throat

$$P_2 = P_3 \text{ if } P_3 > P_1\left(\frac{2}{r+1}\right)^{\frac{r}{r-1}} = 0.53\,P_1$$

and

$$P_2 = P_1\left(\frac{2}{r+1}\right)^{\frac{r-1}{r}} \text{ if } P_3 < 0.53\,P_1$$

If the velocity of the jet is destroyed without doing external work or removing energy in the form of heat, the expansion is said to be one of constant total heat; and it can be shown that the initial temperature T_1 and the final temperature T_2 are the same except for a negligible difference due to the Joule-Thomson effect.

---

[10] For example, see "Technical Thermodynamics," by Zeuner, translated by Klein, vol. 1, p. 236.

If V_2 = specific volume in cu. ft. per lb. of the air after expansion to pressure P_2 and absolute temperature T_2,

WV_2 = discharge in cu. ft. of free air per second

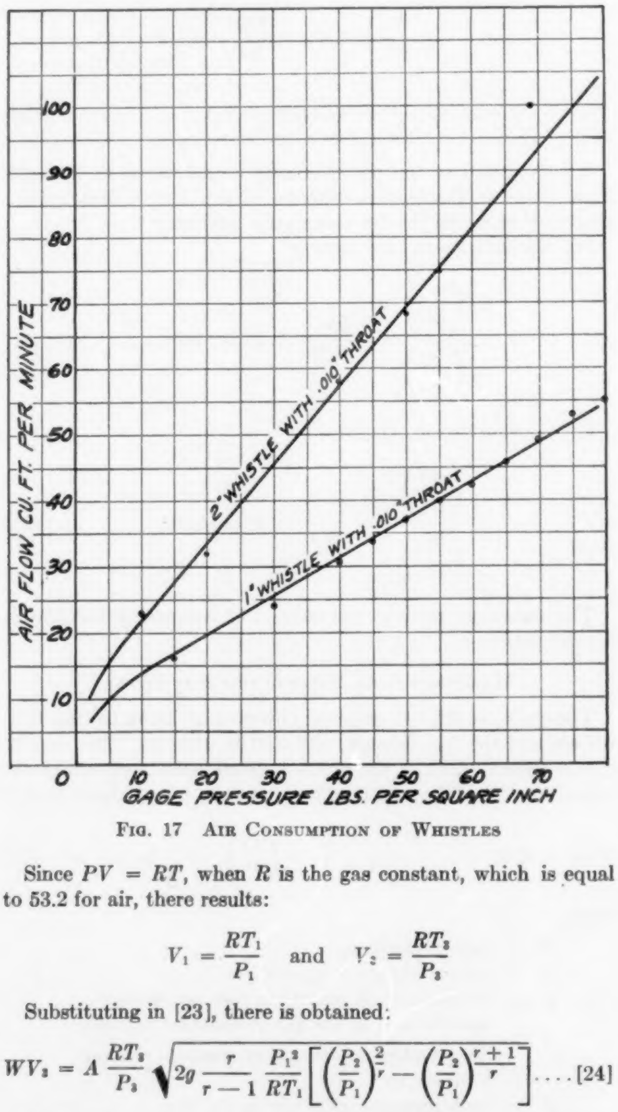

Fig. 17 Air Consumption of Whistles

Since $PV = RT$, when R is the gas constant, which is equal to 53.2 for air, there results:

$$V_1 = \frac{RT_1}{P_1} \quad \text{and} \quad V_2 = \frac{RT_2}{P_2}$$

Substituting in [23], there is obtained:

$$WV_2 = A\,\frac{RT_2}{P_2}\sqrt{2g\,\frac{r}{r-1}\,\frac{P_1^2}{RT_1}\left[\left(\frac{P_2}{P_1}\right)^{\frac{2}{r}} - \left(\frac{P_2}{P_1}\right)^{\frac{r+1}{r}}\right]} \ldots . [24]$$

Taking $T_1 = T_2 = 68$ deg. fahr. = 528 deg. fahr. abs.,

P_2 = (14.7 × 144) lb. per sq. ft.

a = throat area in sq. in.

$$\text{The rate of flow} = 1048a\left(\frac{P_1}{P_2}\right)\sqrt{\left(\frac{P_2}{P_1}\right)^{1.425}\left[1 - \left(\frac{P_2}{P_1}\right)^{0.287}\right]}$$

cu. ft. per min.......[25]

In Fig. 18 there is given for ready reference the flow through a 0.1-sq. in. orifice for different tank pressures in lb. per sq. in. gage.

The velocity of the jet issuing from the throat of a simple orifice is:

$$v = \sqrt{2g\,\frac{r}{r-1}\,P_1V_1\left[1 - \left(\frac{P_2}{P_1}\right)^{\frac{r-1}{r}}\right]} \text{ ft. per sec.} \ldots . [26]$$

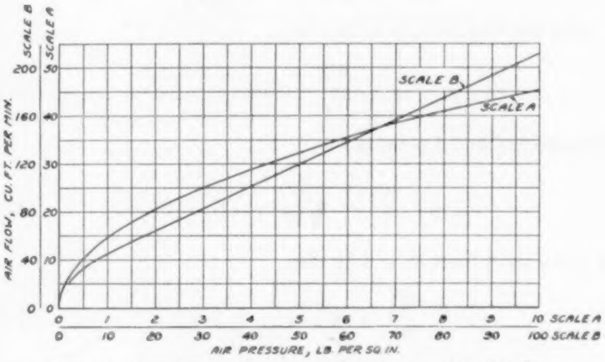

Fig. 18 Air Flow Through Orifice of 0.1 Sq. In.

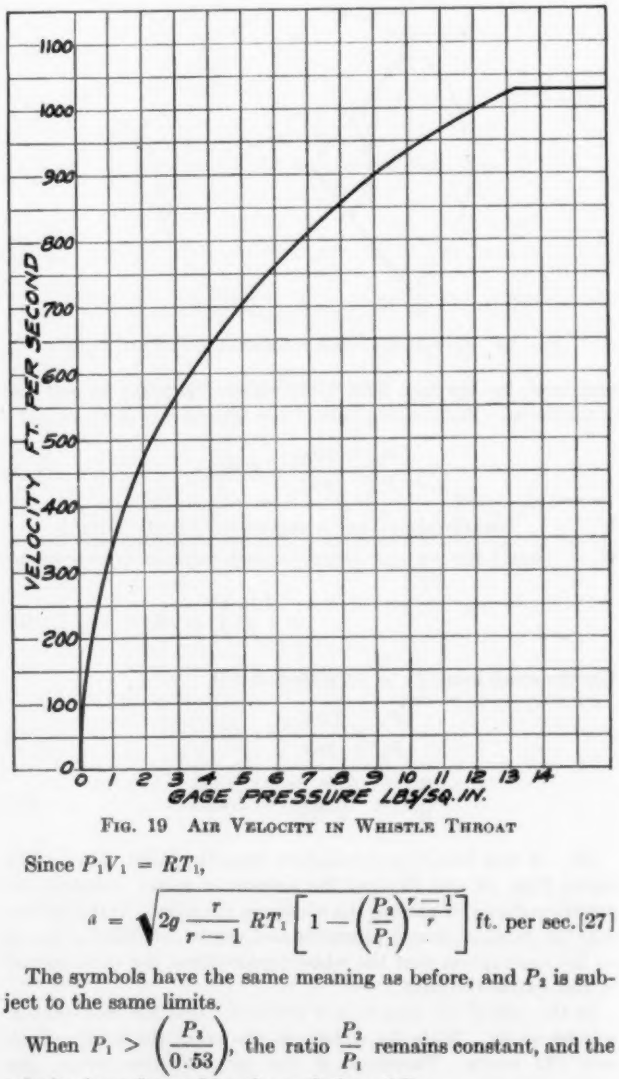

Fig. 19 Air Velocity in Whistle Throat

Since $P_1V_1 = RT_1$,

$$a = \sqrt{2g\,\frac{r}{r-1}\,RT_1\left[1 - \left(\frac{P_2}{P_1}\right)^{\frac{r-1}{r}}\right]} \text{ ft. per sec.} [27]$$

The symbols have the same meaning as before, and P_2 is subject to the same limits.

When $P_1 > \left(\frac{P_2}{0.53}\right)$, the ratio $\frac{P_2}{P_1}$ remains constant, and the velocity is unchanged by the variation of P_1.

With $R = 53.2$ and $T_1 = 528$ deg. fahr. abs., as before,

$$v = 2510\sqrt{1 - \left(\frac{P_2}{P_1}\right)^{0.287}} \text{ ft. per sec.} \ldots\ldots\ldots [28]$$

The calculated velocities from Equation [28] are given in Fig. 19.

The foregoing equations for velocity apply only to simple orifices with frictionless flow. With expanding nozzles of proper design, greater velocities than the maximum shown in Fig. 19 can be obtained.

Power for Isothermal and Adiabatic Compression and Power Available in Adiabatic Expansion

The values given in Table 5 and plotted in Fig. 20 were calculated from the following well-known relations:

The work per cycle of an ideal isothermal compressor is

$$w = P_3 v_3 \log_e \frac{P_1}{P_3} \text{ ft-lb.} \ldots\ldots\ldots\ldots\ldots [29]$$

v_3 = volume of intake per cycle in cu. ft.

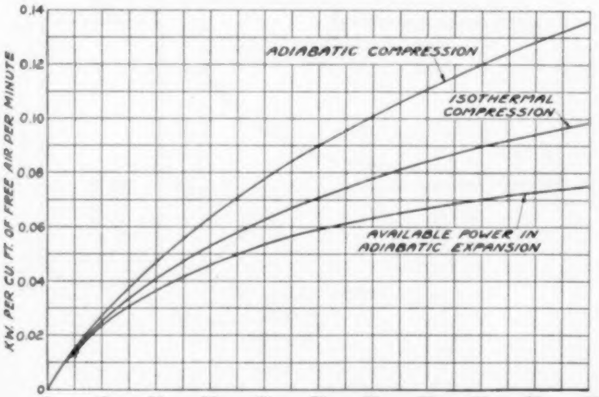

Fig. 20 Power Required for Compression and Available Power in Expansion of Air

Taking $P_3 = (14.7 \times 144)$ lb. per sq. ft., there is obtained the following expression for the power required to compress 1 cu. ft. of free air per minute:

$$\text{Kw.} = 0.110 \log_{10} \left(\frac{P_1}{P_3}\right) \ldots\ldots\ldots\ldots\ldots [30]$$

P_1 and P_3 are the tank and external pressures, respectively, as before.

The work per cycle of an ideal adiabatic compressor is:

$$w = \frac{r}{r-1} P_3 v_3 \left[\left(\frac{P_1}{P_3}\right)^{\frac{r-1}{r}} - 1\right] \text{ ft-lb.} \ldots\ldots\ldots [31]$$

The power required to compress 1 cu. ft. of free air per minute becomes:

$$\text{Kw.} = 0.166 \left[\left(\frac{P_1}{P_3}\right)^{0.287} - 1\right] \ldots\ldots\ldots\ldots [32]$$

TABLE 5

Gage pressure, lb. per sq. in.	Kilowatt for isothermal compression of 1 cu. ft. of free air per minute	Kilowatt for adiabatic compression of 1 cu. ft. of free air per minute	Kilowatt available in adiabatic expansion of 1 cu. ft. of free air per minute
0.1	0.00033	0.00033	0.00033
0.2	0.00065	0.00065	0.00065
0.5	0.00160	0.00162	0.00160
1.0	0.00316	0.00319	0.00313
2.0	0.00613	0.00624	0.00603
5.0	0.0139	0.0148	0.0136
10.0	0.0248	0.0272	0.0234
20.0	0.0412	0.0468	0.0365
40.0	0.0626	0.0778	0.0534
60.0	0.0775	0.101	0.0631
80.0	0.0895	0.120	0.0700
100.0	0.0985	0.136	0.0750

In computing the energy available in the expansion for 1 cu. ft. of free air, it has been assumed that the air in the tank cools to room temperature before being expanded.

If v_1 = volume of air at pressure P_1 and room temperature (T_1 or T_3) having the same weight as 1 cu. ft. of free air (pressure P_3), the work done in adiabatically expanding the volume v_1 to pressure P_3 is given by:

$$w = \frac{r}{r-1} P_1 v_1 \left[1 - \left(\frac{P_3}{P_1}\right)^{\frac{r-1}{r}}\right] \text{ ft-lb.} \ldots\ldots\ldots [33]$$

Since $T_1 = T_3$, $P_1 v_1 = P_3\,(1.00)$ by Boyle's law:

$$v_1 = \frac{P_3}{P_1}$$

Substituting this in [33], there is obtained:

$$w = \frac{r}{r-1} P_3 \left[1 - \left(\frac{P_3}{P_1}\right)^{\frac{r-1}{r}}\right] \text{ ft-lb.} \ldots\ldots\ldots [34]$$

It may be readily shown that the ratio of Equation [34] to Equation [31], where v_3 in [31] is 1 cu. ft., is given by

$$\left(\frac{P_1}{P_3}\right)^{\frac{r-1}{r}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [35]$$

The values in column 4 of Table 5 were accordingly obtained by multiplying column 3 by Equation [35].

Efficiency of 1-In. 3000-Cycle Whistle at Different Supply Pressures

The efficiency curve given in Fig. 21 is based on a curve showing the sound pressure output of the 1-in. 3000-cycle whistle at different gage pressures, which was taken in the early part of the development. The conviction is now reached that the absolute values of the sound pressures given by this early curve were wrong, but that the shape of the curve was correct. The mean spherical sound pressure (783 bars at 3 ft. with 50 lb. per sq. in. gage) of Fig. 10 was accordingly used to obtain a correction factor.

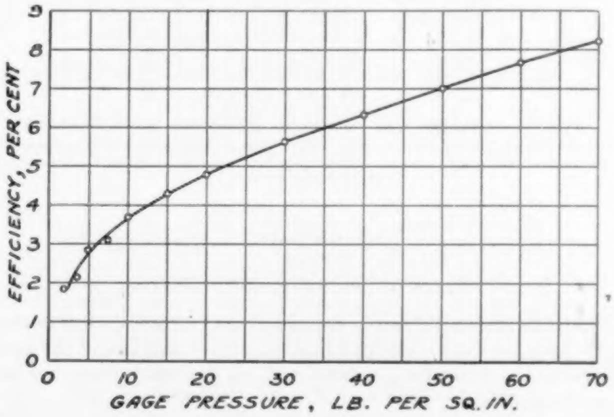

Fig. 21 Efficiency Curve of 1-In. 3000-Cycle Whistle for Various Gage Pressures

As previously stated, the author has consistently divided the sound pressures indicated by the condenser microphone, for frequencies in the vicinity of 3000 cycles, by 3 to allow for pressure doubling and cavity resonance. On this basis the efficiency of the 1-in. 3000-cycle whistle was 7 per cent at 50 lb. per sq. in. gage pressure. If no such allowance had been made, the efficiency would be nine times as high, or 63 per cent. This would bring the whistle up to approximately twice that of the Allan Cunningham horn.

Variation of Sound Pressure With Distance

The data plotted in Fig. 22 give the results of some outdoor sound-pressure measurements. The whistle was pointed vertically upward and was approximately 8 ft. above the ground. The point marked by the large circle at 3 ft. is the 90-deg. point from the booth measurements of Fig. 10. The average line drawn through the points shows that the sound pressure is inversely proportioned to the distance from the source.

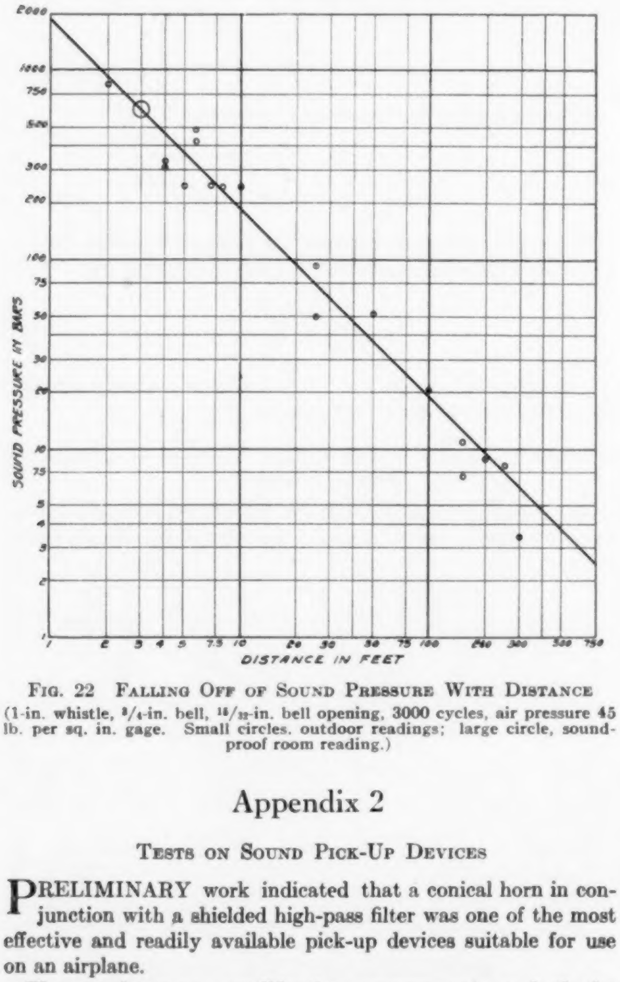

Fig. 22 Falling Off of Sound Pressure With Distance

(1-in. whistle, $^3/_4$-in. bell, $^{15}/_{32}$-in. bell opening, 3000 cycles, air pressure 45 lb. per sq. in. gage. Small circles, outdoor readings; large circle, soundproof room reading.)

Appendix 2

Tests on Sound Pick-Up Devices

PRELIMINARY work indicated that a conical horn in conjunction with a shielded high-pass filter was one of the most effective and readily available pick-up devices suitable for use on an airplane.

The sound-pressure amplification measurements on both the conical horn (*A*, Fig. 23) and the parabolic mirror (*G*, Fig. 23) as well as a 30-in. by 1-in. diameter tube, were made in a 17-ft. by 8-ft. by $9^1/_2$-ft. soundproof booth.

The apparatus set up for the conical horn is shown in Fig. 24. A similar set-up for the parabolic mirror is shown in Fig. 25.

The sound-pressure amplification measurements on the 30 in. long by 1 in. diameter tube were made with a set-up similar to that of Fig. 24, except that the horn was replaced by the tube.

The sound-pressure amplification factors of the horn, parabolic mirror, and 1 in. diameter by 30 in. long pipe were measured in the following manner: Constant sound pressure was assumed to be maintained at the mouth of the horn by holding constant sound pressure on a condenser microphone which was placed ahead of the pick-up device under test, as shown in Figs. 24 and 25. The output sound pressure of the pick-up combination under test was measured by another condenser microphone. This latter condenser microphone was fitted with a plug which left a clearance of approximately $^1/_{32}$ in. between the diaphragm and the plug, the sound being admitted to this cavity through a $^5/_{16}$ in. diameter tube. The voltage output of this condenser microphone was measured after passing through an electric wave analyzer which it is believed eliminated the effects of any harmonics present in the original sound. After running the test, the absolute value of the sound pressure in the plane of the pick-up device was determined by taking the measuring microphone out of its box, removing the plug, and placing it in the position previously occupied by the pick-up device under test.

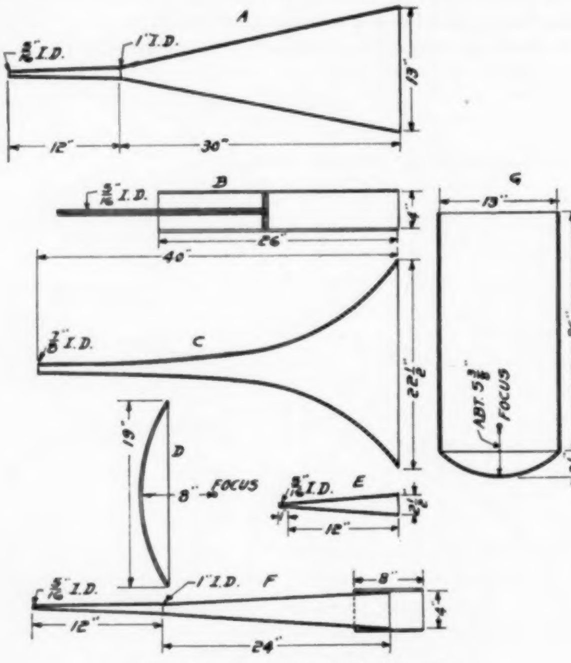

Fig. 23 Sound Pick-Up Devices

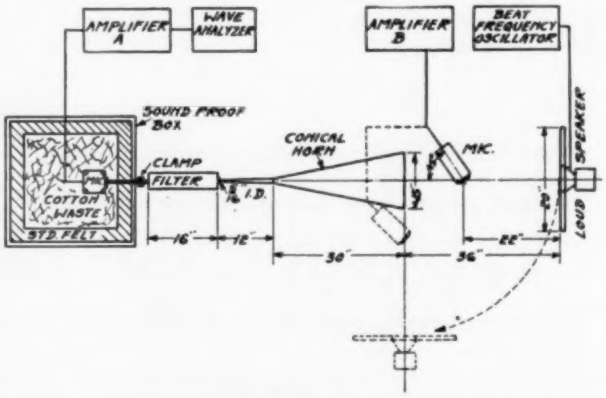

Fig. 24 Apparatus Set-Up for Sound-Pressure Measurements on High-Pass Filter and Conical Horn

The input sound pressures were corrected for pressure doubling and cavity resonance by the curve shown in Fig. 26, which is taken from the work of Ballentine.[11]

Fig. 27 shows the end-on characteristics of the horn with and

without the high-pass filter, and also the effect of mechanical sound transmission. It is seen from this figure that there is obtained approximately a threefold amplification at 3000 cycles for the horn and filter combination. In the low-frequency region the effects of horn resonance are eliminated, and there also is obtained a 10-to-1 reduction in the sound pressure by using the acoustic high-pass filter.

Fig. 28 shows the end-on and sidewise sound-pressure amplification for the large horn and 1 in. diameter pipe. It is seen from this that the horn is not particularly directive at the low frequencies, but gives a ratio of approximately 50 to 1 at 3000 cycles, and is therefore very effective in cutting down the high-frequency components of the engine noise which arrive directly from the engine.

Fig. 29 gives the sound-pressure transmission characteristics of the shielded acoustic high-pass filter, which is shown in Fig. 30. This curve is obtained from Fig. 27 as the ratio of sound pressure with filter to sound pressure without filter at various frequencies. The curve marked "Tube Pinched," which gives the mechanical transmission of sound, was subtracted from the one marked "Filter In" before the ratio was taken. This curve indicates only 65 per cent transmission at 3000 cycles, and it is evident therefore that the filter should be redesigned for a somewhat lower cutoff to obtain maximum 3000-cycle signal.

Fig. 31 shows the end-on and sidewise sound-pressure amplification of the parabolic mirror set-up of Fig. 25. The parabolic mirror was placed at the end of a 26 in. long by 12 in. diameter pipe with the hope of improving the sidewise directivity and to shield the small focal pick-up horn from the slipstream. It is evident from the figure that practically nothing is gained in low-frequency directivity by the large cylindrical shield. At 3000 cycles the tests indicate a sound amplification of approximately 5 to 1 and end-on to sidewise directivity ratio of 25 to 1. Dr. H. F. Olson and Dr. Irving Wolff in their recent paper on "Sound Concentrators for Microphones"[12] obtained a 2-to-1 ratio in favor of their parabolic concentrator at 3000 cycles as compared with their horn. In view of their results it is hoped at some future date to make further tests on parabolic devices.

Comparative listening tests using a 3000-cycle tone in the booth indicated that sound pressures at the ear from the various pick-up devices shown in Fig. 23 varied approximately as the diameters of the pick-up areas. These rough observations, using the ear also, indicated that the useful angle of pick-up for a 13 in. diameter by 30 in. long horn was approximately 10 deg. on either side of the axis.

Appendix 3

DIFFUSE AND SPECULAR REFLECTION AT THE GROUND

If the sound intensity at the small distance d near the source is I_D ergs per sq. cm. per sec., the intensity at the ground, which is at a distance D, will be

$$I_D = I_d\left(\frac{d}{D}\right)^2 \text{ ergs per sq. cm. per sec.} \quad [36]$$

In case it is desired to consider that the sound is assumed to be confined by the megaphone to a cone having a semi-angle α as shown in Fig. 32, the sound intensity over the circular patch on the ground will then be

$$I_D \cos\alpha = I_d\left(\frac{d}{D}\right)^2 \cos\alpha \quad [37]$$

The semi-angle (α = 10 deg.) is small, and one can therefore take $\cos\alpha = 1$. The total sound flux falling on the "illuminated" circle of area A will then be

$$J = I_d\left(\frac{d}{D}\right)^2 A = I_d\left(\frac{d}{D}\right)^2 \pi D^2 \tan^2\alpha \text{ ergs per sec.} \quad [38]$$

The reflected intensity on the axis right near the surface is equal to the incident intensity divided by π. The factor π takes care of the scattering accompanying diffuse reflection. The reflected intensity at a distance R on the axis will then be

$$I_R = K\,\frac{I_d\left(\frac{d}{D}\right)^2 A}{\pi R^2} \text{ ergs per sq. cm. per sec.} \quad [39]$$

where K is the coefficient of reflection of the surface.

To be exact, R in Equation [39] should be measured from the edge of the circle. A good approximation for the intensity off the axis, provided the distance R is large compared with the diameter of the "illuminated" circle, is obtained by multiplying Equation [39] by $\cos\beta$, where β is the angle between the axis and the line joining R with the center of the circle.

For the echo received back at the airplane, substitute $R = D$ and $A = \pi D^2 \tan^2\alpha$ in Equation [39], and obtain

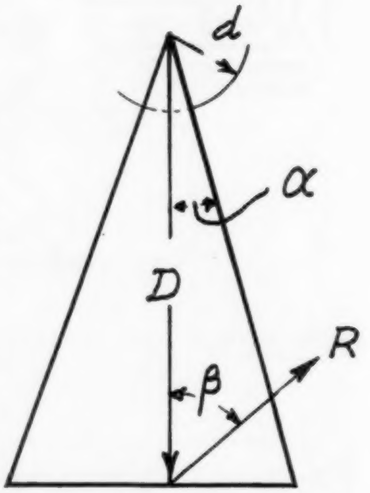

FIG. 32 DIFFUSE REFLECTION OF SOUND

$$I_R = \frac{KI_d d^2 \tan^2\alpha}{D^2} \text{ ergs per sq. cm. per sec.} \quad [40]$$

In the case of perfect specular reflection, there is obtained

$$I'_R = I_d\left(\frac{d}{2D}\right)^2 \text{ ergs per sq. cm. per sec.} \quad [41]$$

The ratio of [41] to [40] gives:

$$\frac{I'_R}{I_R} = \frac{1}{4K\tan^2\alpha} \quad [42]$$

For $K = 1$ and α = 10 deg., there is obtained

$$\frac{I'_R}{I_R} = 8 \quad [43]$$

This corresponds to a sound-pressure ratio of 2.8 to 1. If $K = 0.5$, the intensity ratio becomes approximately 16 and the pressure ratio 4 to 1. For $K = 0.25$, the intensity ratio becomes $7.95/0.25 = 32.8$ and the pressure ratio 5.75.

The author is indebted to Dr. F. A. Benford for the results obtained in the foregoing.

Discussion

WESLEY L. SMITH.[13] The effective range of this instrument is less than 1000 ft., so that its use seems to be limited to that of an aid to landing. While its weight is a trifle high, it no doubt can be consolidated with other instruments to form a very useful part of the landing aids that are needed. A combination of the radio landing beam, the sensitive aneroid barometer equipped with a barometric correction scale, and the sonic altimeter should provide all that is needed to land under conditions of no visibility.

---

[12] *Journal of Acoustical Society of America*, vol. 1, p. 310, April, 1930.

[13] Chief Engineer, National Air Transport, Inc., Chicago, Ill.

It would seem possible to use the gas pressure provided by the sonic-altimeter equipment to drive the gyroscopes in the artificial horizon, the directional gyro, and the automatic pilot, and also to use this same gas pressure to operate the ice overshoes. If this could be done, part of the weight that is necessary for the sonic altimeter could also serve other purposes.

AUTHOR'S CLOSURE

Mr. Wesley Smith has correctly summed up the present status of the sonic altimeter. As stated in the text, the weight of the installation on the Army Douglas plane was 45 lb.; the latest design, of which three have been sold to the Army, has a total installed weight of 28 lb. Further reductions which are immediately possible will bring this down to less than 25 lb.

A recent flight test with the sonic altimeter on the *Los Angeles* demonstrated that good height determinations may be made from 3000 ft. and below.

The immediate applications of the sonic altimeter should be to lighter-than-air craft and to flying boats. In the case of airships the increased weight is amply compensated for by the increased safety should the ship get caught out in a fog. A similar situation exists in the case of flying boats, because water landings will be rendered practical using the sonic altimeter alone, without radio beacons or other special landing aids.

AER-54-10

The Tail Spinning of Aircraft

By GILBERT G. BUDWIG,[1] WASHINGTON, D. C.

Tail spinning of aircraft is a subject of interest to manufacturers and operators alike. There is much to be learned in the application of corrective measures. The problem was investigated by the Department of Commerce, and it was determined that there were four factors which in most cases will determine if an airplane will have satisfactory spinning characteristics: It should be stable about all three axes; the center of gravity should be well forward with respect to the center of pressure; the wing loading should be kept below a certain maximum figure depending mostly upon the characteristic of the particular airfoil; the weights of airplane and cargo should be grouped as closely as possible around the center of gravity. One or more of these characteristics were involved in every airplane that spun unsatisfactorily, and the correction of this factor brought about the desired result.

THE tail spinning of aircraft, together with the structural characteristics relating thereto, is a subject of vital interest to manufacturers and operators alike. Generally speaking, there is yet much to learn about spinning, and this is particularly true in the application of corrective measures to aircraft which inherently have undesirable spinning characteristics.

The problem was forcibly brought to the attention of the Department of Commerce during the latter part of 1928. It became evident from our accident statistics, which were by that time fairly comprehensive, that in certain makes of aircraft the proportion of tail-spin accidents to the total accidents was inconsistent with other makes of aircraft. In light of the fact that four or five, or perhaps more, airplanes were crashing due to tail spins, with a frequency far exceeding other makes, we were led to believe that the cause to a great extent must have been due to peculiar flight characteristics in the airplanes involved. We therefore set out to determine what these characteristics were and how best the corrective measures could be instituted.

First, we spin-tested the airplanes which were apparently causing the trouble. Some rather interesting results were obtained. One of these airplanes, when put into a spin, would continue to spin indefinitely even though the controls were moved back to neutral, recovery being effected only after the controls had been reversed to the extreme position, and then the recovery followed an additional four turns. Another airplane, when put into a spin, developed so much back pressure on the stick that it was necessary to use both hands to force it to neutral, and recovery was possible then only after three additional turns.

Another airplane, when spun to the left, would continue spinning to the left even though extreme right rudder was applied, recovery being effected by reversing the controls and awaiting approximately four additional turns. We also found in a number of cases that, when the controls were moved to the extreme position to commence the spin, they would, if released, remain there, and a considerable amount of physical force would be necessary to return them to neutral.

When this condition was discovered, it became apparent that some test procedure would necessarily be imperative to eliminate the existing hazard. In light of the fact that all of the airplanes tested which had undesirable spinning characteristics were longitudinally unstable, it became obvious that a stability and spin requirement should be made a part of the Airworthiness Requirements.

After considerable study, such a minimum standard was determined and put into effect about Jan. 1, 1929. This standard provided for a determination of longitudinal, lateral, and directional stability and for a measurement of spinning characteristics. It seemed to the department at that time that these standards were not only absolutely necessary, but were also practicable and could well be applied without materially adding to the cost or decreasing the performance of airplanes. The procedure involved was comparatively simple.

As previously, manufacturers continued to submit complete drawings, stress analysis, and other technical data in support of their application for an Approved Type Certificate for a new design of airplane. After these technical data were examined and were adjudged satisfactory, an inspector for the Department of Commerce was assigned to flight-test the airplane in question. These inspectors were carefully chosen for their ability as pilots and for their comprehensive knowledge of airplanes, with particular reference to flight characteristics. They were the best men available for that type of work, and their objective was to determine the stability and spinning characteristics of the airplanes, as well as the workmanship, materials, and methods involved in their fabrication.

A brief outline of the flight-test procedure which was then promulgated and which is still effective follows:

The airplane is tested for balance and for stability longitudinally, laterally, and directionally, and if found satisfactory, the spin test is conducted. The airplane is first spin-tested by the factory test pilot, and the results are confirmed by our engineering inspector on the succeeding tests.

This procedure has since been used continuously in checking all airplanes in certain weight classifications which have been submitted for approval, and this has yielded two years of very valuable and interesting experience. During this time, the principles underlying inherent stability have become generally recognized and well enough understood so that it is a comparatively simple matter to predict the stability of an airplane. The question of spinning is, however, considerably more complicated, and no entirely satisfactory method has yet been evolved

---

[1] Director of Air Regulation, Department of Commerce. Born Nov. 17, 1895, at Cleveland, Ohio. Connected with commercial aviation since 1916 and employed during the World War as civilian instructor stationed at Chanute Field, Rantoul, Ill.; Kelly Field, San Antonio, Texas; Rockwell Field, San Diego, and March Field, Riverside, Calif. Flew the air mail immediately after the war, and then did two years of barnstorming. Later, did a substantial amount of free-lance test piloting, and owned and operated the Budwig Radio Company at Glendale, Calif., for approximately five years. Became affiliated with the Aeronautics Branch of the Department of Commerce in June, 1927, as aeronautical inspector; appointed chief of the inspection service in May, 1928; appointed director of air regulation on Oct. 4, 1929.

Presented at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

for theoretically determining the spinning characteristics of an airplane. A tremendous amount of work has been done on this subject, actively stimulated and made necessary by the Department of Commerce regulations pertaining thereto. Our own experience allows us to state certain general principles which will be of interest even though they are not quantitative and not absolute. The first of these general principles is that bad spinning characteristics are not confined to any one particular type of airplane. We have found them in conventional biplanes, low-wing monoplanes, and high-wing monoplanes.

Another common experience is that many airplanes will develop two or more different types of spins, depending upon the attitude from which the spin is started. Usually we have found that such airplanes have satisfactory characteristics if they are spun in the usual manner from a stalled position, but that they will develop an uncontrollable spin if it is started from some less conventional attitude. One rather serious and important fact in this connection is that biplanes which have entirely satisfactory spinning characteristics when properly rigged have a tendency to develop dangerous spins when allowed to get out of rig even by a small amount. Since many operators of these smaller airplanes are not too careful about maintaining their airplanes in exactly their original rigging condition, we are frequently encountering spinning difficulties of this nature.

Perhaps a brief outline of some of our experiences in conducting these tests will be of interest. One airplane of the high-wing, two-place type, when tested, disclosed that at both cruising speed and full power the plane was unstable longitudinally and directionally under all conditions. The left spin, with light load (half a tank of gasoline, pilot, and parachute), was irregular in that the third, fifth, seventh, and ninth turns were flat. The ship would whip into a steep spin and gradually flatten out until the end of the third turn; the time-elapse in the third turn was 3 seconds; time of the second turn was $1^{1}/_{2}$ seconds. After the third turn, the ship would again whip into the steep spin and gradually flatten out until it would whip off at the end of the fifth turn. The stabilizer position varied from neutral to maximum negative.

With full load, the ship spun about the same, but increased control forces were necessary to force the stick forward. If power was used in the flat turn, the ship would recover immediately; if used in the steep turn, the spin tightened and became flat, making recovery impossible unless the motor was cut.

To correct these spin characteristics, the motor was moved forward 4 in., the wing raised 2 in. and moved back 2 in., and the lift struts were replaced with streamline struts. The ship was again tested and proved satisfactory.

One of the unaccountable spinning characteristics encountered by one of our engineering inspectors in spin-testing was with a three-place low-wing monoplane. One of these airplanes had been reported to have come down in a flat spin with a 245-lb. pilot and a parachute weighing some 20 lb. in the rear cockpit. This case was taken up with the manufacturer's test pilot, who reported that the ship would flat-spin under adverse loading conditions, but would recover if the controls were released. He offered to demonstrate the fact. The same type of aircraft was loaded with 3 gal. of gas ahead of the center of gravity, with the pilot, the parachute, and the sandbags, totaling 215 lb., in the rear cockpit. In putting this plane into a left spin, the first turn appeared normal, but gradually the nose came up during the next two turns until the plane was in an attitude of a flat spin. It was held in this flat-spinning attitude for three turns, after which both the rudder and the stick controls were released. The plane seemed to be swinging considerably ahead and slightly to the left in the left spin of the longitudinal axis of the plane. Considerable centrifugal pressure was noted, tending to throw the pilot against the back of the seat, but not sufficient to prevent him from leaving the ship if necessary. After eight turns the stick control was released and the feet were removed from the rudder. The stick traveled to the inside rear corner, where it remained for about one turn. The nose then started down with the stick moving forward at the same time. The airplane recovered from this spin in three and one-half or four turns after the release of the controls. The spin was then repeated to the right with identical results.

The foregoing case is one of a very few instances of a controllable flat-spin condition, especially since the plane recovered without forcing the controls.

Another very interesting case experienced by one of the inspectors was with a five-place cabin-type airplane. Before this test was started, the plane was loaded with weight equivalent to four passengers. Three attempts were made to spin the plane to the right, but each time the plane would make about a three-fourth turn of a spin and would then spiral out. A left spin was then attempted. This was started by stalling the plane with the nose up at an angle of 45 deg. and by banking to the left at an angle of 50 deg. This was done at an altitude of about 5500 ft. As the plane started falling to the left, the left rudder was kicked sharply and the stick control pulled back to the right in the rearmost position. The plane fell into a spin immediately, and before it had completed one full turn there developed a very severe back pressure on the stick. The rudder was immediately reversed, and an attempt was made to push the stick forward, first with one hand, then with both. It was only possible to get the stick forward about 3 in. back of neutral position, the inspector having insufficient strength to move it any farther. The plane immediately assumed a flat-spinning attitude. After four turns had been made in this position with every attempt made to reverse the controls, the throttle was opened. This caused the nose to rise to a higher position, which also increased the speed of rotation. The motor was immediately throttled, and opposite aileron and rudder control with stick forward were attempted, this being done for six turns with no apparent effect. Then forward stick and opposite rudder with no aileron was attempted for six turns, with no result. The speed of rotation and attitude of the plane remained unchanged. Then several different combinations of controls were tried, none of which had the slightest effect. The plane had then reached an altitude of 2500 ft., and the inspector unfastened his belt to determine whether there were any centrifugal forces which would prohibit him from jumping. None were experienced, so he decided to continue his attempt to regain control of the airplane. At 1100 ft. the airplane for the first time broke from its rhythmic slow turning and appeared to do one-half turn of a slow normal spin, the nose dropping almost to a normal angle. However, reaching this position, it immediately swung back to the same even, slow flat spin. At that time the inspector was using right rudder and forward stick so severely that he unintentionally applied slight left aileron. This apparently released some of the back pressure on the stick, and it advanced slightly forward. He then tried hard left aileron, forward stick, and right rudder. With the controls in this position, the airplane slightly banked to the left to about a 45-deg. angle. The nose then fell slowly, which automatically released the back pressure on the stick, letting it gradually go forward. From this position, the airplane went into a left bank at 800 ft., and was then brought to normal flying attitude. The peculiar spinning characteristic of this airplane was apparently due to the excessive load placed behind the center of gravity and from improper rigging. It completed 28 turns before recovery was accomplished.

It would be possible to continue, almost indefinitely, outlining in detail the experiences encountered in the spin-testing of aircraft. Space, however, prohibits this, and no doubt the foregoing will, to a measure at least, outline the interesting problems involved.

It has been our experience that in all of these types there are four very important factors which will, in most cases, determine whether or not an airplane will have satisfactory spinning characteristics. These four factors are as follows: (*a*) It is necessary that the airplane be stable about all three axes; (*b*) it is necessary that the center of gravity be well forward with respect to the center of pressure, thus producing a nose-heavy moment which is balanced by a down-load on the stabilizer; (*c*) the wing loading should be kept below a certain maximum figure which depends, among other things, upon the characteristics of the particular airfoil; (*d*) the weights of the airplane and its cargo should be grouped as closely as possible around the center of gravity of the airplane.

It has been found in general that one or more of these factors were involved in the case of every airplane which spun unsatisfactorily and that the correction of this particular factor brought about the desired result. Even this statement, however, is not absolute, for in a few cases in which all of these factors were apparently satisfactory, the airplane still continued to spin unsatisfactorily. There are air forces effective in these cases which we do not as yet understand and which will require a great amount of research to thoroughly comprehend.

It will be seen from this rather brief summary that the problem is comprehensive, and while much has been accomplished, there still remains the necessity for further investigation. Perhaps our most valuable contribution in this connection is the impetus which we have given to intensive spin study by focusing a great deal of attention on that particular maneuver. So far as the theory of flight is concerned, additional research work will be of tremendous assistance.

In an effort to determine the actual value of spin-testing from the standpoint of safety, we have made a general study of spinning accidents for the entire period over which we have any record. In addition to this, we have made a detailed study of the year 1929, believing that year to be of particular interest in view of the fact that it was the first year during which spin tests were conducted.

The following table lists the important facts for this four-year period covered by our records. The percentage figures are determined by dividing the total number of spin crashes for a given period by the total number of airplanes which our records indicate were flying at that time.

Date	Number of airplanes	Total spin crashes	Percentage
All of 1927	2759	96	3.5
First half 1928	4284	127	3.0
Second half 1928	5654	186	3.3
First half 1929	7781	149	1.9
Second half 1929	9922	206	2.1
First half 1930	9773	193	2.0
Second half 1930	9863	196	2.0

It will be noted that during the first half of 1929 the percentage of spin accidents dropped very sharply and that from then to the present time the percentage has remained approximately the same. The decrease in accidents amounts to 1.4 per cent for each half year. Since there were some 10,000 airplanes in existence during the last half of 1929 and all during 1930, it is conservative to say that 140 accidents were prevented each half year, or 280 accidents per year, by the introduction of the spin-test procedure. It is reasonable to suppose that the 2 per cent figure indicated will decrease considerably as soon as the older types of airplanes pass out of existence.

The detailed study of the year 1929 shows even more striking results. The accident reports which we have charge 236 crashes during that year to spins. Of these 236 crashes during the entire year, only 11 occurred in licensed airplanes which had been spin-tested by the department. Of these 11 there were only 6 which could even remotely be charged to the airplane, because 5 of them were caused by incompetent pilots or acrobatics at low altitudes. Thus we arrive at the very remarkable conclusion that only 2$^1/_2$ per cent of all the spin accidents which occurred during 1929 were attributable to airplanes spin-tested by Department of Commerce inspectors. If you compare these 6 accidents with the fact that there were 9922 airplanes in existence at the conclusion of 1929, and recall at the same time that most of these so-called spin crashes were the result of stalled turns at low altitudes, you will realize that the department's flight-test procedure was very effective in preventing fatalities during the year.

Of the total of 236 spin crashes, 39 per cent were unlicensed or war-surplus airplanes, and 56$^1/_2$ per cent were licensed airplanes which had not been spin-tested before approval.

A significant fact is that these accidents cannot be charged against any small number of manufacturers nor any particular type of airplane. There were 10 airplane manufacturers whose airplanes were involved in three or more spin accidents during each half year of 1929, in addition to a number of others who had less than three accidents.

The foregoing seems to indicate that no matter how much attention is paid to the design and the manufacture of aircraft, occasionally undesirable spinning characteristics will develop and apparently for reasons at present but little understood.

Our experience has forced us to the conclusion that there is a definite scarcity of good test pilots in this country, and as a result, it is also quite noticeable that many airplanes are insufficiently test-flown and that many undesirable characteristics other than spinning could be corrected to the ultimate advantage of every one concerned. It is becoming increasingly more significant that merely because a manufacturer will meet our minimum requirements, is no criterion that the product is salable. Indications are that airplane manufacturers will shortly face the necessity of manufacturing a product which will more readily serve the purpose for which it was intended, rather than to meet any minimum requirement which the Department of Commerce may establish. The economic problem involved in the utilization of aircraft will necessitate the manufacture of a product which is the best that modern design and construction will permit. It is becoming increasingly evident that aircraft falling below the highest possible standard will, due to competition, be forced into the background.

AER-54-11

Water-Recovery Apparatus for Airships

By C. P. BURGESS,[1] WASHINGTON, D. C.

In order to operate efficiently, an airship must maintain an approximate equilibrium of its weight and buoyancy. Since the former is progressively reduced when liquid fuel is burned, some other means than valving the costly lifting gas, helium, must be employed to compensate for the weight of the fuel consumed. The author states five alternative means, and then briefly outlines the work done in developing one of them—recovering water for ballast from the engine exhaust, following which he sets forth the theory of such water recovery, accompanied by illustrative examples. The desirable features of a water-ballast collector are then dealt with, and the paper concludes with brief notes on the principles of design and construction of the apparatus and on recent developments in ballast collectors.

THE gross weight of an airship burning liquid fuel, and having no means of acquiring ballast during flight, is progressively reduced by the weight of the fuel consumed. In order to fly efficiently, and to make landings, an airship must be maintained in an approximate equilibrium of weight and buoyancy. Prior to the use of helium in American airships, it was the custom to maintain static equilibrium by valving the lifting gas to the outside atmosphere as required to compensate for the progressive diminution of the load carried. The lifting gas, hydrogen, being comparatively cheap, this method of operation was practicable although not entirely satisfactory. The introduction of helium, which was at first very expensive and obtainable only in severely limited quantities, made it imperative to find some means of compensating for the weight of fuel consumed without valving helium.

Alternative Means of Maintaining Equilibrium

The possible methods of maintaining static equilibrium without loss of lifting gas may be classified as follows:

a Condensing and recovering from the exhaust gases the water formed by combustion of the hydrogen contained in the fuel

b Taking water from the atmosphere by means of a hygroscopic material such as calcium oxide

c Lifting water from the sea or other bodies of water on the surface of the earth

d Burning a gaseous fuel of approximately atmospheric density, instead of liquid fuel

e Burning hydrogen in combination with liquid fuel in the proper proportions to maintain equilibrium of weight and buoyancy.

All of these methods have actually been tried in airships, although not always in conjunction with helium as the lifting gas.

A perforated container filled with calcium hydroxide was carried on some of the early flights of the U.S.S. *Shenandoah*. Its weight was found to increase about 50 per cent by moisture absorbed from the atmosphere when flying on days of high humidity. This method of adding ballast during flight is impracticable because of the large initial load of hygroscopic material which must be carried, the slow rate of absorption of water in dry weather, and the corrosive nature of the hydroxide.

During the World War, small quantities of water ballast were sometimes picked up by non-rigid airships operating at sea by the simple expedient of lowering a canvas bucket over the side of the car. This procedure is obviously of no practicable value except on very small airships, intended for carrying not more than three or four persons. Shortly after the war, some experiments were undertaken by the U. S. Navy and also by the Goodyear Tire and Rubber Company in picking up water ballast through a trailing hose. Two different methods were tried for lifting the water to the airship. The Navy depended upon the velocity head resulting from towing a bell-mouth hose through the water; while the Goodyear Company had a more elaborate apparatus using a water turbine driven by towing through the water, and in turn driving a rotary pump which forced water through the hose into the car of the airship. These experiments demonstrated the possibility of picking up water in small airships; but it would be impracticable to bring an airship of any considerable size sufficiently close to the surface to carry out such an operation.

Gaseous fuel of approximately atmospheric density is used with great success on the airship *Graf Zeppelin*. Hydrogen is used as the lifting gas on that airship; and it is doubtful if there would be any advantage in using helium for inflating an airship exposed to the fire risk resulting from carrying a combustible gas in separate cells. If the fuel gas could be carried in the inner portions of double cells, completely surrounded by helium, the combined use of fuel gas and helium might be justified; but the practical difficulties of constructing and handling such double cells are very great. At the present time the U. S. Navy is constructing an experimental non-rigid airship having fuel gas contained in a balloonet surrounded by helium.

The use of hydrogen as a lifting gas to be burned or valved to maintain the equilibrium in conjunction with helium is open to the same objection as fuel gas in that it largely nullifies the safety advantage of helium, unless it can be entirely surrounded by that inert gas; and even then the fire hazard might be considerable.

Hydrogen is not particularly suitable as a fuel gas, but it has been used for that purpose. In 1919, one engine of a U. S. Navy non-rigid airship was equipped with a hydrogen mixing valve, as well as a gasoline carburetor. This airship made a successful

---

[1] Bureau of Aeronautics, Navy Department. Charles P. Burgess was born in Boston, Mass., April 9, 1888. He comes from a noted family of naval architects. He studied naval architecture at the University of Glasgow, Scotland, graduating in 1910. He entered the U. S. Navy Department during the war, and specialized in airship design, which at that time was a new art in the United States, almost without scientific basis. Mr. Burgess applied the older science of naval architecture to building up a new science of airship design. His book on "Airship Design" is recognized as the standard work on its subject. His experience has not been confined to the theoretical side of his profession. He was on the *Shenandoah* when she broke away from her mooring mast in a winter gale, and he has flown across the ocean on the *Graf Zeppelin*.

Presented at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

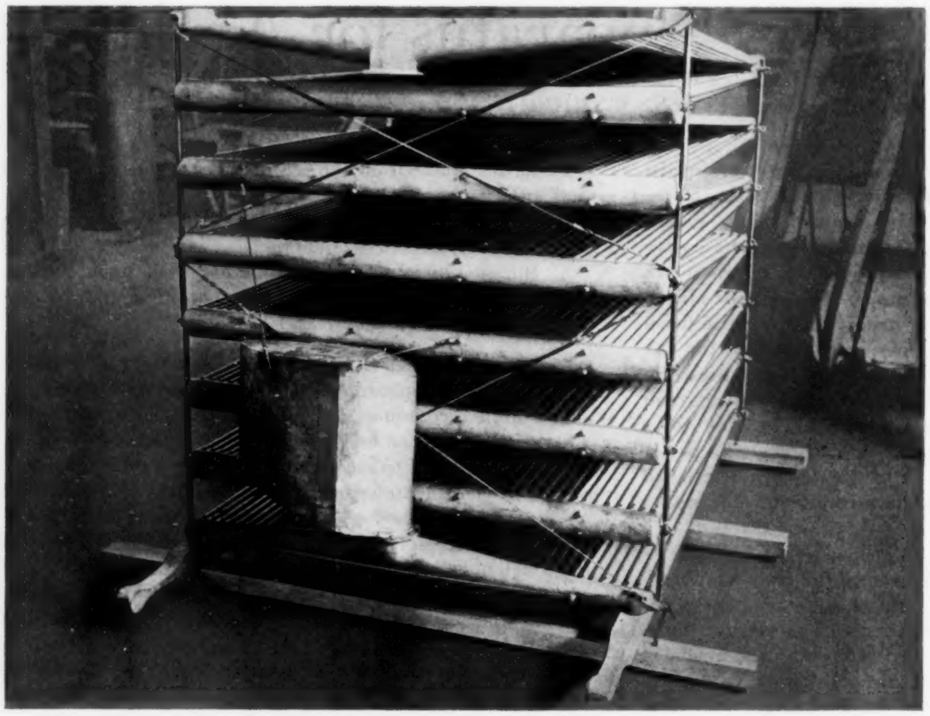

Fig. 1 Water-Ballast Collector for U.S.S. "Shenandoah"

flight from New York to Newfoundland, burning gasoline and hydrogen alternately.

Finally there is the method of maintaining equilibrium by recovery of water from the engine exhaust. When 100 lb. of ordinary aviation gasoline is burned, about 135 lb. of water is produced; and of this 135 lb., eight-ninths, or 120 lb., consists of oxygen taken from the air, and only 15 lb. is hydrogen contained in the original 100 lb. of fuel. Besides its convenience for maintaining equilibrium without loss of buoyant gas, recovered water ballast has other important advantages. The most valuable one is the great gain in safety resulting from having a large amount of ballast available to drop in case of loss of gas from damage to the cells when the ship is far from her base or destination. The extra ballast may also prevent disaster when landing; and it permits fuel or other loads to be taken aboard the airship at an intermediate or emergency landing in exchange for ballast, without any addition of buoyant gas, which might not be readily obtainable.

A disadvantage of the exclusive use of water recovery for maintaining static equilibrium is that the maximum altitude which can be reached on a voyage, without valving helium, is limited by the percentage fullness of the gas cells at the start of the voyage. In order to overcome this difficulty, it has been proposed to use small fuel-gas cells which would be filled at the start of a long voyage and would occupy the space which must be provided to allow for the expansion of the helium in order to rise to any desired altitude. The fuel gas would first be consumed without recovery of ballast; and after that, the liquid fuel would be used in conjunction with the recovery apparatus.

History of Water Recovery

The first known attempt to provide a water-ballast-recovery apparatus was on the British rigid airship *Mayfly*, constructed in 1910. As this punningly named airship did not fly, the apparatus was never put to a practical test. It consisted of about 400 ft. of thin metal pipe led from the exhaust manifold aft along the keel and then forward again to the engine car, where it was fitted with a water separator.

The English aviation magazine *Flight* for June 10, 1911, published a photograph and a short description of "The Zimmerman Ballast Gainer for Airships." This was a rather compact apparatus composed of flattened tubes with fins. It was constructed for a 40-hp. engine; it weighed 97 lb., and is said to have recovered water equal to 90 per cent of the weight of the fuel consumed. So far as is known, the apparatus was never given a practical test on an airship.

U. S. Patent No. 1,071,180, taken out by A. A. Remington, of Birmingham, England, in 1913, is for a water-recovery apparatus in which the exhaust gases are passed through a coiled pipe, cooled by the air flow. The claims for the patent are sweeping and fundamental; but apparently nothing came of it.

In 1917, an experimental water-recovery apparatus was constructed and tested at Kingsnorth, Scotland. The apparatus consisted of a honeycomb radiator of 1-in. tubes, 10 in. long, arranged to take the exhaust gas in the spaces between the tubes. It is said that the recovery of water was satisfactory while the tubes were clean, but decreased seriously after ten hours' run.

At the end of the war, the prospect of adopting helium for the airships of the U. S. Navy made the development of water-recovery apparatus essential. Experiments were carried out at the Washington Navy Yard, using the principle of condensation by injecting water into the exhaust, and cooling the mixture of injected and recovered water in an ordinary radiator. The weight of the apparatus was prohibitive; and little was accomplished by the experiments except to show what not to do. The trouble with cooling the gas by the injection of water is that all the heat taken from the gas must be transferred from the water to the atmosphere at a very low temperature gradient, so that there is no ultimate advantage in the rapid and efficient initial transfer of the heat from the gas to the injected water. Furthermore, deposits of soot and oil in the water-cooling radiators are much more destructive of efficiency than similar deposits in the comparatively large tubes of an apparatus designed for direct transfer of heat from the gas to the atmosphere.

The next step in the development of water recovery was made by the U. S. Army Air Service, based on the results of experiments at the Bureau of Standards. An apparatus was constructed in which the exhaust gases passed through long aluminum tubes, 1 in. in diameter, parallel to the outside air flow. It was installed in the non-rigid airship *D-3* in 1923. The apparatus recovered water reasonably well, but was structurally weak owing to the great length of the tubes.

The Air Service did not continue its work; and the Navy again took up the problem, employing the engineer-physicist who had developed the partially successful apparatus used on the *D-3*. The result was the construction for the U.S.S. *Shenandoah* of a compact apparatus in which each unit consisted of

45 parallel rows of 1-in.-diameter aluminum tubes arranged in ten banks connected by cast aluminum headers, as shown in Fig. 1. This was the first really successful water-recovery apparatus. All engines of both the *Shenandoah* and the *Los Angeles* were ultimately equipped with similar units. The weight was approximately one pound per horsepower, and in average weather conditions, water equal in weight to about 105 per cent of the weight of fuel consumed could be recovered from it.

ATTEMPTED IMPROVEMENTS

In spite of the generally satisfactory performance of the water recovery apparatus developed for the U.S.S. *Shenandoah*, and subsequently installed also on the U.S.S. *Los Angeles*, it is open to the grave objection of having very high air resistance, amounting to nearly 10 per cent of the total resistance of the airship. It is also difficult to remove soot deposited by the exhaust gases inside the tubes; and considerable trouble has been experienced from freezing of the water in the apparatus in very cold weather. The first attempt to reduce the air resistance was the construction of a two-stage apparatus in which the first stage consisted of a nest of duralumin tubes, parallel to the air flow, for cooling the gas to near the initial condensation temperature of about 53 deg. cent., and a second stage, or condensing element, which was virtually a large, flat box constructed of doped outer-cover cloth stretched on a duralumin frame, and occupying four panels of the surface of the hull. Experimental installations of this type were tried on both the *Shenandoah* and the *Los Angeles*. Neither experiment was successful; the amount of water recovered was disappointing; gas leaked badly into the ship; and the pulsations of the exhaust against the fabric produced a terrific drumming noise.

A water-recovery apparatus known as Mark III was tried unsuccessfully on the U.S.S. *Los Angeles*. Tubes with their axes at right angles to the air flow were used for the initial cooling of the gases down to near the condensation temperature; and an element constructed of corrugated plates was used for the remainder of the cooling. The plates cracked on trial after less than one hour's operation. In spite of this disappointing result, it is possible that failure was due to insufficient support of the apparatus against vibratory forces, and the use of corrugations of too great pitch and too long radius of curvature, rather than to a mistaken principle.

FINS FOR COOLING SURFACES

Fins on the air side of radiators designed for extracting heat from liquids greatly increase the efficiency of such apparatus; and it has been proposed to use fins in a similar manner for water recovery on airships. The objection to this proposal is that the problem of transferring heat from gas to air is quite different from transferring it from a liquid to air or other gas. Heat flows with comparative ease from a liquid to the walls of a metal container; but a much greater resistance is encountered in the transfer between gases and metal surfaces. It follows that in cooling a liquid, much larger surface areas are required on the air side than on the liquid side. Fins on the air side of the container afford a ready means of supplying this difference of area. On the other hand, the transfer of heat between air and gases requires equally large areas on both the gas and air side. It is possible to provide these areas in the form of fins; but the heat would be required to flow a much greater distance through metal than in the case of equal areas of thin plates or tube walls directly in contact with gas on one side and air on the other, so that for a given area, the direct method is more effective than fins. An exception occurs in that part of the apparatus which is close to the engine. In order to avoid damaging the metal by high temperatures, it is desirable to expose more area to the air than to the gas, and this additional area is most conveniently provided by fins.

COOLING BY EXHAUST TURBINES

It has been proposed to cool the exhaust gases and, at the same time, make use of their energy by passing them through an exhaust turbine designed to convert their heat into mechanical energy. The scheme is not very promising, because the mechanical equivalent of the heat to be removed from the gas considerably exceeds the total energy output of the main engines; and it has hitherto been impossible to construct an exhaust turbine which, without causing excessive back pressure, would deliver more than about 10 per cent of the horsepower of the engine to which it is attached.

A possibility along this line is to use an exhaust-gas turbine of the type designed by C. Lorenzen, of Berlin, in which the blower is within and concentric with the rotor. The turbine blades are hollow and are cooled by the air from the blower passing through them. It is possible that enough air could be delivered by the blower to cool the exhaust gases, and condense the water in a compact apparatus contained wholly within the hull of the airship. The Lorenzen turbine as hitherto constructed delivers a quantity of air only about equal to the amount used by the main engine. A volume of air many times greater than this would be required for cooling the exhaust gases; and it is by no means certain that the Lorenzen turbine and blower could be adapted to deliver such large quantities of air without having a separate blower unit. Experience with exhaust turbines having more than a few per cent of the power of their main engines has not been very promising.

DEFINITIONS

The term "water-recovery apparatus," which has hitherto been used, is extremely cumbersome. "Ballast gainer," the name given by Zimmerman to his apparatus in 1911, is better; but it is believed that "ballast collector" is better still.

Primary Cooler. The process of cooling the gases and condensing the water vapor may be carried out continuously in one apparatus, or separated into two or more stages. The exhaust gases issue from the engine at temperatures between 650 and 750 deg. cent., which is above the melting point of aluminum. These very hot gases must be conducted through steel pipes until the temperature is reduced to about 500 deg. cent. before they can safely be injected into a cooling element constructed of aluminum. The steel pipes for the initial cooling are sometimes called the "pre-cooler." It is considered that "primary cooler" more correctly describes this part of the apparatus, and is a better term.

Secondary Cooler. From 500 to 53 deg. cent. no condensation of the water vapor occurs, and if this stage of the ballast collector is separated from the primary cooler it may appropriately be called the "secondary cooler."

Condenser. From about 53 deg. cent. to the final minimum temperature of perhaps 35 deg. cent., the water vapor is condensed, so that the part of the apparatus working within that temperature range is actually the condensing element, and may be called the "condenser."

There are, of course, no sharply defined points in the passage of the gases through the ballast collector at which the various temperatures mentioned in the foregoing definitions are reached.

Water Separator. The condensed water is carried along by the exhaust gas in the form of spray, which must be separated from the gas if it is not to be lost. The separator most commonly used consists of an aluminum box containing baffle plates between which the exhaust gas passes in an irregular course.

The drops of water strike the baffle plates and run down small vertical collecting gutters into a sump at the bottom of the separator. The efficiency of this type of collector depends to a very great extent on the velocity of the gas through it. A velocity of about 600 ft. per min. has proved most satisfactory. It has been found that if the velocity is less than 500 ft. per min., the water is not thrown out from the gas; while at more than 900 ft. per min. velocity, the drops of water deposited on the baffles are again torn off, and escape with the gas.

Recently a rotary centrifugal type of separator known as the "Hagan separator" has been tried out with encouraging results.

Theory of Water-Ballast Recovery

The quantity of steam or water vapor in the engine exhaust is only about 8.5 to 9 per cent by weight of the total quantity of gas. Condensation will not even commence until the gas is cooled to the temperature at which it is saturated by this amount of moisture. The saturation temperature is about 55 to 53 deg. cent., depending upon the initial amount of water vapor in the air and the ratio of air to fuel in the mixture delivered to the engine. To condense a weight of water equal to the weight of fuel consumed, the final temperature must be brought down to the neighborhood of 35 deg. cent. These temperatures are emphasized because it is often thought that it is only necessary to reduce the temperature to the boiling point of water, namely, 100 deg. cent., in order to condense the water.

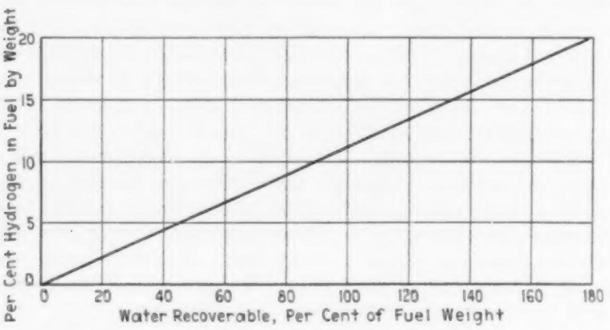

Fig. 2 Effect of Hydrogen Content of Fuel on Weight of Water Recoverable

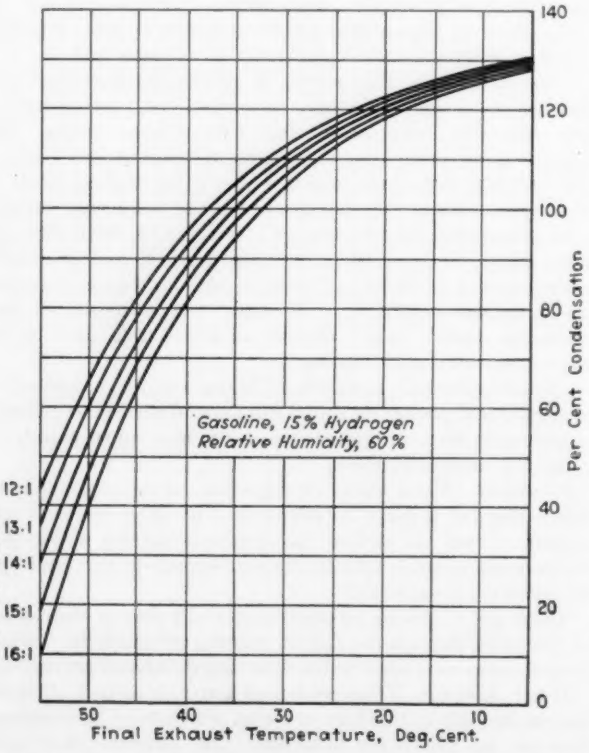

Fig. 3 Effect of Mixture Ratio on Weight of Water Recoverable

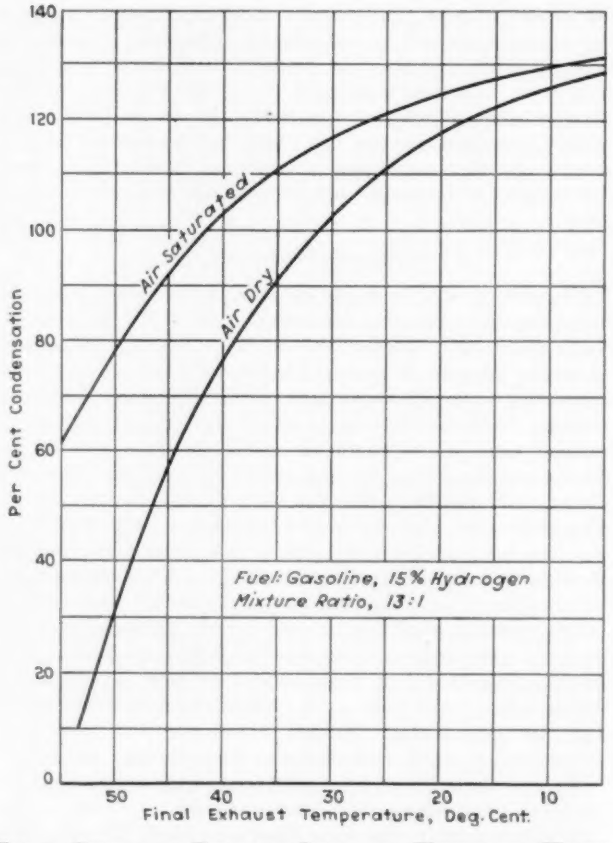

Fig. 4 Effect of Humidity Ratio on Weight of Water Recoverable

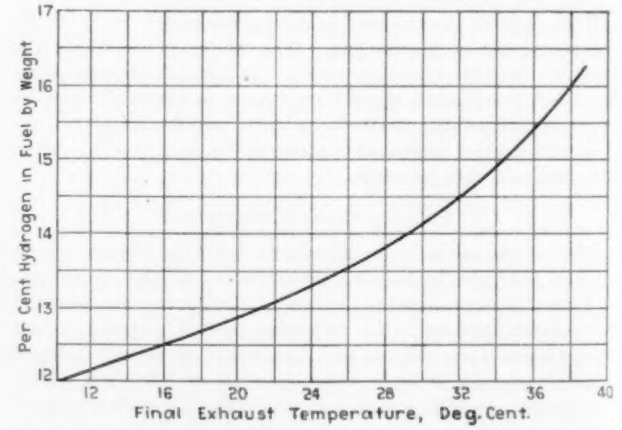

Fig. 5 Final Temperature to Which Exhaust Gas Must Be Cooled to Condense to 1 Lb. of Water per Lb. of Hydrocarbon Fuel Burned

(Assumptions: Air temperature 15 deg. below final exhaust temperature; mixture ratio; theoretical combining ratio; relative humidity, 60 per cent.)

It has been proposed to cool the exhaust gases to this temperature by injecting cold air into them from the outside atmosphere. Such an injection of air would so dilute the water vapor that saturation could hardly be reached at all, except on days of high humidity.

Four variables determine the amount of water which can be condensed from the exhaust per pound of fuel consumed. These variables are:

1 The hydrogen content of the fuel
2 The mixture ratio of fuel to air
3 The humidity of the air, and
4 The final exhaust temperature.

The effects of these variables are shown by the curves in Figs. 2 to 5, inclusive.

Ordinary aviation gasoline is about 15 per cent hydrogen.

Fuel oils suitable for aircraft Diesel engines contain about 12.5 per cent hydrogen by weight. Satisfactory water recovery with Diesel engines will depend upon not having too high a ratio of air to fuel. This may prove a stumbling block, especially with two-cycle engines and at reduced power.

SURFACE AREA REQUIRED

The theory of heat transmission from gas to gas through metal walls is not yet sufficiently comprehensive to permit of accurate calculation of the surface area required for any given conditions. The theory of heat transfer between gases flowing in tubes of circular cross-section has been described in a paper on "Heat Transfer in the Condensation of Water From Engine Exhaust Gas," by Robert F. Kohr and Lucinthia Butler, presented before the Division of Industrial and Engineering Chemistry at the 67th Meeting of the American Chemical Society, in Washington, D. C., 1924.

The theory is summarized here, and certain consequences of it are considered. It is assumed that: (1) the surface temperature of the pipes is the same inside and outside at any given point, and is uniform around the circumference at any point in the length of the pipe; (2) the cooling air flows with uniform velocity in a direction parallel to the axis of the pipe, and is turbulent. On these assumptions, the necessary area of cooling surface is given by the following equations:

For counterflow:

$$S = \frac{\log_e \dfrac{T_a - t_b}{T_b - t_a}}{\dfrac{q_h q_c}{q_h + q_c}\left(\dfrac{1}{H_h} - \dfrac{1}{H_c}\right)}$$

For parallel flow:

$$S = \frac{\log_e \dfrac{T_a - t_a}{T_b - t_b}}{\dfrac{q_h q_c}{q_h + q_c}\left(\dfrac{1}{H_h} + \dfrac{1}{H_c}\right)}$$

where S = total surface area of the tubes, sq. cm.
T_a = initial exhaust temperature, deg. cent.
T_b = final exhaust temperature, deg. cent.
t_a = initial air temperature, deg. cent.
t_b = final air temperature, deg. cent.

The terms H_h and H_c are given by:

$$H_h = M_h C_h$$

$$H_c = M_c C_c$$

where M_h = mass flow of gas through the system, grams per second
M_c = mass flow of air through the system, grams per second
C_h = specific heat of gas at constant pressure
C_c = specific heat of air at constant pressure.

The terms q_h and q_c are derived from the relation between surface cooling and skin friction established by Lanchester and Stanton (Technical Report No. 94 of the British Advisory Committee for Aeronautics, 1913), combined with Lee's equation for skin friction to give the following expression:

$$q = Cm\left[0.0765\left(\frac{\mu}{MD}\right)^{0.35} + 0.0009\right]$$

where m = unit mass flow along the pipe, grams per sec. per sq. cm.
μ = viscosity of the air or gas in poises
D = diameter of the pipe in cm.
C = specific heat at constant pressure in calories per gram per deg. cent.

According to Kohr, the following mean values may be assumed for C and μ:

	Exhaust gas above 53 deg. cent.	Exhaust gas below 53 deg. cent.	Outside air
C	0.26	2.2	0.24
μ	2.4×10^{-4}	2.0×10^{-4}	1.85×10^{-4}

The high specific heat of the exhaust gas below 53 deg. cent. is due to the release of the latent heat of condensation of the water vapor.

The foregoing expression for q is strictly applicable only to tubes of circular cross-section. In most types of ballast collector the air does not pass through circular passages; and in some types the air stream may have no outer boundary surface at all, so that D_c is infinite. Kohr has suggested that when the air passes between the tubes, D_c should be calculated by the following expression:

$$D_c = \sqrt{\frac{4ab}{\pi} - D_h^2}$$

where a and b are the vertical and transverse spacings of the tubes.

A similar difficulty occurs in calculating M_c, since it is not always clear how much of the air is effective in absorbing the heat from the gas.

A curious consequence of the theory is that apparently the highest rate of cooling is not obtained when the air stream is unbounded. Theoretically there is an optimum size of the air stream which should not be exceeded. This curious anomaly follows from the theoretical conclusion that $q_c = 0.0009\ C_c m$ when $D_c = \infty$. It is believed that the actual value of q_c is considerably greater than this, and consequently the theory is inaccurate when D_c is large. It is also inapplicable when the flow of air is across the tubes.

NUMERICAL EXAMPLES

An example will show the method of applying the theory to the computation of the surface area required.

Find the surface area necessary for a ballast collector designed for a 400-hp. engine at 60 knots speed, given that the outside air temperature is 15 deg. cent., and the gas is to be cooled to 35 deg. cent. It is also given that the engine consumes 0.45 lb. of aviation gasoline per horsepower-hour with a 15-to-1 mixture ratio.

$$M_h = 0.45 \times 16 \times 400 = 2880 \text{ lb. per hr.}$$
$$= 363 \text{ grams per sec.}$$

It has been found that m_h may equal 1.6 grams per sq. cm. per sec., without causing excessive back pressure in a collector built of 1-in. tubes with 10 turns of 180 deg. Undoubtedly, higher velocities may be employed in conjunction with larger tubes or fewer turns; but it will be assumed in the present problem that $m_h = 1.6$ grams per sq. cm. per sec.

Let $D_h = 1$ in. $= 2.54$ cm.

Let $D_c = 6$ in. $= 15.24$ cm.

If the density of the air is 0.076 lb. per cu. ft., and flows through the collector at a velocity of 60 knots, or 101.5 ft. per sec.,

$$M_c = 101.5 \times 0.076 = 7.72 \text{ lb. per sq. ft. per sec.}$$
$$= 3.78 \text{ grams per sq. cm. per sec.}$$

Since $D_c = 6\ D_h$, it will be assumed that the aggregate area of the air passages is 36 times that of the gas passages; and consequently,

$$M_c = \frac{36 \times m_c \times M_h}{m_h}$$
$$= \frac{36 \times 3.78 \times 363}{1.6}$$
$$= 30{,}800 \text{ grams per sec.}$$

For the gas above 53 deg. cent.,

$$q_h = 0.26 \times 1.6 \times \left[0.0765 \times \left(\frac{2.4 \times 10^{-4}}{1.6 \times 2.54}\right)^{0.35} + 0.0009\right] = 0.00141$$

Below 53 deg. cent.,

$$q_h = 2.2 \times 1.6 \times \left[0.0765 \times \left(\frac{2.0 \times 10^{-4}}{1.6 \times 2.54}\right)^{0.35} + 0.0009\right] = 0.01160$$

For the air,

$$q_c = 0.24 \times 3.78 \times \left[0.0765 \times \left(\frac{1.85 \times 10^{-4}}{3.78 \times 15.24}\right)^{0.35} + 0.0009\right] = 0.00163$$

Above 53 deg. cent.,

$$\frac{q_h q_c}{q_h + q_c} = \frac{0.00141 \times 0.00163}{0.00304} = 0.00076$$

Below 53 deg. cent.,

$$\frac{q_h q_c}{q_h + q_c} = \frac{0.0116 \times 0.00163}{0.0132} = 0.00143$$

Above 53 deg. cent.,

$$H_h = 363 \times 0.26 = 94.5$$

Below 53 deg. cent.,

$$H_h = 363 \times 2.2 = 800$$
$$H_c = 30{,}800 \times 0.24 = 7400$$

Let the apparatus be designed for parallel flow between the engine exhaust pipe and the beginning of condensation.

$T_a = 650$ deg. cent.; $T_b = 53$ deg. cent.; $t_a = 15$ deg. cent.

The heat taken up by the air equals that lost by the exhaust gas. Whence:

$$\frac{t_b - t_a}{T_a - T_b} = \frac{H_h}{H_c} = \frac{94.5}{7400} = \frac{1}{78}$$

$$\frac{t_b - 15}{650 - 53} = \frac{1}{78}; \quad t_b = 22.6 \text{ deg. cent.}$$

$$\frac{T_a - t_a}{T_b - t_b} = \frac{650 - 15}{53 - 22.6} = 20.9$$

$$S = \frac{\log_e 20.9}{0.00076 \times \left(\frac{1}{94.5} + \frac{1}{7400}\right)} = 374{,}000 \text{ sq. cm.}$$
$$= 403 \text{ sq. ft.}$$

That part of the apparatus in which condensation takes place is designed for counterflow. The conditions here are as follows:

$T_a = 53$ deg. cent.; $T_b = 35$ deg. cent.; $t_a = 15$ deg. cent.

$$\frac{t_b - t_a}{T_a - T_b} = \frac{H_h}{H_c} = \frac{800}{7400} = \frac{1}{9.25}$$

Whence: $t_b = 17$ deg. cent.

$$\frac{T_a - t_b}{T_b - t_a} = \frac{53 - 17}{35 - 15} = 1.80$$

$$S = \frac{\log_e 1.80}{0.00143 \times \left(\frac{1}{800} - \frac{1}{7400}\right)} = 298{,}000 \text{ sq. cm.}$$
$$= 321 \text{ sq. ft.}$$

The total surface area required is 403 + 321 = 724 sq. ft. or 1.81 sq. ft. per hp.

It may be noted that in the course of the calculations it was necessary to make some assumptions which are scarcely justifiable without experimental evidence. One of the doubtful assumptions is that the velocity of the cooling air through the collector is the same as the ship's air speed. Another is that the entire mass of cooling air is effective in absorbing heat from the gas. Both of these assumptions are on the dangerous side, and if incorrect, would lead to underestimating the area required; and yet experience indicates that a cooling surface of 1.81 sq. ft. per hp. is ample for a 60-knot airship. Clearly, there is much room for improvement in the theory of heat transfer. However, refinement in theory is likely to lead to extremely cumbersome calculations taking account of the variations of specific heat, viscosity, etc., with temperature; and even then there will probably remain insurmountable difficulties in determining by calculation the velocity of the air flow in various parts of the apparatus; so that the practical designer is likely to continue to depend largely on experience and experiment in the design of water-ballast collectors.

In the numerical example, the total cross-sectional area of the exhaust passages must be equal to $M_h/m_h = 363/1.6 =$ 227 sq. cm. = 35.2 sq. in. = 45 tubes of 1 in. internal diameter. The total perimeter of these tubes is 11.8 ft., and to obtain the surface area of 724 sq. ft., the length of the exhaust passage must be 724/11.8 = 61 ft.

Desirable Features in a Ballast Collector

The ideal ballast collector should have the following characteristics:

a One hundred per cent recovery of water under average operating conditions

b Low air resistance
c Light weight
d Small back pressure
e Easily cleaned from deposits of oil and soot
f Compactness and ruggedness
g Freedom from freezing in winter.

While the first of these requirements may be regarded as the most important one, it does not require much consideration here, because it is mainly a matter of providing sufficient cooling area. Some forms of ballast collector may require less area than others, but that is not an advantage in itself unless it is reflected in less weight and air resistance. It generally happens that forms designed for maximum cooling per unit area have a high total resistance.

Low air resistance is obviously a matter of prime importance, and is one which has proved most difficult of solution. Since a certain amount of area is necessary, the goal to be sought by the designer is an apparatus having no more resistance than the frictional resistance of its surface. The ultimate ideal is to use the surface of the hull for the cooling area, so that there will be no net resistance at all due to the collector; but there is enormous room for improvement without going to that ultimate refinement. The apparatus at present used on the U.S.S. *Los Angeles* has about fifteen times more resistance than the skin friction of an equal surface.

Tubes running in an approximately longitudinal direction have very little resistance, except skin friction; but they must be connected by headers, and unless these are carefully designed, their air resistance may be large. One solution is to place the headers within the hull; but that is likely to involve structural difficulties, and may cause overheating of the headers. If longitudinal tubes are used, they must not be so clustered together that they obstruct the flow of air between them. They must also be supported at close intervals, usually about two and a half feet, in order to avoid deformation by the heat and vibration. The necessity for closely spaced supports greatly augments the difficulty of eliminating all resistance but skin friction.

Placing the tubes with their longitudinal axes at right angles to the air flow facilitates obtaining an apparatus which is strong and compact, with headers and supports presenting little resistance; but having very great resistance from the tubes if their cross-sections are circular. Tubes of streamlined section would probably not help matters very much unless they were spaced so far apart as to involve excessively large and heavy headers.

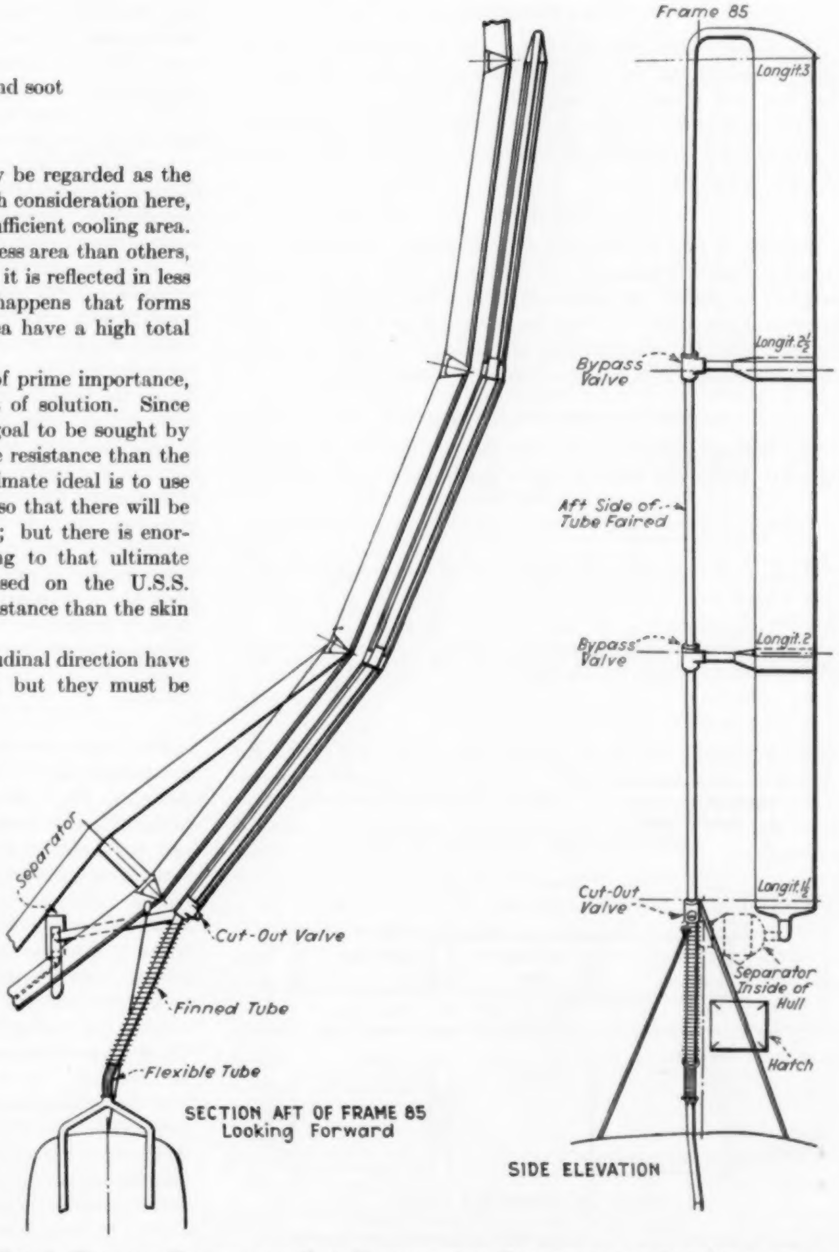

FIG. 6 VERTICAL SECTION AND SIDE ELEVATION OF CONDENSER FOR CAR No. 3 OF THE U.S.S. "LOS ANGELES"
(Scale, 1/80 full size.)

Transverse tubes may be flattened and placed as shown in Fig. 6, so as to present substantially flat surfaces parallel to the air flow. There is at present no experimental evidence to show whether or not tubes may be safely flattened in this manner without encountering the troubles which arise whenever an attempt is made to use flat plates in a ballast collector.

FACTORS DETERMINING WEIGHT

For average speed and operating conditions in modern rigid-airship practice, about 1.5 sq. ft. of cooling surface per horsepower is required for the ballast collectors. Assuming that 1-in.-diameter aluminum tubes with a wall thickness of 0.02 in. are used, the weight of the tubes is 0.29 lb. per sq. ft., or 0.435 lb. per hp. The total weight of the collector is fully two or three times greater, depending upon the design of the headers, supports, etc. In order to avoid the troubles resulting from the use of flat plates, it seems necessary to have aluminum castings for the headers. These are the largest single items of weight in a ballast collector; and their weight varies greatly, depending upon the arrangement of tubes and the general features of the design.

After the headers, the structure required to support the apparatus is the most important variable among the weights. A compact design lends itself to a low weight of supporting structure.

Back Pressure

The ballast collectors in the U.S.S. *Los Angeles* have ten sharp turns, of nearly 180 deg. each, in the gas passages. In spite of this, the back pressure is negligible, so that it is not likely to become an important factor in any ordinary type of apparatus. It is customary to provide gas passages having an area of about 0.08 sq. in. per hp.

Cleaning

Deposits of soot and oil in the tubes reduce the efficiency of the apparatus. It would be advantageous to have the headers designed to permit the insertion of brushes to sweep out the interiors of the tubes; but that has never yet been done. Cleaning can only be accomplished at present by blowing steam through the apparatus, or else completely disassembling it.

Compactness and Ruggedness

The ballast collectors now installed in the *Los Angeles* are probably about the most compact and rugged type which can be designed. Progress toward types of less resistance is likely to involve spreading the apparatus along the sides of the hull, which will certainly involve a loss of compactness. Ruggedness or strength may be obtained with the less compact collectors by more numerous and shorter connections to the ship's structure. Probably additional supporting structure will be required within the hull. The weight of this structure must be regarded as the price paid for better aerodynamic efficiency.

Protection Against Freezing

The problem of preventing freezing of ballast collectors in winter time presents one of the greatest difficulties to the designer seeking the ideal type. The difficulty has been overcome in the *Los Angeles* by closing the sides of the collector with a fabric curtain, and placing ordinary radiator shutters over the front face. Such an arrangement is permissible in an apparatus which already has nearly as much air resistance as a flat plate of the same frontal area; but it would completely spoil the advantages of the low-resistance types which it is hoped to develop.

A collector having fore-and-aft tubes might be provided with shutters having their surfaces and axes of rotation parallel to the air flow, without causing excessive resistance when either open or closed; but they must be very strong to avoid fluttering in the air stream, and their weight is likely to be excessive. An alternative to the use of shutters is to reduce the cooling surface in cold weather by bypassing part of the apparatus. In order to keep the total cross-sectional area of the gas passages constant, the reduction in cooling area should be accomplished by reducing the length of the gas passage; but this is likely to require some rather large and heavy intermediate headers, so that it may be better to keep the length of the passage constant, and cut out some of the tubes in parallel; even at the cost of increasing the back pressure as a result of the reduced cross-sectional area. It may be noted that the total cross-section provided in the *Los Angeles* type of collector is about three times greater in area than the engine exhaust pipe, so that it is probable that many of the tubes could be cut out without causing excessive back pressure, particularly in a collector designed to have fewer turns in the gas passages than the present type.

Principles of Design and Construction

The primary cooler must be constructed of steel pipes, because the temperature is too high for aluminum to sustain without damage. The rate of cooling is approximately proportional to the difference between the temperatures of the gas and the air, and consequently the gas is very quickly cooled through the range between about 700 and 500 deg. cent. This part of the ballast collector requires only about 7 per cent of the total surface area; and it is not even necessary to use small-diameter tubes to increase the cooling area. It is quite satisfactory to pass the gas through a single steel pipe of the same dimensions as the exhaust pipe from the engine. The portion of this pipe nearest the engine may be finned on the outside, so that the temperature of the metal will be nearer to the air than to the gas temperature. A cut-out valve is provided between the engine and the primary cooler, or between the primary and secondary elements. This valve is exposed to very high temperatures, and must be of a type that will withstand great heat without sticking or becoming inoperative. A steel flap valve with an asbestos seat is the only type which has been successful.

The secondary cooler and the condenser are usually constructed as a single unit; and they will be so considered in this discussion. The smaller the tubes of this element, the greater their cooling efficiency; but the greater also are the difficulties of supporting them, and preventing loss of efficiency through clogging with carbon deposits. Amid the conflicting requirements for large and small tubes, experience indicates that aluminum tubes about 1 in. in diameter, with walls 0.02 in. thick, are a satisfactory compromise.

The portion of the collector in which condensation occurs should slope downward so that condensed water will not gather in pockets or flow back into the hotter gases and be re-evaporated.

In the type of ballast collector shown in Fig. 1, the headers are aluminum castings, with sockets to receive the tube ends. These sockets are very accurately machined with a slight taper to fit over the tubes. The tube walls are too thin for screw connections or satisfactory welding. The joints are kept tight by wires which pull the opposite headers together. In order to allow for the effect of temperature variations, the wires are made of monel metal, having half the coefficient of expansion of aluminum, and are placed within the tubes so that they will be at the gas temperature, while the tubes are at temperatures about midway between the gas and air.

RECENT DEVELOPMENTS IN BALLAST COLLECTORS

A novel type of ballast collector is contemplated for the new 6,500,000-cu. ft. airship *Akron*, now under construction for the U. S. Navy. The collector consists of 14 banks of longitudinal tubes about 8 ft. in length, having elliptical cross-sections and placed close against the hull of the airship. The ends of the tubes fit over elbows which are welded to headers inside the ship. These headers connect the successive banks of tubes, and being inside the hull, they add nothing to the ship's air resistance.

The apparatus should have a high rate of cooling in proportion to its surface area; and the air resistance will be very low. The chief difficulties to be overcome are mechanical, since welds and flat surfaces are involved, and these features have hitherto proved stumbling blocks in other ballast collectors.

A very simple ballast collector is being constructed for trial on the U.S.S. *Los Angeles*. It comprises four rows of aluminum tubes, 3 in. in diameter by 0.025 in. wall thickness, extending aft and upward along the side of the ship for a length of 50 ft., and then turning forward and down for an equal distance. The tubes are inclined at about 10 deg. to the longitudinal meridian lines of the ship. At this angle their air resistance is but slightly greater than that of longitudinal tubes and is only about 2 per cent as much as transverse tubes. Their comparatively large diameter, 3 in. instead of the usual 1 in., tends to reduce their cooling efficiency, but this is compensated by higher gas velocity, which is considered to be permissible because the directness of the gas passages should more than offset the effect of the increased velocity in building up the back pressure.

The principal advantages of this type of apparatus are its simplicity and ruggedness and the elimination of headers. It is not new; since as noted in the historical summary, a collector of this type was installed, but never put to the test of service, in the British airship *Mayfly* in 1910. The keel condensers, formerly much used in small steamboats, were similar in principle.

Another type of ballast collector once tried in Great Britain is to be given a retrial in the *Los Angeles*. This is a honeycomb radiator, constructed as a high and narrow unit with air passages consisting of 1-in. tubes, 36 in. in length. It has the merits of compactness and great facility of temperature control. The resistance is not particularly low; and the ill-success attained with an apparatus of this type in tests at Kingsnorth in 1917 indicates that there may be trouble from too rapid a deposit of soot upon the outside of the tubes. On the other hand, the cleaner exhaust obtainable with modern engines may eliminate this trouble.

Discussion

T. G. W. SETTLE.[2] It is of great value to the profession to have the subject of water-recovery apparatus so fully and concisely covered. The following comments are offered more in the way of elaboration upon some of the author's material than as disagreement with him.

At the beginning of the paper, two additional methods of maintaining equilibrium might well have been listed:

(*f*) Collecting atmospheric moisture (rain, fog, etc.) in scuppers on top of the ship. This method has been developed by the British, and was used in both the *R-100* and *R-101*. It is a rather haphazard and uncertain method, of course. It is often available when not needed and unavailable when badly needed. However, it is very cheap in weight and drag, and it should be considered as possibly a valuable secondary means of obtaining water.

(*g*) Valving hydrogen from "trimming" cells submerged inside the main helium cells. It is understood that the newest German ship, the *L.Z. 129*, will utilize this method.

Brief comment will now be made on the other methods of maintaining equilibrium, as listed by the author.

(*a*) *Condensation of Water Vapor in Engine Exhausts.* This is the only method that has been developed to what may be termed a practical service state, except for the isolated example of the *Graf Zeppelin* and her gaseous fuel. This method will be discussed further in a following paragraph.

(*b*) *Hygroscopic Materials.* Impracticable, as indicated by the author.

(*c*) *"Picking Up" Sea Water.* The author dismisses this possible method with a few remarks on partially successful tests by non-rigid ships in early years. It is significant that this method has never been tried by modern airships (rigids) so far as is known. On the *Akron* class, with ample electrical power available for winches to hoist large "bags" of water, it is believed that this method has at least enough theoretical merit to warrant a full-scale trial. The "spy" winch and cable could be utilized. Sea-water ballast would have the added rather great advantage that it would be anti-freezing in character in all except extremely low temperatures, thus minimizing the quantity of alcohol to be carried on board. The corrosiveness of sea water on structure would have to be accepted and guarded against.

(*d*) *Gaseous Fuel.* Used very successfully by the *Graf Zeppelin*. However, it is regarded as a "passing phase" in airship development; in fact, it may be considered as having already "passed," since the *L.Z. 129* will not employ this means. Probably the biggest consideration against gaseous fuel is the fire hazard involved, especially in a helium ship. However, power-plant factors enter also, some in favor of and some opposed to gaseous fuels. Many independent considerations seem to indicate future power plant evolution toward compression-ignition engines of large unit horsepower ratings, using fuel oils, rather than toward electric-ignition engines using more volatile fuels.

(*e*) *Burning Hydrogen With Liquid Fuel.* Not practicable, principally because of tendencies toward pre-ignition and detonation when using hydrogen, especially in high-compression-ratio engines.

Condensing Apparatus. In designing this equipment several somewhat mutually antagonistic factors enter into the problem, and the best that can be hoped for is a fair compromise. Some of these factors are heat transfer, aerodynamic characteristics, structural integrity, fouling of gas-side surfaces, temperature control, and weight. The only type that has been used successfully in routine service conditions to date is the so-called *Los Angeles* type, a "block" type, having transverse tubes arranged in zigzagged banks between headers. This type is very poor aerodynamically and has other disadvantages, as pointed out by the author, but it has served its purpose admirably in the absence of anything better, since 1924, on the *Shenandoah* and the *Los Angeles*. Many substitutes and attempted improvements have been tried, none of which has yet proved itself. These have failed for various reasons, but probably the most common cause of failure has been structural weakness. It is hoped and believed that one or more practical substitutes, comprising improvement in one or more of the essential characteristics, may be available shortly. The paper covers the detailed design and principles of construction of cooling and condensing units very thoroughly, and no comment thereon is possible except a "well done."

---

[2] Lieutenant, U. S. Navy; Inspector of Naval Aircraft, Goodyear-Zeppelin Corporation, Akron, Ohio.

General Considerations as to Exhaust Recovery Systems. Present operational practice in this country is wholly premised on "100 per cent recovery" ability in usual operating conditions. While it is believed that some exhaust-recovery equipment will be necessary and desirable for a long time, perhaps indefinitely, it is at the same time believed that the "100 per cent recovery" ability will not persist. The advent of heavy-oil engines, which is looked upon as a certain eventuality, will force attention to other means of maintaining static equilibrium, even if such other means are not perfected prior to that time. This is because the exhaust from a heavy-oil engine has far less "relative humidity" than that from a gasoline engine; so much less as to make a 100 per cent recovery standard impracticable with heavy-oil engines.

It is believed that the two possible alternatives will be picking up sea water and hydrogen trimming cells submerged in helium. It is further believed and recommended that airship designers should not wait to have their "hand forced" in this matter by the advent of Diesel engines, but should thoroughly investigate the two apparent alternatives without delay. It would appear that a water pick-up technique, if successfully developed, would have many arguments in its favor for replacing a portion of the present 100 per cent exhaust-recovery equipment on airships.

AUTHOR'S CLOSURE

Lieutenant Settle's discussion calls for no reply, except thanks for his appreciation of my efforts. I agree with him that picking up sea water remains a possibility for maintaining equilibrium in airships operating at sea. Experiment along that line is well worth while, although it is a difficult problem to devise means of taking large quantities of water at a time without danger of imposing sudden shocks upon the airship.

AER-54-12

Engine Cowl Rings

By PAUL M. BOYD,[1] BUFFALO, N. Y.

The radial air-cooled engine is a popular power plant. Its reputation with the public can be said to date from the summer of 1927, when it demonstrated its reliability and ruggedness in the hazardous long-distance flights of that year. Since then many refinements and improvements have been brought forth, but the drag of the radial engine has always been high. Large frontal areas are inherent with the radial engine, and as the power output of the present radial has increased, so has its frontal area. Until recently it did not seem likely that the radial engine could ever successfully compete with the liquid-cooled type as the power plant for use in high-speed airplanes. However, with the development of the N.A.C.A. type of cowling and the engine cowl ring by various aerodynamical laboratories, the big gap existing in actual ship's performance between these two widely divergent power plants has been eliminated.

A STUDENT of history is often impressed with the way old ideas have of recurring under slightly different guise as something entirely new. One generation conceives an idea, develops it, employs it for a while, and then discards it for something else which is considered superior; a succeeding generation being pressed for the solution of a problem often works out an answer practically identical with that obtained before, but none the less original despite its similarity to earlier work. So it is with the present refined cowlings for the radial engine. Fifteen years ago airplanes were equipped with practically the identical cowling that is being heralded today as the savior of the radial engine, the main difference being not in the cowling itself, but in the reasons for its use. Today the purpose is to reduce drag. Fifteen years ago the purpose was to catch oil thrown by the engine.

The designers of the first air-cooled engines were confronted with many difficult problems. Perhaps the most difficult was that of obtaining satisfactory cooling of the power plant. It was soon found that an air-cooled power plant that rotated cooled itself satisfactorily. The rotary engine was therefore developed and remained the most popular airplane power plant to the end of the war. The carburetion problem in the rotary engine developed some rather drastic lubrication systems. It was necessary to use castor oil, and the rotary engine was capable of slinging this unpleasant substance quite as effectively as a pinwheel throws sparks. The designers of the early tractor airplanes soon came to the conclusion that this situation was too much for the pilots of even those hardy days. One of the first attempts to minimize this fire hazard and source of filth was made in 1911 by Blériot, who installed a square, box-like cowl, open at the front, over the engine.

Blériot's design was soon improved, and by 1916 the majority of military airplanes were equipped with engine cowlings similar to those shown in Figs. 1, 2, and 3. The cooling air entered the cowl ring through a large annular opening at the front, was carried around by the engine, and passed out through a hole in the under side of the cowling. These cowl rings did not have the annular discharge openings around the complete circumference as do the present designs, but they did possess that external symmetrical smoothness which is so favorable to good propeller efficiency, and lessened turbulence and drag. Fig. 3, particularly, represents a power plant faired into the fuselage lines in a manner which can be compared favorably with present design conceptions. Fig. 4 illustrates a bi-motored Caudron with rotary engines covered with cowlings which remind one at once of the present N.A.C.A. type. Fig. 5 illustrates an American design, an Elias airplane constructed in 1924. The engine cowl rings shown in place could be termed exact duplicates of present-day design. It is doubtful whether the designers fully appreciated the aerodynamic benefits obtained through the use of this type of cowling; more likely they looked upon it more as a necessary expedient required for cleanliness. That this was the case is borne out by the fact that when the radial engine replaced the rotary, the engine cowl rings were forgotten.

The rotary engine had many undesirable features—limited power output, objectionable flying qualities resulting from the gyroscopic torque, dirtiness, etc. Engine designers meanwhile had advanced the radial type of engine by 1919 to the point where it gave satisfactory service. Figs. 6 and 7 illustrate military airplanes built just after the war, with fixed radial engines. The cowling of these engines is not unlike that in use at present, as the various types of engine cowl rings in vogue are not as yet employed on all airplanes.

The poor performance, particularly in high speed, obtained with airplanes powered with air-cooled engines showed that there was room for great improvement. Late in 1927 the National Advisory Committee for Aeronautics started a comprehensive research program for the development of suitable low-drag cowling for the air-cooled engine. The work was carried on with a full-scale model in the 20 ft. diameter wind tunnel. At about this time the Engineering Division of the U. S. Army Air Corps began working on the same problem at Wright Field. Through these efforts was developed an engine cowl ring with a long skirt, extending in some cases for nearly 2 ft. aft of the line of engine cylinders. This type of ring is now known as N.A.C.A. or Wright Field cowling.

At practically the same time the National Physical Laboratory in England had undertaken a similar experimental program. The engine cowl ring developed by the N.P.L. has a short chord and does not extend to the rear of the engine cylinders. Abroad this cowl is styled the Townend ring, H. C. H. Townend being the man who carried through the development work.

The illustrations show that both these cowlings are adaptations

---

[1] Curtiss Airplane and Motor Co., Inc. Mr. Boyd was born in St. Paul, Minn., in 1900. He learned to fly in 1922, and subsequently was a pilot with the Curtiss Northwest Airplane Company until 1924. In that year he received the degree of B.S. in M.E. from the University of Minnesota. He took post-graduate work in aeronautical engineering at M.I.T. in 1924–1925, receiving the degree of M.S. in 1926. In June, 1925, he joined the Curtiss Company as a draftsman. At present he is devoting his attention to airplane power-plant installation design and to test flying.

Presented at the National Aeronautic Meeting, Baltimore, Md., May 12 to 14, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

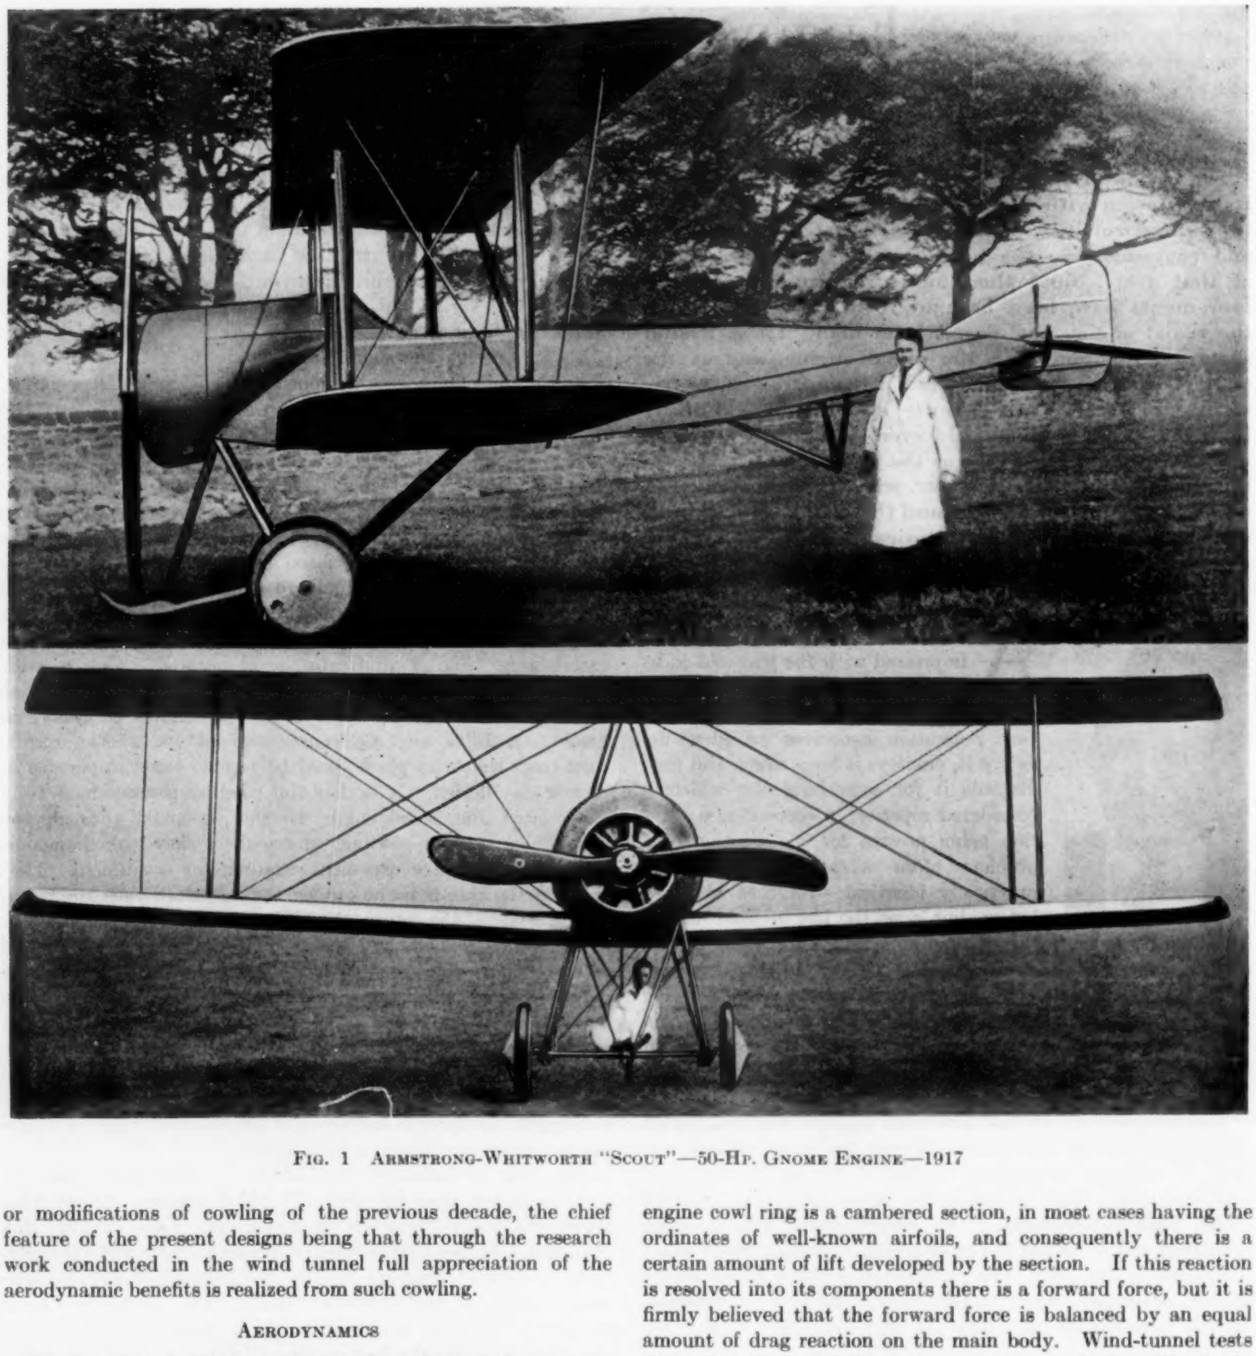

FIG. 1 ARMSTRONG-WHITWORTH "SCOUT"—50-HP. GNOME ENGINE—1917

or modifications of cowling of the previous decade, the chief feature of the present designs being that through the research work conducted in the wind tunnel full appreciation of the aerodynamic benefits is realized from such cowling.

AERODYNAMICS

Advancement in aviation is largely dependent on the progress made in eliminating drag or improving the L/D ratio. The new types of radial-engine cowling are the latest contribution toward this end. Considerable credence has been given by some, particularly in regard to the small-ring type of cowling, to the belief that the benefit derived from these new forms of cowling is due to the forward component of the lift forces acting on the ring, the idea being that the effective thrust is increased by an amount equal to the forward component. This idea appears to be fundamentally wrong, since it seems to violate the fundamental principles of mechanics, and suggests perpetual motion. "Appears to be" is said advisedly, because it is rash to state that any alleged aerodynamic phenomenon is impossible. The engine cowl ring is a cambered section, in most cases having the ordinates of well-known airfoils, and consequently there is a certain amount of lift developed by the section. If this reaction is resolved into its components there is a forward force, but it is firmly believed that the forward force is balanced by an equal amount of drag reaction on the main body. Wind-tunnel tests show that the total drag of a cowl-ring and streamline-body combination is greater than that for the body alone.

When the nose of a body, however, is covered with protuberances such as the cylinders of a radial air-cooled engine, there is a different answer. This condition results in turbulence, and turbulence means drag to the airplane designer. Here lies the answer to the source of the improvement secured through the use of engine cowl rings. An uncowled radial engine excites a turbulent flow of air whose cross-section may have a diameter two or three times as great as the diameter of the body to which the engine is attached. When this same combination is fitted with a cowl ring, the downwash flow from the cambered ring section contracts this region of turbulence, and the lines

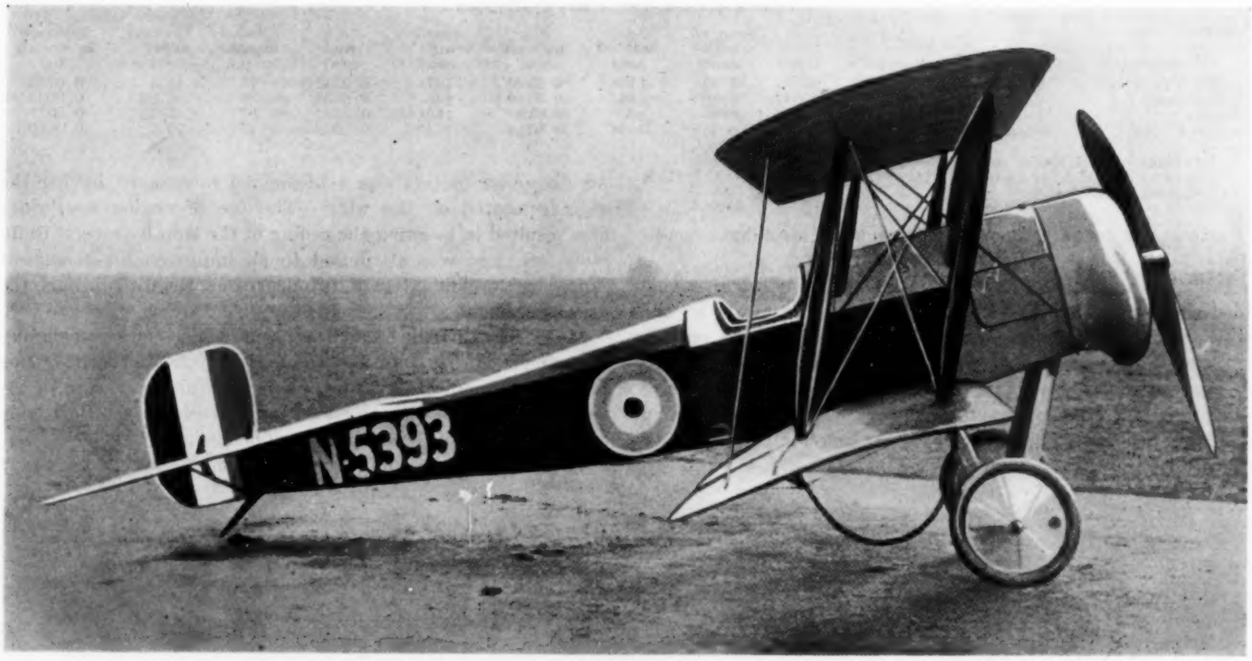

FIG. 2 BRISTOL "BULLET"—130-HP. CLERGET—1918

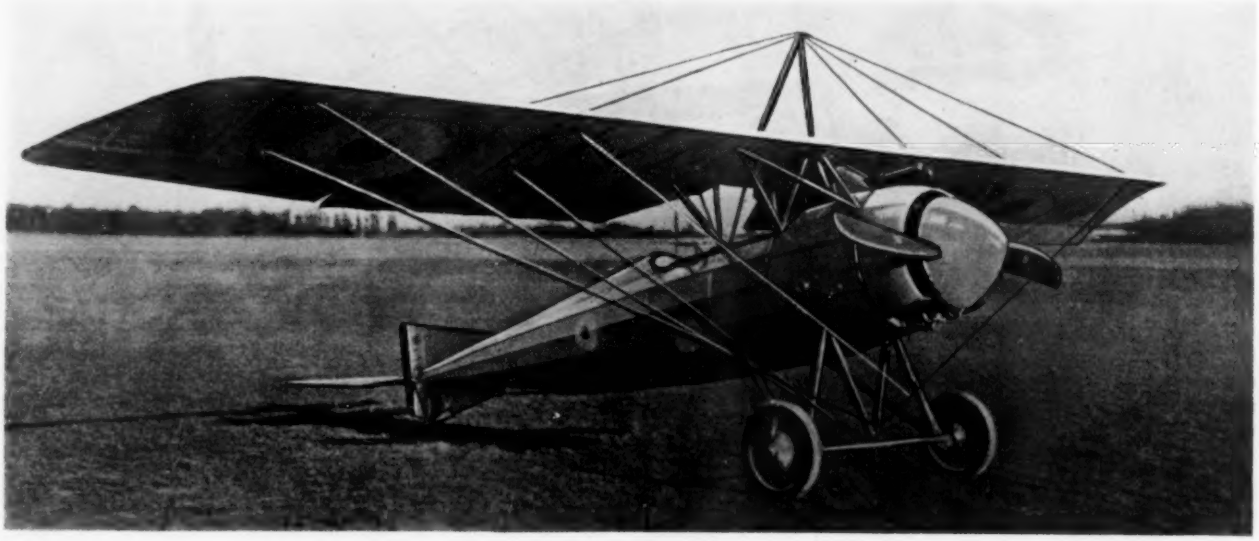

FIG. 3 TYPE P MORANE-SAULNIER—110-HP. LE RHONE—1918

of flow then closely parallel the body. This is borne out by the following facts:

1 The benefit derived from a cowl ring becomes markedly improved as the number of cylinders in the engine increases, the optimum results being obtained on a nine-cylinder engine.

2 An engine cowl ring can be installed on an engine with such a large negative angle of attack that no benefit whatsoever is realized from the downwash of the ring. In fact, it may be so attached that the resultant speed is even slower than that obtained with no cowl ring.

3 The use of the cowl ring brings about more effective tail-control surfaces, indicating that the air passing over them is without turbulence. There is also usually a slight increase in elevator and rudder control loads.

In some cases it has been found that the adoption of engine cowl rings has had an adverse effect on the stability of the ship on which it has been installed. This is far from being the usual result, and when encountered, the change in stability is usually not excessive, and may be due to several causes. As already stated, the use of engine cowl rings tends to make the tail surfaces more effective. Therefore, less stabilizer movement will be required to trim the ship for any condition of level flight. Once the ship is disturbed, however, from this state of equilibrium, it is found that the stabilizer does not build up the proper righting moment until the oscillations of the disturbance have been carried to greater extremes than was necessary before. This results from the fact that the cowl ring, in the majority of cases, is beneficial only throughout a limited range of angles

of attack, the range corresponding to normal level-flight conditions.

Probably another factor contributing to the effect of engine cowl rings on stability is the influence the ring exerts on the position of the center of pressure of the fuselage. On the average long-nosed, well-streamlined body the center of pressure is ahead of the center of gravity, this combination giving a negative pitching moment at low angles of attack and positive pitching moments at high angles, in general making for poor stability characteristics. Most radial-engine-powered ships, however, have shorter fuselages, so that the center of pressure lies aft of the center of gravity. The moments resulting from any disturbance are therefore opposite to those of the previous case and conduce to good stability characteristics. When an engine cowl ring is added, a situation analogous to that of a slotted wing is created. The center of pressure of an airfoil with an open slot is well forward. The center of pressure of a fuselage with an engine cowl ring is likewise brought forward, probably in some cases ahead of the center of gravity, with a resulting detriment to dynamic stability characteristics.

It has been mentioned that the engine cowl ring is of benefit only in level flight. This fact is hard to accept. One would normally assume that any great reduction in overall drag would be also reflected in improved climb and ceiling. Generally this is not the case, these particular performance characteristics remaining unchanged by the addition of engine cowl rings. This falling short of expectations is due to a change in the flow of the relative air over the ring when the ship is in a climbing attitude. The normal ring possesses a constant angle of attack throughout its entire circumference. At the best climbing angle for the ship the relative wind strikes the top arc of the ring at a greatly increased angle. The ring being an airfoil, this portion of it becomes stalled, and the effect of infinite aspect ratio obtained in level flight is lost. The resulting drag becomes practically equivalent to that existing when no ring is in place. An exception to this was a bi-engined monoplane having the engines located on the wing. The use of engine cowl rings here resulted in boosting the ceiling of the ship by several thousand feet, and was attributed to an improved lift coefficient caused by the elimination of turbulence over the wing through the use of the rings.

Much more could be written concerning the aerodynamics of engine cowl rings, but it would carry beyond the scope of this paper. The subject is more capably and fully gone into in the various reports of the American and British aeronautical laboratories. A list of these reports is appended.

Table 1 illustrates improvements in high speed obtained on several ships with the N.A.C.A. type of cowling The differentials obtained with the two cantilever monoplanes illustrate a comparable improvement in each case. The differentials in the case of the two Curtiss Hawks are far from checking as closely. The AT5-A was a Curtiss Hawk powered with a 200-hp. J-5 engine, and was credited with an official top speed of 122 m.p.h. by the Army at Wright Field. If this value is taken and the cube root of the power ratio applied it is found that the 300-hp. J-6 Whirlwind Hawk should make 140 m.p.h., which is the figure with which it is actually credited. The AT5-A was provided with an N.A.C.A. cowl and the speed of that particular ship was increased 19 m.p.h. An identical ship with the exception of the greater power was equipped with an N.A.C.A. type of cowl by other parties with an increase in speed of only 6 m.p.h. While it is not expected that the higher-powered ship would give an equivalent differential, one would naturally anticipate more than the 6 m.p.h. actually obtained. This comparison serves to point out the sensitiveness of the N.A.C.A. type of cowling. The development of a successful cowling of this type calls for considerable research on each installation. Apparently no hard and fast rules can be established, and each different application must assume the proportions of an entirely new research problem.

Table 2 shows the increases in high-speed performance obtained through the use of the small cowl ring. The improvements

were all obtained through the use of the Curtiss anti-drag ring. The design on this ring is standardized. All the rings employed in these tests had the same chord and airfoil section, approximately the same angle of attack, and approximately the same location in reference to engine cylinders. The ships on which these rings were tested range from a twin-engined bomber to a single-seat pursuit ship. Because a number of the military ships are still in the experimental stage they are referred to by number. Ships Nos. 1, 4, and 5, on which particularly gratifying results were obtained through the use of a cowl ring, all had what one might refer to as complete streamlining. The wheels were incased in spats, landing-gear knuckles were faired, strut and wire terminals were covered by cuffs, and the tail wheel was streamlined. Thus the fuselage with its radial-engined nose remained as the single source of most of the drag. For example, wind-tunnel tests on ship No. 5 showed that its engine-fuselage combination without a cowl ring had a K_D of 0.0166, which amounts to 53.9 per cent of the total K_D of 0.0308 for the ship. The addition of the engine cowl ring reduced the K_D for the entire ship to 0.0209. For all practical purposes, it can be stated that the saving was all accomplished on the engine-fuselage unit, though some of the reduction may be due to lessened interference. This example establishes the conditions which indicate how much benefit can be expected from the use of engine cowl rings. The bigger the percentage of the total K_D caused by the engine-fuselage unit, the greater will be the improvement realized through the use of engine cowl rings. With conventional cowling the K_D for an engine of the size of the Hornet

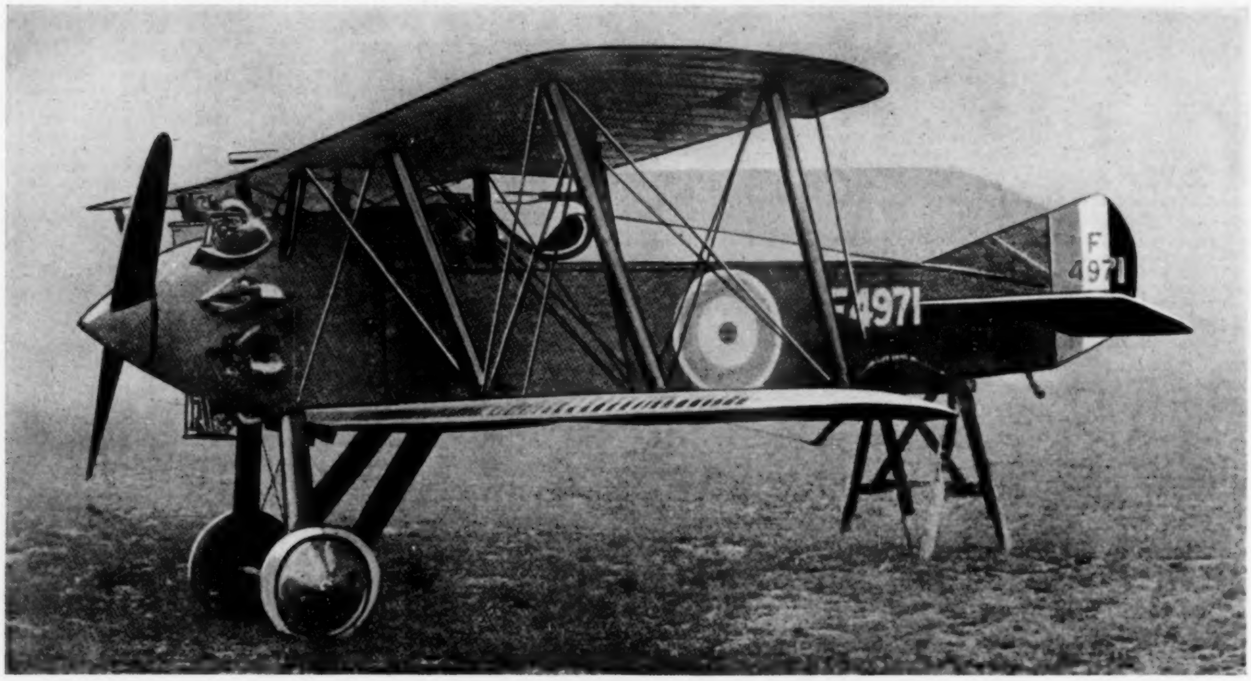

Fig. 6 Armstrong-Whitworth "Ara"—320-Hp. A. B. C. "Dragonfly"—1919

is estimated at 0.0090. If one then considers the engines entirely removed from this ship and the nacelles of a perfectly streamlined airship shape, with the same power, the best speed that could be expected would be 124.8 m.p.h., an increase of 3.8 m.p.h. The use of the engine cowl rings therefore resulted in securing 71 per cent of the improvement that was theoretically possible. This case serves to indicate that the improvement to be expected in a large ship, where the drag of the nacelles is a small percentage of the total, will be small.

Test-stand experiments brought forth the fact that the engine cowl ring in addition to its principal function of reducing turbulence, in some cases also contributed a certain amount of external supercharging, the amount depending on the location of the carburetor air scoop. Tests indicated that 10–15 hp. was realized in the case of the Cyclone engine with its regular air scoop. On ship No. 2 a special air scoop was constructed to replace the unit provided on the engine. Its use gave a speed increment of about 2.7 m.p.h., which indicates a power increase of about 25 hp. If special air scoops had been provided on the twin-engined bomber, ship No. 6, it is quite likely the speed increment due to the engine cowl rings would have been increased to 3.5–4 m.p.h.

The tabulated results indicate that, on a clean military ship, an average speed increase of approximately 10 per cent can be realized. For the slower commercial ship having a top speed of around 135 m.p.h. a 5 per cent improvement can be expected. For slower ships in the 110-m.p.h. class 3 per cent is more likely to represent the improvement to be gained. It must be recognized that these results were all obtained with the same design of ring, and that the optimum condition did not necessarily exist in any case. The results are those obtained by adding an engine cowl ring over the engine, retaining the original engine cowl without alteration. Experimenting with the angle of attack of the ring or the ring's position in each case might have led to better results. The angle of attack is not a particularly critical characteristic, however, as the N.A.C.A. found that with a Curtiss XF7C-1 the speed did not vary more than a mile from the best results obtained with the ring set in different positions through an angular range of 6 deg.

Relative Merits

Both types of ring cowling have certain fields of application in which the one excels the other. The N.A.C.A. cowling has shown its ability to give wonderful results as evidenced by the large increase in speed secured when it has been employed on various familiar cantilever monoplanes. The field of application of the N.A.C.A. cowling, however, is much more limited than that of the smaller cowl ring. The relationship between the cowling itself and the fuselage lines is much more critical than is the case with the smaller cowling. Most of the successful adaptations of the N.A.C.A. cowl to date have been on large, smoothly faired fuselages. The smaller cowl will give a consistent improvement in performance on practically any fuselage. This fact is established by the speed increase obtained on numerous airplanes with the Curtiss anti-drag ring. All these rings have the same airfoil section and angle of attack, and give worthwhile improvements in speed. It is appreciated that the installation might not be the best possible in some cases, and that greater performance might be obtained with a modified ring, but these changes would mean that the production program now possible by standardizing on one style ring would be lost.

In regard to accessibility, weight, and cooling, the small cowl ring is definitely superior. In the case of the Curtiss anti-drag ring the loosening of two clamping turnbuckles is the only step necessary to remove the ring. The ring comes off complete in one unit, leaving the uncowled engine clear for ready servicing.

The N.A.C.A. type of cowling is not as readily disposed of when it becomes necessary to service an engine.

The weights of the small cowl ring are also proportionately lower than other types of radial-engine high-speed cowling. The following figures illustrate the weights of Curtiss anti-drag rings for various engines:

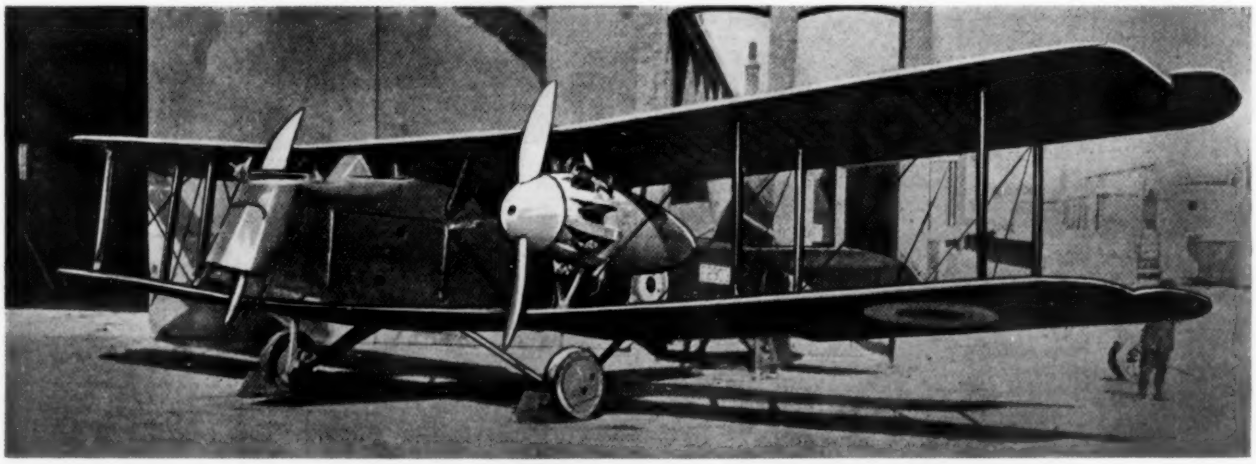

FIG. 7 BOULTON AND PAUL "BOURGES" BOMBER—A. B. C. ENGINES—1919

J-6-7	Whirlwind	16 lb.
J-6-9	Whirlwind	$17^{1}/_{2}$ lb.
	Wasp	$17^{1}/_{2}$ lb.
	Cyclone	$19^{1}/_{2}$ lb.

The weight of the normal engine cowling must, of course, be added to the above, but the figures quoted are a small penalty for the superior performance obtained.

The small cowl ring has no adverse effect of any consequence in regard to engine temperatures. There is a slight increase in head temperatures in some instances, but it is so slight as to cause no concern. With the N.A.C.A. cowling, it is generally necessary to have a rather elaborate baffling system to keep engine temperatures within the allowable limits.

Both types greatly enhance the outward appearance and general lines of whatever aircraft they happen to be installed upon.

DETAILS OF CONSTRUCTION

The Curtiss anti-drag ring is a cowl of the small-ring type constructed from a single cambered sheet of 0.051 aluminum bumped to conform to the upper surface of the Curtiss C-72 airfoil. It has a chord of 12 in. and a uniform angle of attack of —8 deg. A $^{3}/_{8}$-in. outside diameter by 0.035-in. steel tube is rolled into the leading edge as a reinforcement, while the trailing edge is stiffened with a $^{1}/_{8}$-in.-diameter steel wire. The ring is split at the bottom, permitting it to be lifted over the propeller for installation on the engine, and is held in place by clamping it over the engine rocker-arm housings by means of two steel turnbuckles. Fig. 8 illustrates the details of construction. For every rocker-arm housing on the engine a support pad is provided. These supports are made from dural, heat treated, and have two pieces of $^{1}/_{4}$-in. felt pinched into place. These units are then riveted to the cambered shell so that each shall rest on a rocker-arm housing. The ring is reinforced locally where the turnbuckles are attached by 0.064 dural sheets $2^{1}/_{2}$ in. in width. The turnbuckle trunnions engage in heat-treated steel hooks. Lateral rotation of the ring, which would permit the supporting pads to slip off the rocker-arm housings, is prevented by steel fittings having prongs which extend down, and rest against the sides of two different housings. The fabrication of the entire assembly is expedited by the use of Thompson rivets.

The support pads are located as far as possible toward the trailing edge of the ring as, in general, best results are obtained with the ring in the most forward position. This puts the trailing edge approximately at the rear of the rocker-arm housings. Figs. 9 and 10 illustrate one of these rings in place on a Curtiss Helldiver powered with a Cyclone engine. It has been found possible to use practically the same design of support pad for all types of engines, the length in some cases having to be varied. Where the design of the rocker-arm housing was such as to make for poor support, it was found desirable to furnish stampings of sheet brass which could be attached to the engine with the regular inspection-plate screws, this step permitting the use of the standardized support pad.

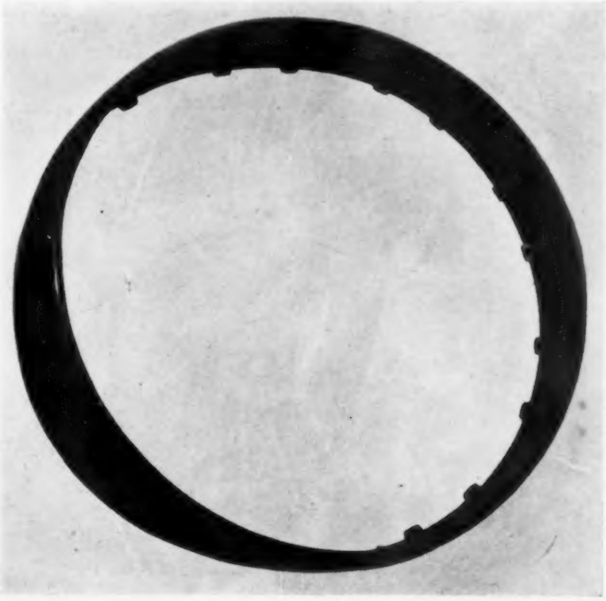

FIG. 8 CURTISS ANTI-DRAG RING

The only precaution to observe in placing the ring in position is not to tighten up too heavily on the turnbuckles. The ring needs only to be snugly fitted, too much tightening tending to distort it from a true circle. The two thicknesses of felt provide plenty of "give" for whatever increase in overall diameter of the engine takes place under operating conditions and at the same time insure room for additional take-up at some future date.

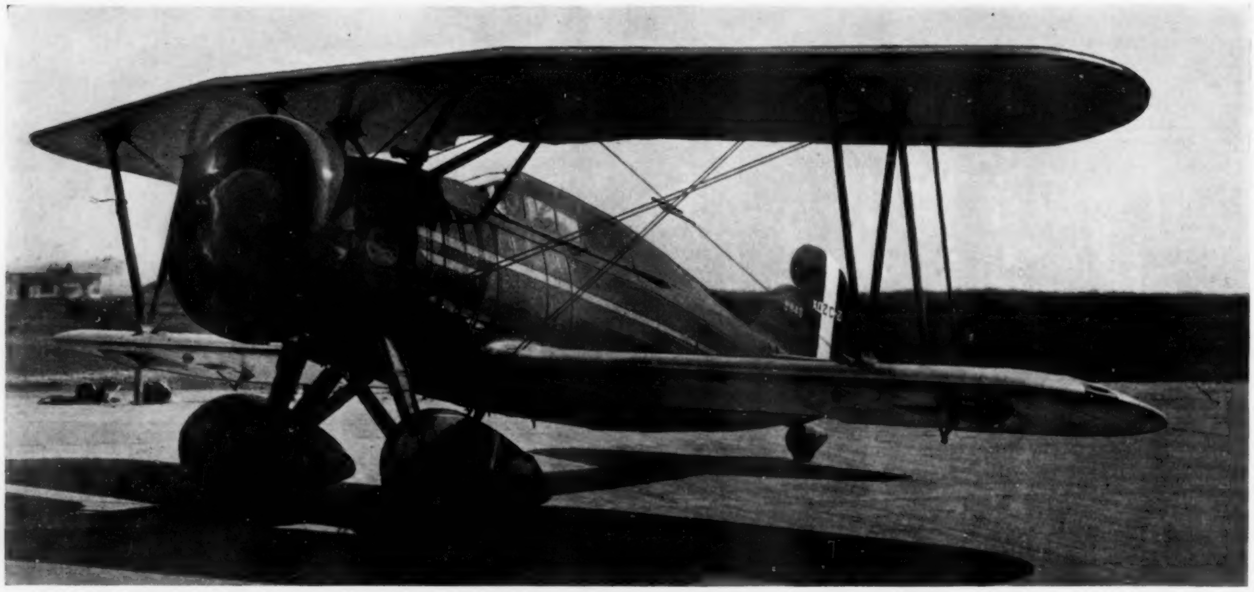

FIG. 10 CURTISS ANTI-DRAG RING INSTALLED ON NAVY HELLDIVER

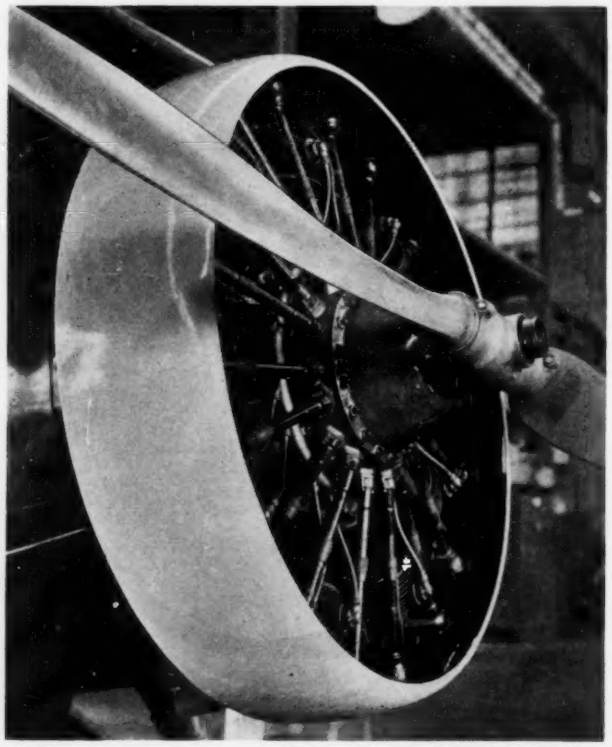

FIG. 9 CURTISS ANTI-DRAG RING INSTALLED ON CYCLONE ENGINE

ECONOMICS

The economic benefits to be derived through the use of engine cowl rings are easily appreciated. For the air-line operator and the private owner doing much cross-country flying their use results in worth-while savings. Higher cruising speeds may be realized, resulting in better schedules and lower gas consumption with reduced fuel costs if the original cruising r.p.m. is retained. Or, on the other hand, if the original cruising speed met the existing requirements satisfactorily the same schedule can be retained at lower engine r.p.m., resulting in reduced fuel costs and longer time intervals between engine overhaul. The realization of a 5 per cent speed improvement in a 135-m.p.h. ship powered with a 240-hp. engine through the installation of an engine cowl ring is equivalent for level-flight conditions to having a power plant of 275 hp.

In the military field the use of engine cowl rings results in increased speeds and greater radius of action, the relative weight of the improved characteristics depending on the particular mission on which the ship is employed.

Discussion

KARL D. WOOD.[2] The author's statement of the conditions under which the drag saving due to a ring cowl is important may be graphically represented as shown in Fig. 11. Using data from Table 2, the per cent increase in maximum speed of the airplane due to the ring cowling has been plotted against the maximum speed without the cowling. The points scatter somewhat, but exhibit a marked trend, and justify the statement that the faster the airplane, the greater the effect of the ring.

It is worth noting that the author's specific statement regarding the power saving due to the use of a ring may be generalized

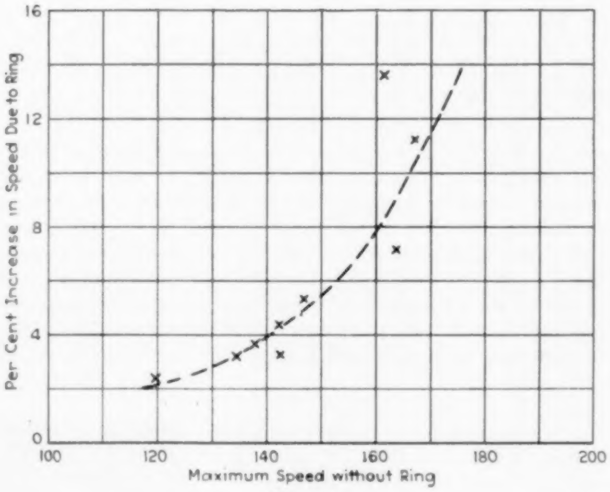

FIG. 11

by saying that 5 per cent increase in top speed permits 15 per cent reduction in power if the speed is not increased. This is consistent with C. B. Millikan's equation for maximum speed $V_{max} = 48.6 \sqrt[3]{(Thp/f)}$, where f is the flat plate equivalent of parasite and profile drag. It can moreover be shown that for most airplanes 15 per cent increase in power will permit carrying 30 per cent more weight at cruising speed. Mr. Boyd's statement that 20 lb. ring weight is small penalty may thus be amplified by saying that for a 2000-lb. airplane of top speed 150 m.p.h., the ring would save power even if it weighed 30 per cent × 2000 = 600 lb. This argument is of course for a given airplane weight and wing area. For a given landing speed the maximum permissible ring weight is more conservative. A general study of this sort, giving an equation for the maximum permissible increase in weight for a given percentage reduction in drag, is presented by the writer in the *Sibley Journal of Engineering* for December, 1931.

G. W. LEWIS.[3] One fact that is distinctly brought out as a result of papers such as this is that some type of cowling for a radial air-cooled engine is desirable. The type of cowling best suited for a given design depends entirely upon the character of the installation, the degree of maintenance necessary, and the desired improvement in the high-speed characteristics of the aircraft.

The National Advisory Committee for Aeronautics, in the investigation of the cowling and cooling of radial air-cooled engines, endeavored to obtain a cowling which would give the minimum of drag, with satisfactory cooling of the engine. The resulting value of N.A.C.A. cowling does not in itself consist of the cowling alone, but of the afterbody of the fuselage or engine nacelle structure. The N.A.C.A. cowling, to give the best results, is necessarily a part of a streamline body. When this type of cowling is used without a streamline body, the decrease in drag is not greater than that obtained with the ring-type cowling.

AER-54-13

Engine Ring Cowlings

By W. H. EVERS,[1] BALTIMORE, MD.

The fairing of engines, either with the N.A.C.A. or the Townend type of rings, is becoming more and more the general practice with newly designed or revamped planes. There is a possibility of higher speed without increase of power, combined with a reduction of operating cost. The author points out the differences in the two types of cowling, and gives a description of test results and construction and suggestions for new experiments. Latest changes on several engines show accessories that affect installation of ring cowlings.

THE fairing of radial engines, either with N.A.C.A.- or Townend-type ring cowlings, is becoming more and more the general practice with newly designed and revamped planes, because the possibility of higher speed without increase in power, combined with a reduction in operating cost, is very tempting to every operator and designer.

Although the theory of the N.A.C.A. cowling and that of the Townend-type ring differ, the aim and ultimate result are the same. The reduction of drag, with resulting increase in speed, gives a more efficient plane for the commercial operator and the private owner. The theory of both types of cowlings is most likely known to all aeronautical engineers from publications of the N.A.C.A. and the British Aeronautical Research Committee, etc.

For general information the author will point out briefly the differences between the two types of cowlings before going into a description of test results, construction, and suggestions for new experiments.

The early type of N.A.C.A. ring cowling is designed to fair an engine with a fuselage in a very efficient way and at the same time to guide the air flow for cooling the engine around the cylinders and back into the outside flow by means of a circular opening in front and a slot between the trailing edge and the fuselage at the rear.

The fairing or streamlining of engine and fuselage is producing the major part of the drag decrease, while the minor part is due to the decrease of turbulent area back of the engine, by smoothing out the air flow disturbed by projecting cylinders and other parts, as illustrated in Figs. 1 and 5.

The combined factors give a considerable reduction of parasite drag, which results in the difference of speed between a cowled and an uncowled ship.

Later type N.A.C.A. cowlings are somewhat modified, and very promising results have been obtained with the wide exhaust collector-ring cowling according to T.N. No. 334.

The Townend-type ring cowling differs from the N.A.C.A. cowling in respect to fairing of the engine with the fuselage. The ring cowling is not a fairing, but due to the ring location in the area of divergent and disturbed flow has the same effect as the N.A.C.A. cowling in smoothing out the air flow back of the engine and thereby reducing the turbulent area. This, in turn, produces the minor part of drag decrease, while the major part is due to the difference between the drag of the ring and the forward component of the resulting force created by the high lift of the circular airfoil or ring, as shown in Fig. 4.

Fig. 5 illustrates the air flow over an uncowled engine as observed and measured during test flights. The angle between the thrust line and the direction of air flow between the cylinders and back of the engine was approximately 20 deg. The air flow over an engine with ring cowling is shown in Fig. 6 for comparison with Fig. 5.

The history of these cowlings goes back to the early days of aviation, although at that time the cowlings served primarily as oil-collector rings on rotary engines; but the thought of reducing parasite drag by fairing engine with fuselage entered as far back as 1912, as the author remembers distinctly; otherwise a plain oil-collector ring instead of a complete cowling would have served the purpose.

In 1915, Prof. Hugo Junkers filed a patent which reminds one of a ring cowling, as Fig. 7 shows. Instead of an engine, a radiator was enclosed in an airfoil-shaped ring to reduce the drag, as the description states.

Lincoln Beachey's plane with pusher-engine installation was also equipped with a Townend-type ring cowling, as shown in Fig. 12. The cowling of course was acting as oil guard, but probably increased the efficiency of the plane without Beachey or Curtiss knowing it.

The experimental N.A.C.A. cowlings used for comparison tests with Townend-type rings are shown in Figs. 1, 2, and 3.

Cowling 3 gave the most promising results on a Wasp-powered plane in respect to speed and engine temperature, but the cost of production runs very high on account of the exhaust manifold being a part of the cowling.

Experimental flight tests with N.A.C.A. cowlings 1 and 2 were made in Hornet- and Wasp-powered ships, and cowling 1 proved to be superior in speed to cowling 2. The cause of the difference in drag between the two cowlings is thought due to the fact that in cowling 1 the cooling air is guided back into the outside flow parallel to the outlines of the fuselage without an outward component or deflection of the air flow as observed on cowling 2, which causes a turbulent area at the point of outlet.

Several times the writer has been asked about the superiority of N.A.C.A. or ring cowlings, but the answer depends entirely on the type of plane and the purpose for which the ship is used.

---

[1] Aeronautical Engineer, Z.A.P. Development Corporation, Berliner-Joyce Aircraft Factory, Dundalk, Md. Mr. Evers entered aviation from the automotive industry in 1910. He built his first plane, with a few mechanics and carpenters. It was a monoplane, with completely covered fuselage and tractor propeller, which hopped and flew very well. Later he associated with the Northwest German Flying Machine Works as designer, manager, and test pilot. In 1913 he returned to America to join the Benoist Aircraft Corporation, St. Louis, Mo., which founded and operated the first commercial airline in the world, between St. Petersburg and Tampa, Fla. In 1914 he connected with the engineering staff of the Hanseatic Flying Machine Works, in Hamburg and Travemunde, which had about 2400 workmen and where he became production manager. After the war the name of the firm was changed to Caspar Werke A.G., with which Mr. Evers was manager. In 1924 he returned to the United States. He was with Babcock & Wilcox and Combustion Engineering Corporation, and then joined the engineering department of Atlantic Aircraft, later called Fokker Aircraft of America, as project engineer.

Presented at the Fifth National Aeronautic Meeting, Baltimore, Md., June 12–14, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

FIG. 1 EXPERIMENTAL N.A.C.A. COWLING 1; FIG. 2 EXPERIMENTAL N.A.C.A. COWLING 2; FIG. 3 EXPERIMENTAL N.A.C.A. COWLING 3; FIG. 4 TOWNEND RING COWLING; FIG. 5 AIR FLOW OVER UNCOWLED ENGINE; FIG. 6 AIR FLOW OVER COWLED ENGINE

For racing and larger type sport planes, speed is very likely the sole factor entering, but if cowling is to be used on commercial planes the question becomes more complex. Although the highest possible speed with minimum power is desirable, the most efficient cowling can be determined only by considering weight, accessibility of engine, time and labor required to remove and install cowling for servicing and inspection, and in addition initial cost and life of cowling.

Comparison tests with the same ship equipped with N.A.C.A. and ring cowling showed that the increase in speed is greatest with the N.A.C.A. cowling. Both cowlings have the same characteristics—the higher the speed of the plane without cowling the greater will be the speed increase with engine cowling, because the drag reduction is more pronounced on a high-speed ship, on account of the larger ratio of engine drag to total drag.

The front part of the fuselage should be cylindrical or as close to it as possible for N.A.C.A. cowling installation, because this will not only improve the lines of the ship and will please the eye, but will also improve the efficiency of the cowling. The designer should always keep in mind that the N.A.C.A. cowling is a *fairing* between engine and fuselage and that maximum efficiency can be obtained only if the two parts are faired as ideally as possible.

The foregoing discussion indicates that the N.A.C.A. cowling is not so readily adaptable for square fuselages, because the outlet slot becomes very irregular and a proper fairing is almost impossible, and therefore the maximum efficiency is not obtainable. If N.A.C.A. cowling is to be adopted for a new ship, the fuselage should be designed for the cowling to avoid disappointments.

The Townend-type ring cowling on the other hand is readily adaptable for any type and shape of fuselage, and if the ring is designed and located right, the increase in cruising speed should be about 70 to 80 per cent of the speed increase obtainable with the N.A.C.A. cowling. In a series of tests made with N.A.C.A. and ring cowlings, it was found impossible to equal or better the increase in performance obtained with N.A.C.A. cowlings with Townend-type rings.

This proves, at least for the types of ships tested, that the N.A.

C.A. cowling is superior to the Townend-type ring if speed is considered alone, which of course is limited to a few types of planes built for special purposes only.

If weight has to be considered in addition to speed, the superiority of the N.A.C.A. cowling is considerably reduced in favor of the ring cowling. The average weight of a N.A.C.A. cowling for a 400- to 500-hp. engine is about 80 lb., including brackets and braces, as compared to 20 lb., the weight of a complete ring cowling.

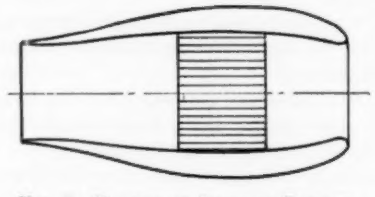

FIG. 7 DESIGN OF JUNKERS PATENT

The ring cowling is therefore 80 — 20 = 60 lb. or 60 ÷ 80 = 75 per cent lighter.

Only under exceptional conditions is it necessary to take into consideration the extra cowling weight, added to boost the speed of the plane, because a reduction in payload of revamped planes is not necessarily the consequence, as the following discussion will show.

In calculating operating cost, the payload is generally estimated to be about 60 per cent of the actual payload, because very seldom is the ship loaded to full capacity, and the weight of the cowling within certain limits is therefore of little consequence. Besides, an increase in empty weight of about 2 per cent of the gross weight is permissible, and in most cases the added weight is within this limit. In addition, the fuel consumption for a given distance is reduced on account of the increase in speed without increase in power, and therefore the amount of fuel in the tanks can be reduced at the starting point, if the load on board should make this necessary.

Almost every run between landings on our air lines is shorter than the maximum range of the plane, and a decrease of $3^1/_2$ gal. of fuel for the ring and 13 gal. for the N.A.C.A. cowling as equivalent weight is possible, without reducing the necessary margin of safety. On new planes originally equipped with engine cowlings or rings, the weight is included in the empty weight of plane.

A positive point in favor of the ring cowling is the accessibility of the engine, which is very poor on N.A.C.A.-cowling installations. Of course this condition can be improved considerably by eliminating the inside bell and hinging the skirt of the cowling so that it will open up like an automobile hood, as shown in Fig. 13.

The time required to remove and install the cowling for engine inspection and servicing is another factor in favor of the ring cowling, as will be shown.

Other features in favor of the Townend-type ring are initial cost and lower depreciation, because the life of the cowlings is considered to be the same.

It is therefore the opinion that the N.A.C.A. cowling is the favorite where speed alone is essential, but for commercial planes, which are flown and thoroughly inspected daily, the ring cowling is surely to be preferred.

The ring cowling hides nothing from the view of the mechanic and inspector, and really has to be removed only when servicing the rocker-arm boxes, which of course means daily, on most of our commercial lines, and these should require as little time and effort as possible.

For revamping of ships in service the ring cowling is in every way superior to the N.A.C.A. cowling, because the low weight does not change the balance. Reworking of the fuselage to suit the ring is not necessary, and therefore the only cost to boost the speed at a reduced cost of operation is the price of the cowling, which again pays for itself in about 100 hours of flying time with a cowling life of at least 1000 hours.

An important question the operators generally ask is about the return on the investment for cowlings.

Let us consider two different ships, a single engine and a trimotor job, to answer the question satisfactorily.

The single-engine ship is equipped with a Hornet and the trimotor job with three Wasp engines.

Performance at cruising speed will be considered only, because it is the speed the commercial operator is interested in.

The single-engine ship equipped with Hornet engine and N.A. C.A. or ring cowling has the following characteristics:

Average cruising speed with conventional cowl, m.p.h.	115.0
Average cruising speed with N.A.C.A. cowl, m.p.h.	120.0
Average cruising speed with ring cowling, m.p.h.	119.0
Average gain with N.A.C.A. cowling m.p.h.	5.0
Average gain with ring cowling m.p.h.	4.0
Payload of ship, lb. m.p.h.	1600
Operating cost per plane per hr. incl. 35% overhead m.p.h.	$42.00[a]
Cost per plane mile (conventional cowling) m.p.h.	$0.365[a]
Cost per pound payload per hour m.p.h.	$0.04375[a]
Cost per pound payload per mile m.p.h.	$0.00038[a]
Initial cost of N.A.C.A. cowling. m.p.h.	$600.00
Initial cost of ring cowling m.p.h.	$130.00
Cowling life in hours of flying time m.p.h.	1000
Depreciation per hour flying time of N.A.C.A. m.p.h.	$0.60
Depreciation per hour flying time of ring m.p.h.	$0.13
Weight of N.A.C.A. cowling, lb. m.p.h.	80.0
Weight of ring cowling, lb. m.p.h.	20.0

---

[a] Based on 115-m.p.h. cruising speed and 60 per cent average payload = 960 lb.

The saving per hour of flying time is approximately as follows:

(a) *Equipped with N.A.C.A. Cowling.*		
Saving due to increase in speed = 5 miles at 36.5 cents per plane mile		$1.83
Depreciation per flying hour	$0.60	
Additional labor for servicing engine	0.10	0.70
Total saving per hour of flying time		$1.13
(b) *Equipped with Ring Cowling.*		
Saving due to speed increase = 4 miles at 36.5 cents per plane mile		$1.46
Depreciation per flying hour	$0.13	
Additional labor for servicing engine	0.05	0.18
Total saving per hour flying time		$1.28

At a first glance the saving in operating cost and time may seem very small, but if daily operation of several planes is considered, the matter begins to look different.

Now let us consider a trimotor ship equipped with three Wasp engines and with three ring cowlings of the following characteristics:

Average cruising speed with conventional cowl, m.p.h.	119.5
Average cruising speed with ring cowling, m.p.h.	126.0
Average gain with ring cowling, m.p.h.	6.5
Payload of ship, lb. m.p.h.	2700
Operating cost per plane per hr. incl. 35% overhead m.p.h.	$87.00[a]
Cost per plane mile (conventional cowling) m.p.h.	$0.73[a]
Cost per pound of payload per hour m.p.h	$0.0537[a]
Cost per pound of payload per mile	$0.00045[a]
Initial cost of three ring cowlings	$375.00
Cowling life in hours of flying time	1000
Depreciation per hour flying time	$0.375
Weight of three ring cowlings, lb.	60.00

---

[a] Based on 119.5-m.p.h. cruising speed and 60 per cent average payload = 1620 lb.

The savings per hour of flying time is approximately as follows:

Saving due to increase in speed = 6.5 miles at 73 cents per plane mile		$4.75
Depreciation per flying hour,	$0.38	
Additional labor for servicing engine	0.15	0.53
Total saving per hour of flying time		$4.22

These figures, based on actual test results, show that ring cowlings on single-engine and trimotor ships pay for themselves in about 100 flying hours. After that the operator really gets something for nothing, because the increase in speed is connected with a decrease in operating cost of from one to four dollars per flying hour.

It is probably interesting to know that Western Air Express ships equipped with ring cowlings lowered the flying time between Kansas City and Los Angeles by one hour on the 14-hour trip.

The life of the ring cowling in the foregoing calculation is estimated very conservatively and is based on inspection of cowlings more than 600 flying hours in service, which are still without any sign of fatigue.

Another point of interest, at least to operators, is the fact that by cruising against headwinds the reduction in speed is decreased on cowling-equipped planes, due to the higher initial speed, as the following figures show:

Cruising speed with conventional cowling, m.p.h.	119.5
Cruising speed with ring cowling, m.p.h.	126.0
Headwind, m.p.h.	20.0

The speed reduction of the first plane is 20 ÷ 1.195 = 16.7 per cent, as compared with the decrease on the second plane of only 20 ÷ 1.26 = 15.8 per cent.

The cooling of the engine is not affected by ring-cowling installations; in fact, on several test flights and certain cowling locations a slight temperature reduction was observed; but there is one exception, and that is a 2-to-1-geared radial engine of 500 hp. which was used on several experimental flights.

With ring cowling installed, the temperatures increased very rapidly, and several wide-open throttle flights had to be discontinued after 4 to 5 minutes' climb on account of excessive temperatures. After removing the cowling the temperatures could be held within certain limits, although higher than on straight-drive radial engines.

The foregoing experience was most likely due to the wrong location of the cowling in relation to the propeller, because the cowling was designed for a straight-drive engine on which the leading edge of the cowling is much closer to the propeller. But this conclusion could not be checked by moving the ring forward, because the test with this engine had to be discontinued for other reasons.

During ring tests and experiments with N.A.C.A. and ring cowlings it was found absolutely essential to have a properly designed temperature control of the mixture to prevent high cylinder temperatures on days with outside temperatures below 60 deg. fahr.

With hot spot in the "on" position and cylinders 8 and 9 exhausting, through the hot spot, the cylinder temperatures dropped about 30 deg. fahr. on head and 10 deg. fahr. on base. At the same time the engine began to smooth out and the vibrations disappeared, because the evaporation of fuel and distribution of gas improved, and with it the irregularity in mixture. If the carburetor preheater was closed in addition to the hot spot, keeping the engine r.p.m. constant, the temperatures again dropped an additional 20 deg. on head and 20 deg. on base within 2 min.

Cowling tests on six different ships from 300 to 2300 hp. made with special attention to flight characteristics showed no changes in static or dynamic stability, and no change on controllability, either in stall or dive. According to information received, it seems that certain ships have become unstable after ring-cowling installation, probably due to change in air flow, and therefore the Department of Commerce requires a flight test on every type of ship to which a ring cowling is added, after issue date of A.T.C.

The ring cowlings used for comparison tests with the N.A.C.A. cowlings were designed on lines following the investigation of Townend.

The airfoil-shaped rings had a chord length of 12 and 14 in., set at an angle of incidence of —5 deg. and —8 deg., equal to an angle of attack of about 15 deg., the stalling point of the profile used being at about 17 deg.

In selecting the airfoil for the ring cowling, it was kept in mind that the most efficient section is the one which has a high L/D at the stalling point.

The angle of incidence was calculated after the angle at which the airflow over the engine diverges had been determined by tests and measurements.

No difference in efficiency between 12-in.- and 14-in.-wide ring cowlings was noted during tests; therefore the 12-in. section is to be preferred on account of lighter weight.

For maximum efficiency it is not advisable to use one type of ring cowling for different types of ships, but a good average speed increase can be obtained by using a ring of about 12-in. chord and —5- to —8-deg. angle of incidence, as experimental test flights indicate.

Another factor of importance is the location of the ring cowling in relation to the propeller trailing edge, which seems to vary with the speed of the plane and the shape of the nose.

The gap between the trailing edge of the propeller blade and the leading edge of the ring cowling should be between 4 and 5 in. for the best performance.

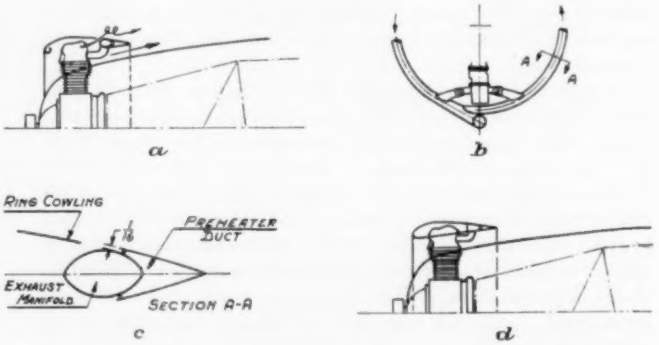

Fig. 8 Type of Ring Cowling as Designed in 1929 and as It Might Be Reworked

In positions with decreased and increased gap, a drop in speed up to 2 per cent was observed.

For new designs the location and the most efficient angle of incidence of the ring cowling should be determined in the wind tunnel to get maximum performance.

The same airfoil section can be used on all cowlings, but it should be remembered that the most efficient wing profile is not always the best for the ring cowling, as has been stated before.

It is not possible to give complete data of all tests and observations made within the limited space of this paper, but the following experience is most likely of general interest.

On some of the experimental flights it was quite annoying when exhaust gases were forced into the closed cockpit after ring installation. This phenomena was caused by the convergence of air flow after the ring was installed, and therefore leaky exhaust manifolds should not be tolerated, for the benefit of the pilot, whenever the plane is equipped with ring cowling.

Following is a brief description of the construction of our ring cowling, developed from flight tests and observations made in the field and shop and in handling cowling for engine servicing.

Fig. 14 shows a close-up of a Hornet ring cowling of 12-in. chord. The ring itself is quickly detachable, and can be removed in about 5 min. for servicing rocker-arm boxes and inspection of engine. Reinstallation of ring takes from 6 to 8 min., including time for safety wiring, by one man without extra help. The construction of the ring in three sections makes complete removing very easy. The parts to handle are small and weigh only 5 to 6 lb. each, depending on size of engine.

Our first experimental rings were made in one piece, and on account of the large diameter were very awkward to handle, especially in the field. When not completely removed, the engine was partly covered, which made servicing much more difficult than with the present three-piece ring.

To remove the ring the three wing nuts are backed up and the steel straps are thrown forward. After removing the self-locking nut, each section can be removed individually, and the cowling is completely out of the way.

Figs. 8*A*, 8*B*, and 8*C* show another type of ring cowling designed in 1929 and tested for comparison with other cowlings described before.

The exhaust manifold with fairing is part of the ring. The fairing forming the trailing edge of the cowling is used to supply preheated air to the carburetor as shown in Figs. 8*B* and 8*C*. The front part of the cowling is not connected to the manifold, as can be seen from Fig. 8*A*.

Part of the cooling air escapes through the slot to circulate around and cool the manifold. The speed increase with this type of cowling was about the same as with plain-ring cowlings used on previous tests. It was observed during flight tests that the cooling air leaving the forward slot has an outward component which creates a large turbulent area all around the ring.

If the ring is reworked, as in Fig. 8*D*, the flaring out of the air flow is eliminated, and the performance should be considerably better. The dissipation of the heat of the exhaust manifold should be sufficient, because more than half of the surface is exposed to the cooling air. Of course the speed of the ship must improve considerably to compensate for the higher weight and the cost of this cowling compared with the plain ring; otherwise the installation is not warrantable, even on a newly designed ship.

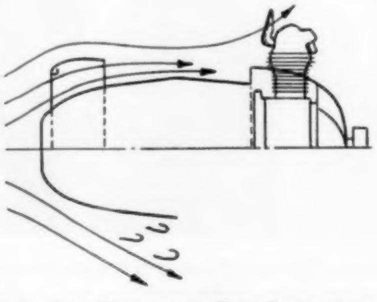

FIG. 9 RING COWLING TO TEST PERFORMANCE INCREASE OF PUSHER INSTALLATION

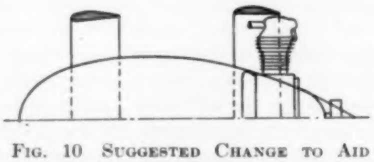

FIG. 10 SUGGESTED CHANGE TO AID COOLING EFFICIENCY

To gain data on the possible performance increase of a pusher installation, tests and experimental flights have been made with a ring cowling installation as shown in Fig. 9. Most nacelles on pusher installations are generally not perfectly streamlined on account of structural interference, oil-tank installation, etc., which prevent the designer from getting the most efficient finesse ratio of cowling.

Preliminary investigation of the nacelle cowling used for test flights showed that the air flow at the cowling nose diverged at an angle of about 20 deg. from the normal direction, creating a turbulent area ahead of the engine as shown in the lower half of Fig. 9.

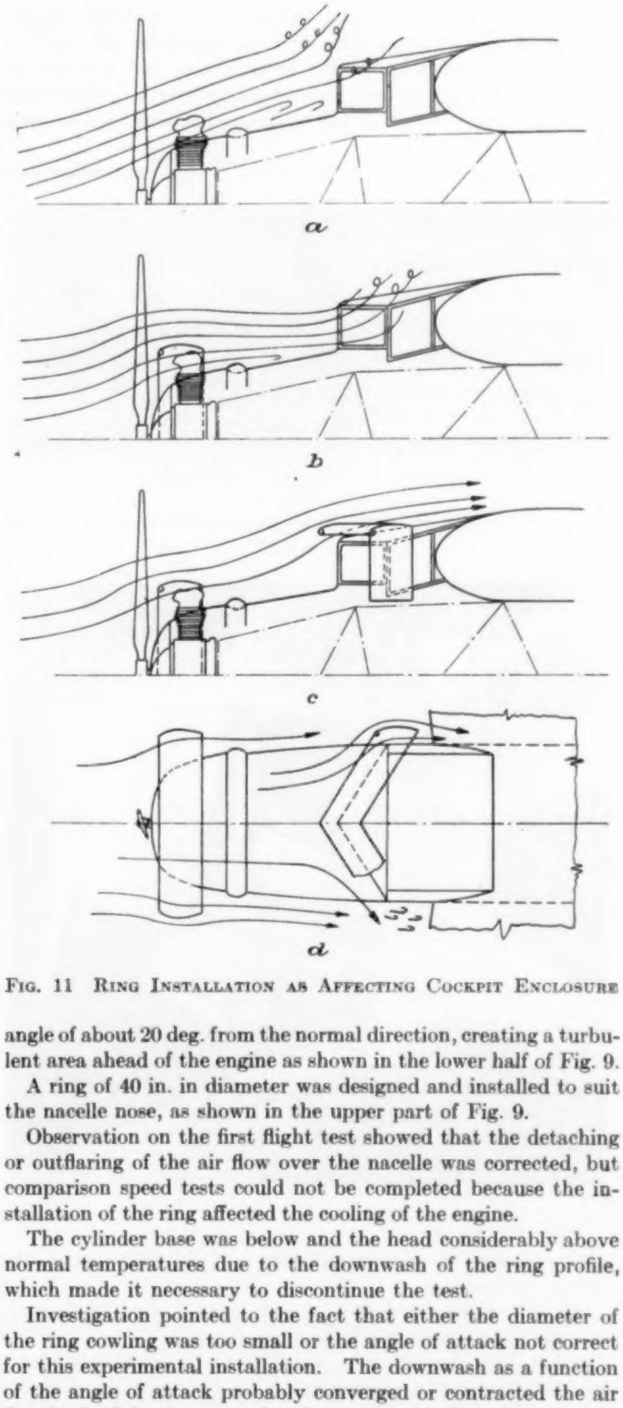

FIG. 11 RING INSTALLATION AS AFFECTING COCKPIT ENCLOSURE

A ring of 40 in. in diameter was designed and installed to suit the nacelle nose, as shown in the upper part of Fig. 9.

Observation on the first flight test showed that the detaching or outflaring of the air flow over the nacelle was corrected, but comparison speed tests could not be completed because the installation of the ring affected the cooling of the engine.

The cylinder base was below and the head considerably above normal temperatures due to the downwash of the ring profile, which made it necessary to discontinue the test.

Investigation pointed to the fact that either the diameter of the ring cowling was too small or the angle of attack not correct for this experimental installation. The downwash as a function of the angle of attack probably converged or contracted the air flow back of the ring to such a degree that it affected the cooling of the cylinder heads as observed during test flights.

Another cause for overheating of cylinder heads is illustrated in the upper part of Fig. 9.

The outer layers of the air flow around the nacelle cowling, between the ring cowling and the engine, probably detaches from the inner layer and flares out again due to the propeller action, and thereby decreases the cooling efficiency. A change of this angle of incidence or the installation of a second ring for cooling purposes only, just forward of cylinders, as shown in Fig. 10, probably would have corrected the trouble.

A check has been made in the wind tunnel which shows that the installation of two rings with different angles of incidence is superior to one ring on pusher installations, but conclusions cannot be reached until tests have been terminated. Flight tests will be made soon to check the actual performance and cooling efficiency.

The experiments with a ring installation on the nacelle nose point the way to another problem spot on cabin ships, the cockpit enclosure.

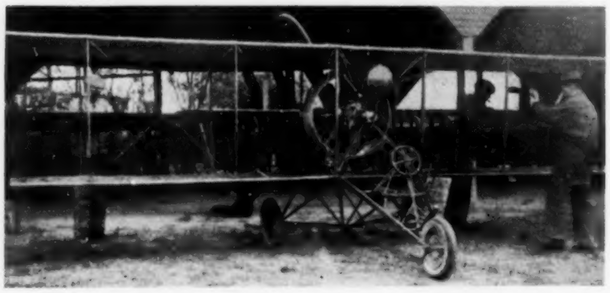

FIG. 12 "CURTISS PUSHER," LINCOLN BEACHEY'S PLANE, WITH ENGINE RING

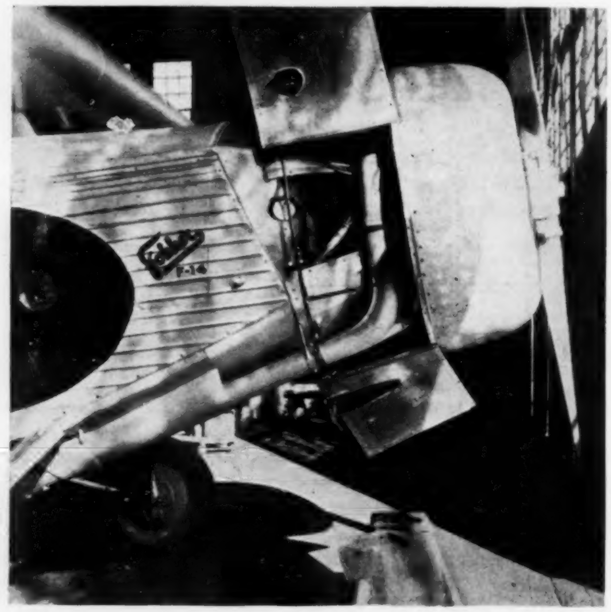

FIG. 13 EXPERIMENTAL N.A.C.A. COWLING FOR HORNET ENGINE

Fig. 11*A* shows the air flow over the front part of the fuselage, with the cockpit enclosure in a typical location.

In Fig. 11*B* the probable direction of the air flow is shown after installation of a ring cowling. The flow over the nose and the engine has improved, but diverges again on top of the fuselage by the vertical or sloped windshield of the cockpit.

By installing an airfoil-shaped cowling over the cockpit, as shown in Figs. 11*C* and 11*D*, it is likely that the same results can be obtained as with a ring around an engine or pusher nacelle nose. Of course the general direction of air flow over the windshield of cockpit enclosure would have to be determined first, either in a tunnel or actual flights, before it would be possible to fix the most efficient angle of incidence of the top and side airfoil.

It is likely that the angles of incidence of the two airfoils will be different depending entirely on the angle of outflare in relation to normal flow, parallel to the thrust line.

If the performance increase on actual flight tests warrants the adoption of this type of cowling, a transparent material can be used for manufacturing the airfoils to prevent impairing the visibility of the pilot upward or to the sides. Actual tests with this type of cowling will be made soon.

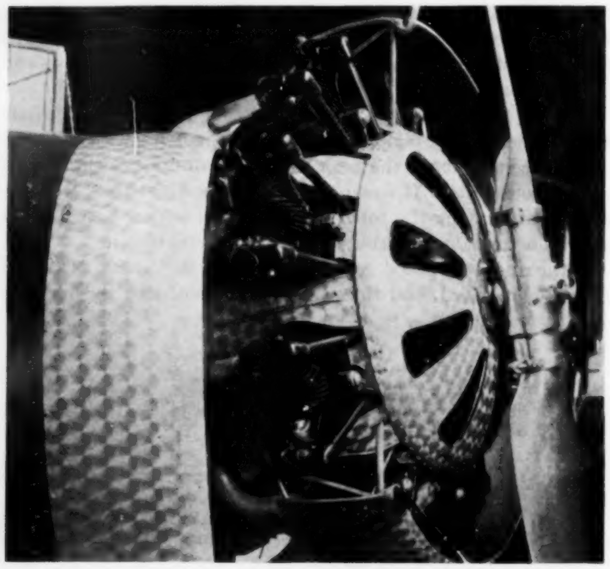

FIG. 14 RING COWLING FOR HORNET B ENGINE, WITH ONE SECTION REMOVED

The value of engine-ring cowlings on new planes or as additional equipment to planes in service has been proved in experimental tests and in flights over our airlines, as test data show.

Latest changes on several engines show accessories that almost prevent installation of ring cowlings or at least make installation complicated and reduce the efficiency considerably.

The interfering parts, such as exhaust manifolds, carburetor heaters, etc., should be designed by the engine manufacturers for ring-cowling installation, because it is very difficult to design a ring to clear these parts and still maintain maximum efficiency and rigidity combined with quick detachable features.

It is hoped that the foregoing suggestions will guide engine designers and manufacturers in the future when changes of parts are contemplated, interfering at present with ring-cowling installation.

AER-54-14

Some Effects of Corrosion Fatigue on Streamline Wire for Aircraft[1]

By HUGH E. HAVEN,[2] ANNAPOLIS, MD

Several years ago aircraft designers began using what is commonly known now as "streamline wire" in the construction of tension members of aircraft. Wires of approximately elliptical section were adopted for the purpose of reducing parasite resistance. These wires are subjected to vibrations of varying frequencies, believed to be mainly of the torsional type. They are also under a pure tension stress when the plane is in dead air or on the ground. In addition to the aforementioned stresses, the wires are always subject to the very deleterious effects of corrosion. Corrosion, obviously, is a serious factor where naval or sea planes are concerned. Some of the effects of the combination of these conditions are discussed in this paper, in which the author presents data thus far obtained in an investigation at the Engineering Experiment Station, Annapolis, Md.

THE ALTERNATING-torsion machines used in this investigation were developed at the Engineering Experiment Station. Essentially, the machines are modifications of the Upton-Lewis alternating-bend machines. The initial purpose of the modified machines was to subject cylindrical specimens to alternating torsion. Later, changes were made so that streamline wire of approximately elliptical cross-section could be tested. For this purpose grips were designed to secure the specimen in proper alignment with the axis of the horizontal driving shaft of the machine. The rotation of the specimen is resisted by opposing springs, and a torsional moment is thus applied to the specimen. Since this torsional moment is proportional to the strength of the springs and their displacement, the nominal maximum stress on the specimen can be calculated.

Fig. 1 shows the machine. In this the arm *C* is caused to oscillate by means of an adjustable eccentric attachment to the rotating wheel *A*, thus rocking the shaft *D*. The driving grip *E* is rigidly attached to the end of the shaft *D*, and the specimen *F* is clamped in it and in the driven grip *G*. Alternating rotation of the shaft *D* is thus transmitted through the specimen to the spring arm *O*. Since this rotation is resisted by the action of the springs *J* on the arm *O*, an alternating torsional stress is applied to the specimen which can be varied by altering the throw of the eccentric attachment on wheel *A*. The range of stress can be varied by means of the turnbuckle *B*, and in the present investigation lay between a maximum positive value and an equal maximum negative value.

The machine is driven by a constant-speed motor at the low speed of 360 r.p.m. through the belt *M*. The large flywheel on the shaft helps to maintain a constant speed. A pencil record of the stress is made by the mechanism shown at *L*. The total number of cycles is counted on the revolution counter *N*. Fig. 2 is an enlarged detail of the grips and specimen. No attempt is made to polish the specimens, and they are tested in the "as-received" condition.

Determination of Stress

In this test the torsional stress depends on two variables: (1) the torsional moment due to the action of the springs on a lever arm, and (2) the moment due to inertia of the oscillatory parts. The stress due to the former will be designated S and that due to the latter S_1. The stresses in a wire of elliptical cross-section are calculated by the following formula, which holds within the elastic limit:

$$T_1 = \frac{\pi S a b^2}{2} \qquad [1]$$

where T_1 = torque in in-lb.
S = maximum shearing stress in lb. per sq. in.
a = semi-major axis in inches
b = semi-minor axis in inches.

As alternating torsional stresses are applied to the specimen due to the action of a lever arm on the springs and also as a result of inertia of the oscillating parts of the machine, the torsional moment T due to the latter, in absolute units, is expressed by the equation:

$$T = \frac{4\pi^2 I \tan\theta}{t^2} = 4\pi^2 I n^2 \tan\theta$$

where I = moment of inertia of oscillating parts
θ = amplitude of angular oscillation in degrees
n = frequency of oscillation = $1/t$
t = time in seconds for one revolution of wheel A.

To express the value of the torsional moment T in inch-pounds, the equation must be multiplied by 1/384, which expresses the relationship between absolute units and inch-pounds.

Then:

$$T_1 = \frac{\pi^2 I n^2 \tan\theta}{96} \qquad [2]$$

where T_1 = torsional moment in in-lb.

Equating [1] and [2], and replacing S by S_2 where S_2 = stress

[2] Lieutenant, U. S. Navy Engineering Experiment Station. Lieutenant Haven was graduated from the U. S. Naval Academy in 1919. After completing a post-graduate course of instruction in mechanical engineering at the U. S. Naval Academy Post-Graduate School and Columbia University in 1926, he received the degree of M.S. in M.E. from the latter institution. During his 12 years' active service since graduation from the Naval Academy, he has spent over 10 years in various kinds of engineering work, and during the past year and a half has been in charge of test work at the Engineering Experiment Station, Annapolis, Md.

Presented at the National Aeronautic Meeting, Baltimore, Md., May 12 to 14, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers, are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 1 RESULTS OF TENSION TESTS

Material letters	Original dimensions, in.	Ultimate strength, lb.	Tensile strength	Yield point	Johnson's limit	Proportional limit	Elongation	Reduction of area
			lb. per sq. in.				per cent	
LCA	0.185 × 0.750	15,355	145,900	133,900	109,250	61,400	8.2	36.2
KXA	0.185 × 0.750	20,670	188,200	185,900	.....	....	6.5	46.9
KZA	0.162 × 0.640	12,250	151,200	131,300	107,700	53,250	7.5	39.3
LXA	0.190 × 0.690	23,250	225,900	179,700	149,800	66,000	7.8	41.7
LXA 17.5	0.190 × 0.690	11,500	111,600	35,000	25,900	21,300	50.3	63.6
LYA	0.185 × 0.748	17,800	161,300	155,700	.....	....	7.7	40.8

Material LXA 17.5 was heat-treated to 1750 deg. fahr., held for 1/2 hr., and allowed to cool in the furnace.

in an elliptical specimen in pounds per square inch due to the inertia of the oscillating machine parts:

$$S_2 = \frac{\pi I n^2 \tan\theta}{48\, ab^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad [3]$$

Since the stresses in the specimen due to inertia are proportional to the square of the frequency, it is imperative that these stresses be kept small in comparison with the stresses produced by the action of the springs. A slight increase in the speed of the machine greatly increases the stress in the specimen. The present machines are not adapted for testing the smaller sizes of streamline rods due to the large inertia stresses.

TABLE 2 CHEMICAL COMPOSITION OF MATERIALS TESTED

Material letters	C	S	P	Mn	Si	Ni	Cu	Cr	Fe

[c] Electroplated with cadmium.

Admittedly, the section of a streamline wire is not a true ellipse, but the foregoing formulas are given to show how the stresses which have been plotted on the graphs, Fig. 3, are computed. Detailed information as to these stress computations may be obtained upon application to the Engineering Experiment Station, Annapolis, Md.

MATERIALS

The tension results of the materials tested to date are given in Table 1. To facilitate their identification, each material has been arbitrarily assigned letters. In each case "A" after the letters indicates the material in the streamline-wire form.

In tensile tests for a few of the sizes of wire it was impossible to use the extensometer. In no case was it possible to release the load and return to zero, due to the fact that grips were used to hold the specimens.

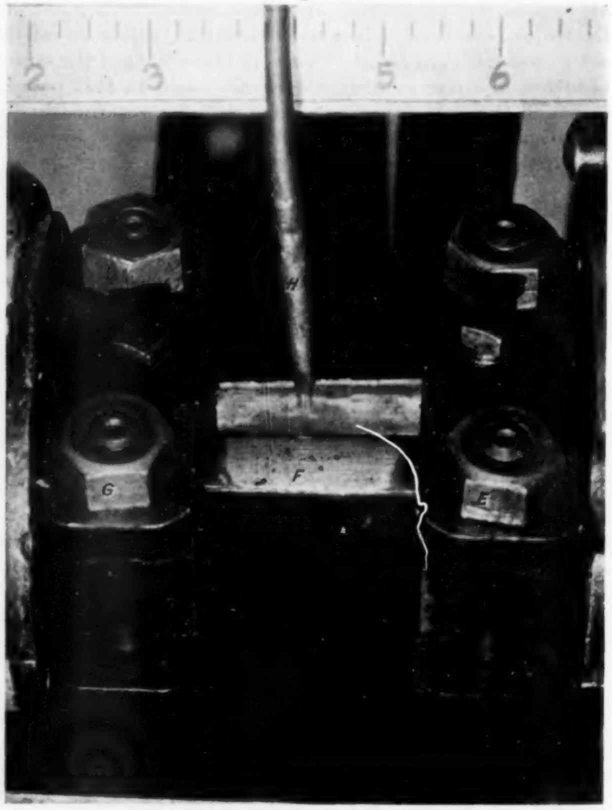

FIG. 2 GRIPS AND SPECIMEN

The chemical compositions of the various materials are given in Table 2.

ALTERNATING TORSION TESTS

Graphs showing the results of tests of streamline wire in alternating torsion are shown in Fig. 3. In these graphs the ordinates represent the half-stress range and the abscissas represent cycles on a logarithmic scale. Each graph has its own scale of abscissas, which are indicated in numerals in the vicinity of the respective plotted points. The decimal figures at the bottom of each graph indicate the average dimensions of the individual specimens in inches.

Under alternating torsion the directions of the principal tensile and compression stresses make an angle of 45 deg. with the axis of the specimen. The directions of the principal shear stress, however, are longitudinal and transverse. Examination of the surfaces of fracture of failed streamline-wire specimens has shown the region of maximum stress to be at the end of the minor axis, as would be expected.

In Fig. 3 the results of ordinary endurance tests in air are indicated by the small circles, and the stress-cycle relationship by the curved solid lines.

The results of corrosion fatigue in carbonate water are indicated by triangles. The fatigue graphs are typical ones, as they do not differ in any particular way from results obtained with rotating-cantilever specimens. They consist of curves descending toward a horizontal asymptote, the ordinate of which represents the endurance limit.

The alternating-torsion endurance limit for the LCA material is approximately 36,500 lb. per sq. in. The alternating-torsion corrosion-fatigue limit for the same material is about 18,000 lb. per sq. in. In this material considerable scatter of the experimental points of failure of the specimens under alternating-torsion corrosion fatigue will be noted.

Although material LXA has the highest physical properties of any of the groups reported in this paper, it appears to have a materially lower torsional-endurance strength. Too few specimens of this material have been tested to make it possible to determine definitely the torsional-endurance or corrosion-fatigue limits, but the former is estimated to be somewhat above 20,000 lb. per sq. in. Since the alternating-torsion endurance limit depends on the transverse as well as the longitudinal strength of the metal, it is probable that the abrupt descent of the graph of material LXA is due to the lack of transverse strength. Tensile results have shown that the material has high strength longitudinally.

The graph in the upper right-hand corner of Fig. 3 presents the endurance and corrosion-fatigue results of material LXA annealed at 1750 deg. fahr., all strain effects of cold working being thus relieved. The stresses represented in this graph are only nominal, since working due to the testing process itself has undoubtedly increased the elastic values of the material over its primitive ones. However, these results seem to indicate that some relief of the severe working strains found in material LXA is desirable for sections subjected to alternating torsion. Additional specimens of this material, drawn at 1200 deg. fahr., are to be tested.

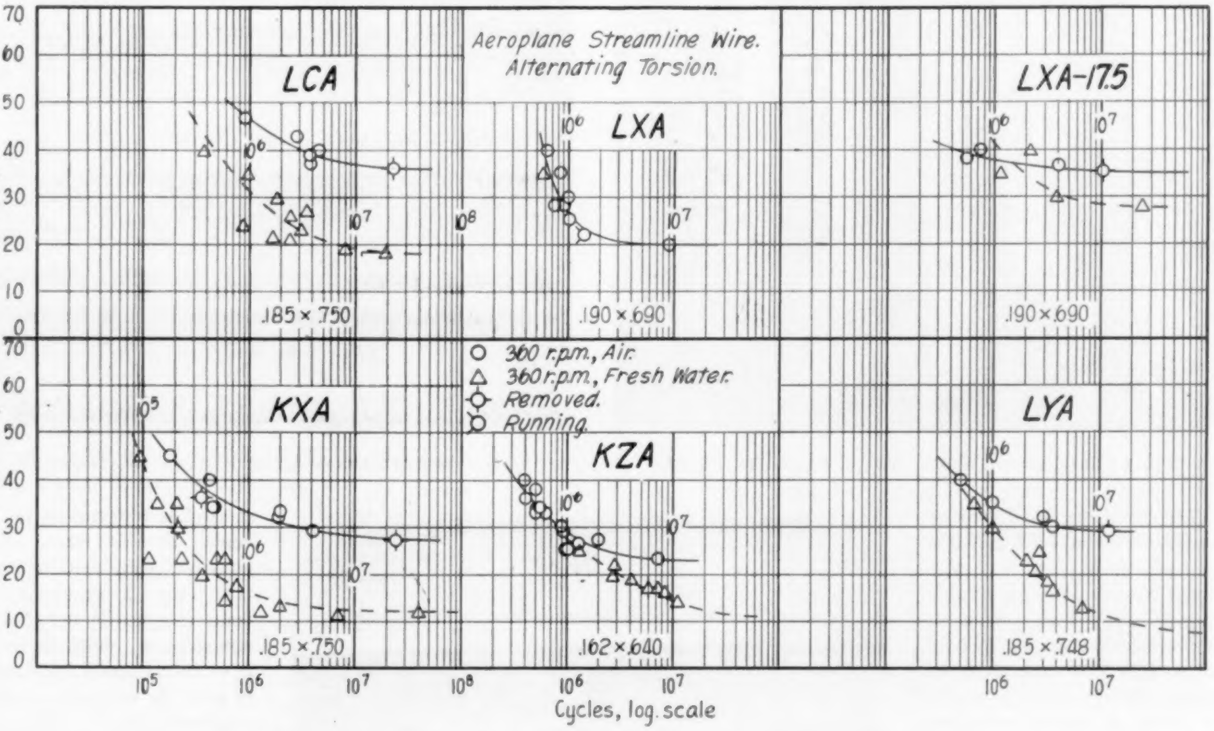

FIG. 3 RESULTS OF TESTS OF STREAMLINE WIRE IN ALTERNATING TORSION

The torsional-endurance limit for material KXA is 27,500 lb. per sq. in. The torsional corrosion-fatigue limit is 12,000 lb. per sq. in. Attention is called to the scatter of the experimental points of failure of the specimens.

Material KZA has a torsional-endurance limit of 23,000 lb. per sq. in. and its corrosion-fatigue limit is 11,000 lb. per sq. in. It will be noted that there is much less scatter of the experimental points than for the LCA and LXA materials.

TABLE 3 RESULTS OF PRINCIPAL PHYSICAL AND FATIGUE TESTS

Material letters	Ultimate strength, lb.	Tensile strength	Yield point	Johnson's limit	Proportional limit	Torsional endurance limit	Torsional corrosion-fatigue limit	Elongation	Reduction of area
		per sq. in.						per cent	
LCA	15,355	145,900	133,900	109,250	61,400	36,500	18,000	8.2	36.2
KXA	20,670	188,200	185,900	.....	....	27,500	12,000	6.5	46.9
KZA	12,250	151,200	131,300	107,700	53,250	23,000	11,000	7.5	39.3

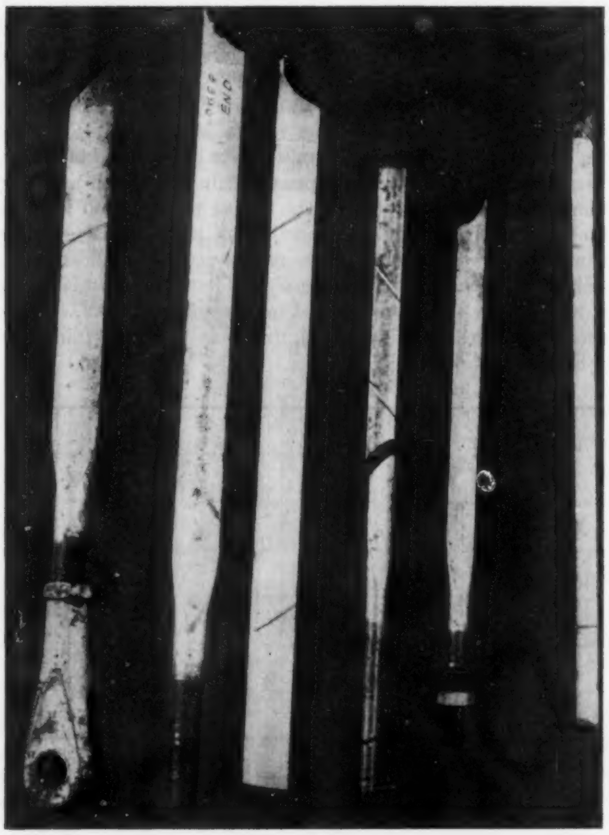

FIG. 4 STREAMLINE WIRES WHICH FAILED IN SERVICE

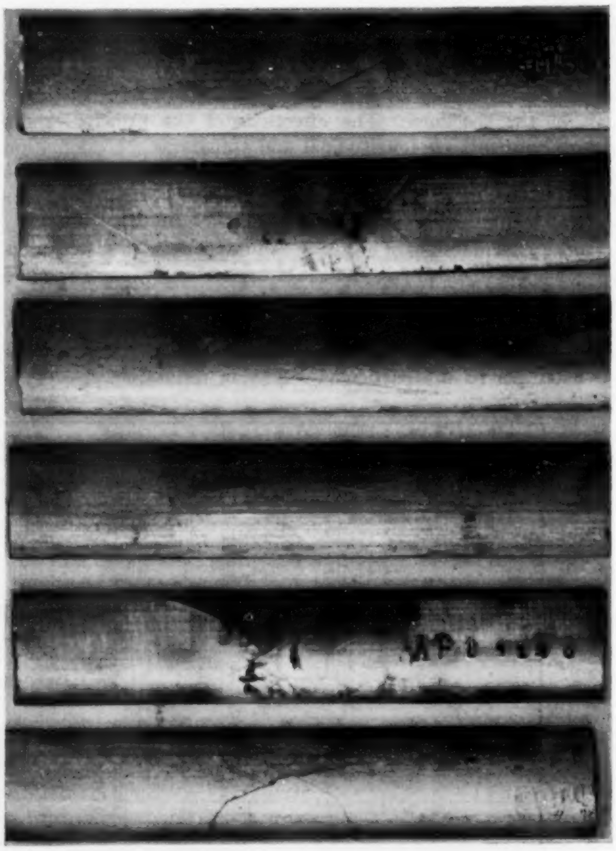

FIG. 5 TEST SPECIMENS AFTER FAILURE—MATERIAL LCA

The torsional-endurance limit for material LYA is 29,000 lb. per sq. in., and the torsional corrosion-fatigue limit is comparatively low, having an estimated value of only 7500 lb. per sq. in. This material shows little or no scatter in its points of failure in either endurance or corrosion fatigue. In Table 2 the LYA material is seen to be a carbon steel of approximately 0.5 carbon. The surface of the elliptical section electroplated with cadmium, but this coating has given little or no protection to the material in corrosion fatigue in alternating torsion.

Table 3 gives a ready means of comparing the physical and fatigue properties of these materials. As seen from this table, a high ultimate or tensile strength does not indicate a high torsional-endurance or corrosion-fatigue limit.

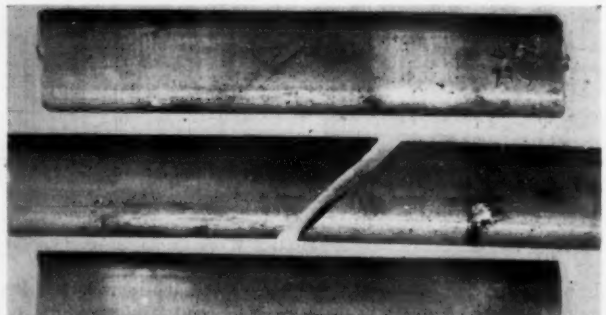

FIG. 6 TEST SPECIMENS AFTER FAILURE—MATERIAL KXA

As no experiments have been made with round rods, the effects of cold working on the streamline wire cannot be discussed at this time. Since, however, cold working raises both the longitudinal and transverse tensile and shearing strengths of sheet materials, it would naturally be expected to raise the alternating-torsion endurance limits. The only property, longitudinal or transverse, that is not increased by cold working is ductility; instead it is especially decreased by cold working. Ductility seems to affect the alternating-torsion endurance and corrosion fatigue limits very materially, as shown by a comparison of the two materials LXA 17.5 and KZA.

From the work so far completed it appears that high tensile strength has been accompanied by a reduction in the shear strength of the materials. It is believed that a correct balance between the amount of cold working and heat treatment of the material will appreciably increase its resistance to alternating torsion. An investigation of the effects of heat treatment is indicated by the marked change in properties between materials LXA and LXA 17.5.

The wide scatter of points of failure in torsional fatigue of materials LCA and KXA as compared with the little or no scatter in materials KZA and LYA, is believed to be caused by lack of uniformity of material, even in the same wire, and to the presence of internal strains in the wire due to cold working.

Several samples of streamline wire which have failed in service are shown in Fig. 4. The material in these samples is a high-strength carbon steel, coated with aluminum paint. It should be noted that the failures in all cases occur at an angle of approximately 45 deg. with the longitudinal axis of the wire.

Several failures of test specimens of materials LCA, KXA, and KZA are shown in Figs. 5, 6, and 7, respectively. In these test specimens the failures have occurred at an angle of 45 deg. to the axes, as is found in the actual failures shown in Fig. 4.

CONCLUSIONS

No definite conclusions can be given as yet, because only a small portion of the investigation has been completed. The few conclusions which have been drawn, as well as the graphs presented, are only tentative and are subject to change as the work progresses. Considerable work remains to be done, particularly in the investigation of the effect of cold working and of heat treatment on the torsional-fatigue properties of streamline wire.

ACKNOWLEDGMENT

The author wishes to acknowledge the encouragement received from Captain H. R. Greenlee, U. S. Navy, Officer-in-Charge, Engineering Experiment Station, and the assistance received from W. C. Stewart, Associate Metallurgist, Engineering Experiment Station. Suitable acknowledgment will be made in a later paper on the subject to the manufacturers who have furnished material for this investigation.

Discussion

D. J. McADAM, JR.[3] The investigation described was under my supervision from January to October, 1930, it being the outgrowth of an extended investigation of stress corrosion of metals that the writer has described in a number of papers. As the inertia of the alternating-torsion machine cannot be estimated accurately, the speed has been limited to 360 r.p.m. With higher speeds the inertia stress would be so large that accurate estimates of the total stress (even with accurate speed regulation) would be impossible. Even at 360 r.p.m., with the smaller streamline wires, the machine cannot be used, because the inertia stress would be too large a part of the entire stress.

As the austenitic steels and monel metal could not have been strengthened by heat treatment, the degree of cold working received by alloys KXA, LXA, and KZA can be obtained by comparing the tensile properties with those of fully annealed material. The degree of cold working received by the wires of stainless iron LC and carbon steel LY could be roughly estimated in the same way, if we knew the tensile properties of the bars from which the wires were made. Assuming that these steels had been strengthened considerably by heat treatment before cold working, it seems probable that the metals used in this investigation had been strengthened by cold working approximately as follows: LCA, 25 per cent; KXA, 50 per cent; KZA, 80 per cent; LXA, more than 100 per cent; LYA, 40 per cent.

The torsional-endurance limit is normally not much less than one-fourth the tensile strength. (By "endurance limit" is here meant the fatigue limit obtained with specimens as free as possible from stress concentration due to surface defects or to corrosion.) The fatigue limit obtained with stainless iron LCA probably is little, if any, below the normal endurance limit. For the other materials "as received," the torsional fatigue limits seem to be abnormally low. The greater the probable amount of cold working the greater is the deficiency in the fatigue limit obtained with these wires.

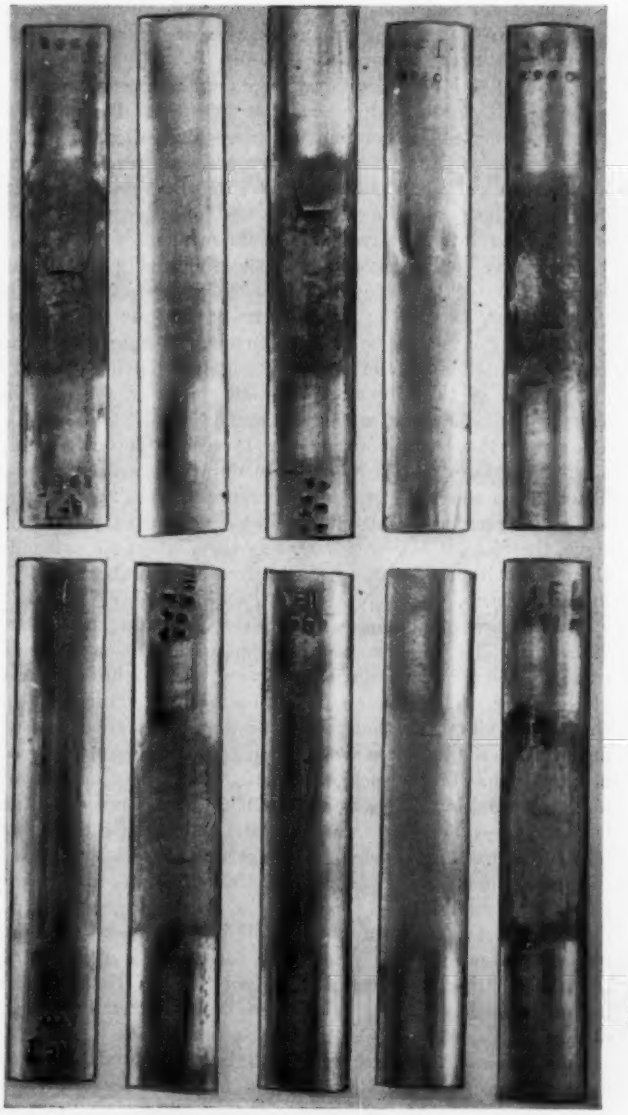

FIG. 7 TEST SPECIMENS AFTER FAILURE—MATERIAL KZA

The "corrosion fatigue limit," unlike the endurance limit, is not an absolute limit. Nevertheless, the estimated corrosion-fatigue limit is of considerable value in comparing the behavior of metals under stress and corrosion. The corrosion fatigue limits obtained with the stainless iron LCA and carbon steel LYA are about normal. (The corrosion fatigue limit for stainless iron normally is about twice the limit for carbon steel.) For the high-chromium steel LXA, Allegheny metal KXA, and Monel metal KZA, the corrosion fatigue limits are abnormally low.

The low torsional-fatigue limits probably are due in part to internal stresses. As shown by the writer and by others, internal stresses may have great effect on the fatigue limit. Even in the form of round rod, cold-worked alloys may have high internal stresses. In the form of streamline wire, the internal stresses are probably even greater.

---

[3] Metallurgist, Bureau of Standards, Dept. of Commerce, Washington, D. C.

Cold-worked Monel metal may be practically freed from internal stresses by prolonged annealing at 800 to 900 deg. fahr. It has been asserted by some manufacturers that Allegheny metal cannot be freed from internal stresses without great loss of the strengthening effects of cold working. It seems probable, however, that long annealing at the lowest effective temperature would reduce internal stress without important loss of strength.

There may be another cause for the abnormally low fatigue limits of some of these alloys. The deficit may be due in part to "notch effect" caused by irregularities or flaws on the surface. The lowering of the fatigue limit due to notch effect increases with increase in hardness of the metal. Even blunt notches may take away some of the advantage of high tensile strength. The sharper the notch, the less is the advantage of high strength. The greater the strength of the metal, the greater is the damaging effect of surface irregularities due to normal manufacture, and hence the greater is the probable difference between the ideal and actual fatigue limits. As streamline wires are subject to fatigue, therefore, it is doubtful whether there is any advantage in the use of wire with tensile strength greater than about 150,000 lb. per sq. in.

Most failures of streamline wires in service are due to torsional vibration. The greatest amplitude of oscillation is at mid-length. The twist is clockwise at one end and counter-clockwise at the other. The nodes, at which failures occur, are near the ends. The vibrations that cause failure probably are due to repeated torsional impulses synchronizing with the natural period of oscillation. Under such conditions, failure may occur even if the material is of satisfactory quality. The number of cases of failed streamline wire received at the Naval Experiment Station and at the Bureau of Standards suggests the idea that most of these failures may be due to excessive vibrations rather than to defective material.

There are two possible methods of diminishing the synchronous torsional vibration: (*a*) increasing the stiffness of the wire, (*b*) providing means of damping the vibrations. If the second method cannot be used, it would seem desirable that the design of the wire be changed so as to increase the stiffness.

To increase the stiffness, and thus raise the natural frequency and decrease the amplitude of vibration, it is not necessary or desirable that the cross-section should be increased at the mid-length. As the torsional stress near the mid-length is very small, the cross-section need not be increased here. In fact, the vibrational stress will be less if the inertia of the middle portion is kept small. The increase in cross-section is needed at and near the ends.

The ideal streamline wire to resist torsional vibration therefore would have largest cross-section at the ends and would decrease in cross-section from the ends toward the mid-length. Manufacture of such wires would be more difficult than manufacture of the wires now in use. Wires now in use, however, are designed chiefly to resist tensile stress, whereas the frequent torsional-fatigue failures seem to indicate that wires should be designed especially to resist torsional fatigue as well as tensile stress.

ROBERT WORTHINGTON.[4] The writer would like to ask how it happens that deflection of streamline wire is of a twist nature rather than an entirely simple bend and whether failures are not related to very excessive and avoidable whipping.

The materials were tested in the as-received condition and, as the author suggests, probably carried irregular cold-working strains. It has been our experience that these strains in Monel metal may be relieved without a lowering of strength by a low-temperature annealing treatment at 550 to 600 deg. fahr. for 15 to 30 min. This treatment, rather than softening the metal, results in a marked increase in strength and a slight increase in ductility. In one case, for instance, the proportional limit of rather severely cold-worked rod was increased by this stress-relief annealing from 36,000 lb. per sq. in. to 105,000 lb. per sq. in. and the tensile strength from 131,000 lb. per sq. in. to 140,000 lb. per sq. in. At the same time the elongation improved from 9 per cent to a value of 11 per cent. It seems likely that release of these strains would improve the transverse strength in streamline wire even more than the tensile strength.

It is surprising to see that the greater degree of cold work gave a lower degree of torsional strength in the case of stainless iron. For Monel metal we have found that torsional strength runs parallel to tensional in respect to improvement with cold work.

Has the degree of stressless corrosion damage for cadmium plate been determined? This would seem to be very important, as so much of the damage to steels, as pointed out by Dr. D. J. McAdam on reports of his work at Annapolis, is due to stressless corrosion. It is interesting that it required only 14 days to reduce the torsional fatigue strength of this material from 29,000 to 7500 lb. per sq. in., and it would be still more significant if nearly as much damage should result from stressless corrosion.

Are salt-water tests being made? Dr. McAdam has shown that salt-water exposure leads to considerably greater damage to fatigue strength of steels and chromium steels than fresh, whereas in the case of Monel metal salt water is at least no more damaging than fresh.

The author called attention to the scatter of points on the corrosion fatigue graphs of the chromium alloys, and the relative lack of scatter on the graph for the Monel metal. Since the scatter is much more marked in the corrosion fatigue determinations than the air fatigue, the cause of the scatter would seem to lie in variations in corrosion behavior rather than in the lack of uniformity in the metal or the presence of internal strains, as suggested by Lieutenant Haven.

AUTHOR'S CLOSURE

In answer to the questions by Dr. D. J. McAdam: It was pointed out in the paper that the alternating-torsion machines described were not adapted for testing the smaller sizes of streamline rods due to the large inertia stresses occasioned in the specimens by the oscillating machine parts. This condition was understood, and at the time the paper was presented plans were being considered for eliminating this difficulty as far as possible. Two additional machines have been constructed in order to test the smaller size tierods. These machines are designed so that the oscillating parts on the spring side of the machines are much lighter than the corresponding parts of the machines described. In this way the stresses due to inertia are reduced.

The tensile values for the round wires from which the elliptical rods LXA and LYA were made are not available. The tensile values for the other three materials in the round form are as follows: LCA, 107,000 lb. per sq. in.; KXA, 123,000 lb. per sq. in.; KZA, 135,000 lb. per sq. in.

Tensile tests of the round rods in the fully annealed condition have not been made.

Attention was called by Dr. McAdam to the possibility of freeing cold-worked Monel metal and Allegheny metal from internal stresses by a prolonged annealing. It has been the practice at this station to anneal cold-worked Monel metal in this way before making fatigue tests. For practical reasons, it was considered advisable to make the initial tests of the streamline wires in the condition used in actual service before introducing heat-treatment of the samples. Likewise, no attempts were made to remove the surface irregularities for the same reason.

---

[4] Development and Research Department, International Nickel Company, New York, N. Y.

Undoubtedly, much can be done by the way of rod design to reduce synchronous torsional vibration. Nevertheless, the torsional-fatigue properties are an important index in the selection of the most suitable material for streamline wires. This investigation has shown that the tensile strength is not a dependable index as to the resistance of streamline wires to torsional fatigue.

In answer to the questions by Robert Worthington: The examination of service fractures of streamline tierods has indicated that the failures were occasioned by stresses set up by torsional vibration. The fractures examined were not those of simple bending. Frequently failure occurs in the threaded ends of the tierods, where stress concentration is present and the torsional stress is high.

It was previously mentioned that, ordinarily, it is the practice to relieve the internal stresses of cold-worked Monel metal by a low-temperature anneal. However, for practical reasons, it was considered advisable to make the initial tests of the rods in the condition as fabricated for actual service.

The degree of stressless damage for cadmium plate has not been determined. The determination of damage due to stressless corrosion involves two-stage tests—a corrosion stage and a fatigue stage.

So far no alternating-torsion tests of streamline wire using salt water have been made. The present program includes tests made in Severn River water. This water has a salt content about one-sixth that of sea water. Monel metal shows good resistance to salt-water corrosion fatigue.

Considerable scatter of experimental points is usually encountered on making fatigue and corrosion-fatigue tests of the stainless irons and steels. However, the tendency of the material to show scatter is intensified by the presence of internal stress. Doubtless the surface condition of the rods, referred to as lack of uniformity, was responsible for some of the scatter.

AER-54-15

Some Design Factors Which Influence Aviation Insurance Rates

By JEROME LEDERER,[1] NEW YORK, N. Y.

The five principal factors which insurance underwriters consider when they are asked to estimate aviation hazards are: (1) the aircraft itself, (2) operational management, (3) the pilot, (4) the geographical limits, and (5) the uses for which the aircraft will be insured. The relative importance of these factors depends on the coverage being considered, and the connection of various aircraft design factors with these coverages is set forth.

ENGINEERS, generally speaking, regard aviation insurance as an obscure business, managed by a band of uninformed pessimists, who, realizing that commercial aviation would be impossible without insurance, dictate rates out of all reason with the risks involved. Notwithstanding this opinion, aviation underwriters of the leading companies have had a long experience in aviation. Some of them are well-known war "aces;" others were flying and operating aircraft several years before the war. Such experience is an essential qualification for intelligent underwriting. Underwriters know a good airplane when they see one, and the rates they promulgate are about as sound as the aircraft they insure.

The various coverages which insurance companies offer are: fire on the ground only; fire under all circumstances; accidental damage including fire during flight and/or following a crash; tornado; theft; cargo; public liability; passenger liability; property damage; personal accident; and workmen's compensation. The present cost of full protection will generally aggregate from 15 to 20 per cent of the value of the aircraft for the first five coverages. The cost of public liability, passenger liability, and property damage will vary with the limits desired by the insured. In public liability, for example, the coverage with limits of $5000 for any one individual and $10,000 for any one accident will cost from $86 to $105, and the coverage with limits of $10,000 for any one individual and $20,000 for any one accident will cost from $103 to $120. Passenger liability with a $10,000 limit per passenger costs from $60 to $150 per seat. Property damage, $5000 limit, costs from $86 to $110.

The five main factors which underwriters consider when they are asked to estimate aviation hazards are: the aircraft, operational management, the pilot, the geographical limits, and the uses for which the aircraft will be insured. Their relative importance depends on the coverages being considered. The connection of various aircraft design factors with these coverages follows.

Aircraft Performance—Loadings

Landing Speed. Wing loading and power loading give important indications to the underwriter. Knowing the wing loading, the underwriter can estimate the stalling and consequently the landing speed of an airplane. The landing speed is considered important, because the amount of damage sustained by aircraft on the ground will generally vary with this speed. Devices which reduce the landing speed and the landing run, such as slots, rotors, flaps, and brakes, are favorably regarded by underwriters if the experience with them is satisfactory.

Climb. Wing loading in combination with power loading indidicates take-off and climbing ability—important in getting out of small fields, clearing obstacles at the ends of fields, and making emergency ascents. Wing and power loadings in the vicinity of ten are considered normal. However, as power-plant reliability increases, underwriters may look upon higher loadings without undue apprehension where good landing fields are available.

Angle of Descent. Aircraft which, because of high aerodynamic efficiency, land at a relatively flat angle or which have a tendency to float on landing, receive the disfavor of underwriters. In this connection, the attempt of a British manufacturer to increase the angle of descent by mechanically increasing the drag of certain undercarriage struts is worth remembering.

Stability. Stability, stalling characteristics, controllability, and ground maneuverability are usually considered satisfactory if the aircraft carries an approved-type certificate, unless experience with the aircraft proves otherwise. On aircraft used for scheduled operations the stability should be considerably greater than on the average aircraft. For satisfactory longitudinal stability on such airplanes the center of gravity should be located at about 28 per cent of the chord on a wing where the most forward position of the center of pressure is 30 per cent.

Ground Loop. The tendency of some aircraft to ground loop, generally because of insufficient rudder control in the three-point position, poor tail-wheel castering, or defects in the design of the undercarriage, is strongly disfavored, especially on large fast-landing aircraft where a ground loop generally results in heavy damage.

Multi-Engined Aircraft. Multi-engined aircraft are regarded with suspicion unless they prove their ability to maintain level flight with authorized flying load and one or more engines out of commission. The authorized load is assumed to be the load allowed under the approved-type certificate unless the operator reduces it. A further consideration is the altitude of the terrain over which the multi-engined aircraft will fly. A ceiling of, say, 5000 ft. on two out of three engines would be dangerous matter for an aircraft operating out of Cheyenne where the terrain would be higher than the ceiling with two engines.

Marine Aircraft. Landing speed, take-off, climb, and gliding

---

[1] Chief Engineer, Aero Engineering and Advisory Service, Inc. Assoc-Mem. A.S.M.E. The author was born in New York City. He attended New York University and received the M.E. degree from the College of Engineering, receiving the David Orr prize in mechanical engineering upon graduation. While in college, Mr. Lederer specialized in aeronautical engineering and was assistant instructor for one year after graduation, devoting considerable time to wind-tunnel research. Following this, he investigated in Europe the application of certain aluminum-silicon alloys, and then served as aeronautical engineer with the U. S. Air Mail Service. This experience was supplemented by acting as consultant in designing and stress analyzing airplanes in connection with obtaining approved type certificates from the Department of Commerce.

Presented at a meeting of the Metropolitan Section of the A.S.M.E., New York, Feb. 25, 1931.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of the authors, and not those of the Society.

angle are not so important on marine aircraft because of the larger landing areas, fewer obstructions, and the assumption that the aircraft will always fly over water. However, stability, stalling characteristics, and controllability receive the usual consideration.

Small Aircraft. Small aircraft with a high degree of maneuverability induce acrobatics, and for this reason are often regarded with diffidence by underwriters.

THE POWER PLANT—RELIABILITY

The first consideration in the power plant is reliability. This not only includes the reliability of the engine, but also the fuel system, the location and construction of tanks, the location of carburetor intake, and the general reputation of the engine. An approved-type certificate or acceptance by the military services is not regarded as proof of power-plant reliability. However, such acceptance is generally prerequisite because it indicates sound design and manufacture. Reliability can be proved only by a good experience covering continuous service under actual operating conditions.

New Engines. Among new engines, those made by established and reliable manufacturers will receive more favorable consideration than others. Changes in the design of a good engine, such as using different materials in the crankcase, put it in the category of a new engine.

ENGINE TYPES

In-Line Engines. So far as accidental damage is concerned, the in-line or V-type engine will generally suffer less severely in a crash than other types. In case of an accident such as nosing over, the crankcase of an in-line engine is occasionally cracked, front cylinders ruined and the crankshaft sprung, yet the rear cylinders, pistons, rods, valves, and valve-actuating mechanism often remain unharmed. Also accessory material, drives, carburetors, magnetos, and starters, being in protected spots, remain undamaged.

Radial Engines. Air-cooled radial engines generally suffer more damage than in-line engines because the crankshaft is more likely to be sprung, the crankcase cracked, and the lower part of the engine damaged beyond repair.

Inverted Engines. Worse than the radial engine, from the point of view of damage sustained in accidents, is the in-line inverted engine. All the cylinders, valve-actuating mechanisms, and accessories are more exposed to injury by reason of their location. However, this is indirectly compensated to some extent by the apparently greater ease of inspection and maintenance.

Air-Cooled Vs. Liquid-Cooled Engines. Considering air-cooled engines in general as against liquid-cooled engines, underwriters would prefer to limit the operation of liquid-cooled engines to organizations which are prepared and trained to take care of the additional maintenance and inspection, because of the fragile construction of radiators and the additional plumbing at present.

Materials. Materials are considered for cost of replacement and susceptibility to damage and corrosion. Some crankcases can be submerged in sea water for a considerable time and put back into service without trouble, while others will deteriorate rapidly and require replacement. These factors are considered when seaplanes or flying boats come up for insurance.

The tendency of castings or other parts of the engine to warp and crack when suddenly cooled, sometimes occasioned by the immersion of an aircraft, is also considered by underwriters. Most engines can withstand this test with only slight damage, requiring a good overhauling and perhaps a few new parts. The loss in the temper of parts due to the heat-treating effect seems to be remote as the operating temperatures are below the point where quick immersion would affect the temper of either steel or aluminum alloy.

Location. The location of an engine in a well-protected position, such as is commonly found on amphibians, is regarded with favor. Twin-engined aircraft, with an engine on each side, are preferred to the three-engined type with one engine in the nose. Pusher installations where the engine is protected by easily repaired parts of the fuselage or wings would also be favorably looked upon, although the passenger liability rates would probably be affected adversely. The cooling and performance of pusher or tandem installations are regarded suspiciously until experience proves the reliability of the installation.

Fire Hazards. The inverted engine probably has the smallest fire hazard because the chances of fuel or oil dripping on the ignition system or hot parts of the engine are reduced, the hot exhaust stacks are farther away from gasoline tanks, and the general tendency of the fluids is to drop away from the aircraft rather than on to the fire wall and the fuselage. The upright engine with the carburetor near the ignition system and the fuel lines in the V offer a greater fire hazard in the air. The radial engine has an advantage over the in-line engine in quicker cooling of cylinder heads and exhaust manifolds after power-plant failure, important for fire following crash coverage.

Fuel Systems. Gravity fuel systems are preferred from the point of view of accidental damage because of their simplicity and lower maintenance requirements. However, the more complicated systems using hand and engine pumps appear to be as reliable as the gravity system if properly maintained. Here, as with water-cooled engines, underwriters prefer to have the gravity system on aircraft operated by private owners, possibilities of poorer maintenance being present. Wabble pumps, engine pumps, relief valves, and the additional connections on pump systems require constant attention, especially with connections on the suction part of the line. The inverted engine because of the low position of the carburetor and cylinders appears to have the advantage here as the gravity system can almost always be used with this type of engine.

Air Locks. A large number of accidents are due to power-plant failure immediately after take-off. It is believed that such failures are frequently due to an air lock caused by locating the shut-off valves close to the tanks and allowing a large length of tubing between the valve and the carburetor. It is customary to close these valves after the aircraft is landed, permitting the engine to run on the gasoline which remains in the lines and carburetor until all the gasoline in the lines is drained, thus leaving an air or vapor space between the valve and the carburetor. When the valve is opened, preparatory to taking off, the gasoline must force this air or vapor out of the lines before a satisfactory flow is obtained. Very often the fuel will trickle down to the carburetor in a sufficient amount to operate the engine on the ground while it is being warmed up at slow running speed, and enough will collect in the carburetor bowl to take the aircraft off the ground. However, soon after take-off, when the demand for a full flow of gasoline is continuous, the carburetor will suck in the air or vapor which remained in the lines, the engine will miss, and a forced landing will often result, sometimes with disastrous consequences.

This danger can be avoided by placing the valves close to the carburetor so that the distance in which air or vapor can accumulate is very small.

Screen strainers, sudden changes in the diameter of the fuel lines, and certain types of flexible tubes will tend to collect air and create air locks.

In addition to air locks, vapor locks will often cause a forced landing. When an engine is running through the air, the carburetor and plumbing are cooler than the engine. When the engine is stopped, and no cooling takes place, the heat flows from the engine to the carburetor and plumbing. When the gasoline is allowed to flow again, the pipes and carburetor may be hot enough to vaporize the gasoline, causing vapor locks and consequent trouble. Fuel lines which are located close to the hot parts of the engine may also give trouble. A good example of this is the location of the fuel lines in the V of a V-type engine.

Aircraft equipped with fuel-pump systems where there is considerable lift of gasoline from the tank to the pump may work satisfactorily at sea level, but at higher altitudes will also experience vapor-locking troubles due to lower atmospheric pressure if the temperature is not sufficiently reduced at higher altitudes.

Generally speaking, fuel systems which have been accepted by the military services are preferred to those which the average commercial manufacturer installs. There should be more cooperation between the airplane and the engine manufacturers in fuel-system design.

Lubrication. It is believed that putting the oil tank behind the firewall, as some engineers have suggested, might place the tank inconveniently far from the engines. An oil tank so located may reduce fire hazards and the longer return line might retard oil foaming. However, in the conventional airplane the fumes from the oil would reach the pilot and passenger more readily; it would increase the difficulties of cooling the oil in hot weather and keeping it warm in cold weather, especially in the lines. But most important of all is the longer suction line which would be required, with greater danger of developing leaks from the added vibration and therefore chances of losing oil pressure. Of course, if a satisfactory installation can be made behind the firewall, so much the better.

The oil tank should be high enough to keep the pump primed and located so as to be easily cooled when necessary. Installations are found where oil tanks receive very little of the cooling air due to poor location of louvers in the cowling.

Tanks. Fuel tanks are not sufficiently rugged on many aircraft. The force with which fuel is ejected from the hose, especially where the nozzle slightly constricts the flow, is sometimes responsible for damage to shallow wing tanks. Many tanks are made of rather thin material, not too well baffled, and repeated refueling with the fuel striking the tank bottom with unnecessary force is often responsible for leaking seams and loosened baffles. The manufacturer would do well to arrange a screen or deflector in such a manner that the full force could not be directed against the bottom of the tank. A coarse-mesh screen should be placed in each filler neck also. The tank supports are often found to give way, permitting the tank to sag, with the possibility of breaking fittings and affecting performance.

Where a multiplicity of tanks is used, it would be well to have some device which warns the pilot when the tank is almost empty. The ordinary fuel gage is not sufficiently accurate. Most pilots depend upon watches and the r.p.m. of the engine. If they permit a tank to run dry, an air lock is likely to form before they can switch over to another tank.

The tanks should be installed so that in case of fire in the air the gasoline can be dumped rather than to have droppable tanks. This is because pilots seldom care to embarrass themselves by losing parts of the aircraft. However, they will be less hesitant in disposing of the fuel. The danger of public injury and property damage must also be considered with droppable tanks. The dump valves should be located so that the contents will not pour over the engine or other parts of the aircraft.

The location of tanks in the wing of high-wing aircraft increases the fire hazard following a crash because the tanks generally fall on top of the engines.

The capacity of fuel tanks should be in considerable excess of minimum requirements for any particular route.

Batteries and Ignition. The propeller on an airplane is always a source of danger, and this is especially true when it is possible to accidentally start the engine, as, for example, when a plane equipped with a booster magneto is left unattended without the gas being shut off. Two recent accidents resulting in painful though not fatal injuries were sustained by persons who knew better than to touch the engine switch but who could not resist finding out what the booster lever was for. As a safety measure, the booster switch should be grounded through the engine switch, so that it cannot be used unless the engine switch is on. This is considered from the point of view of workmen's compensation and public liability.

Batteries should be installed in such a way as to prevent the danger of fire due to dripping fuel or oil. Often fittings which hold batteries in place are not strong enough for the job, resulting in loose terminals and dangerous sparking.

Engine Controls. The control systems employing steel tubes and bellcranks or Arens controls are preferred to the Bowden cable type. Controls and valves should be located where passengers cannot disturb them. Valves located near the floor where they can be unwittingly kicked are especially dangerous.

Strainers. Strainers should be located so that they will be very accessible and so that the draining fluid will not run over the aircraft. It would be well to have them installed so that they could be drained in flight.

Starters. From the point of view of workmen's compensation, underwriters prefer aircraft equipped with starters.

Exhaust System. The most frequent cause of fire following a crash is the contact of fuel or oil with hot exhaust manifolds. Any means by which exhaust manifolds are cooled are very favorably regarded by underwriters.

The seams of exhaust pipes should be turned away from the fuselage so that, if they open, the flame will not strike the fabric. The ends of the exhaust manifolds or stacks should not be too close to holes in the bottom of the fuselage through which any fuel can drip, and they should be well away from any part of the fabric. Stainless-steel exhaust manifolds are preferred if ethyl gasoline is used.

Fire Extinguishers. The ordinary hand fire extinguisher is not considered very useful for fires in the air unless they occur in the cockpit. It is not unusual to find the hand type of extinguisher locked in the luggage compartment. Pressure fire extinguishers should be installed so that the fire-extinguishing medium covers the more dangerous parts of the engine, especially the carburetor. In the event of a crash, a pilot is supposed to shut off the gasoline valve, cut his switch, and turn on the pressure fire extinguisher. The last two operations could be reduced to one by arranging the switch so that by turning it further, the pressure extinguisher would automatically be put into operation. Types of extinguishers which operate automatically in a crash are approved. The National Fire Protection Association, 16 Batterymarch Street, Boston, Mass., has a pamphlet entitled "Fire and Life Safety in Aviation" which thoroughly covers the fire-extinguishing requirements for aircraft.

Fire Wall. The bottom of the fire wall should have a small sloping channel or other means to guide the oil which splashes against the fire wall or drips from the oil tank away from the bottom of the fuselage, possibly to a drain on the landing gear.

THE AIRCRAFT—GENERAL TYPES

Were it not for the mooring risks and difficulties in salvaging, marine aircraft would be considered more favorably by the underwriters than the average land aircraft. Unfavorable metacentric heights, danger of waves piling over the wings, puncturing of hulls and pontoons, chances of drifting against obstructions or of being hit by other watercraft while moored, must be considered.

Fire following crash is not so seriously considered on marine aircraft as on other types, but the chances of fire on the water and during flight are as great as on land planes. Consideration should be given to a means of preventing fuel and oil from overflowing on to the water during refueling and drainage operations.

High-wing monoplane types are preferred because of better seaworthiness and less chance of corrosion in the wings.

There is room for considerable development in making marine aircraft more seaworthy. In present designs there are no provisions for heaving to, for keeping way on, and for steerage way. A ship out of control in the trough of the sea is quite likely to have a beam sea climb aboard. Eight- or ten-foot swells would be disastrous to the toughest of sailing craft if they were as thoroughly out of control as any seaplane would be once down on the water. One of the first things that would happen to most flying boats in any kind of sea would be the abolition of the glasswork of the pilot's cockpit and the flooding of that compartment. This would have her down by the head. From then on it would only be a question of time. But if there were any sort of control in the water, there would be a much better chance. The following precautions are suggested:

1 Facilities for relentless engine inspection
2 Marine equipment including:
  a Water rudder or steerage device
  b Means for keeping way on—small sail or outboard motor
  c A sea anchor for heaving to
3 Emergency radio and antenna
4 Generous signal equipment
5 Life preservers for moral effect as well as safety
6 Sextant, charts, log tables
7 Chronometer.

Amphibians are favorably regarded except for the proximity of the hulls to the ground and danger of landing on the ground with the wheels up or on the water with wheels down.

Fuselage Construction. The conventional steel-tubular construction or that using duralumin tubes or angles is easier to repair in the event of damage than are most monocoque fuselages. Riveted duralumin with a metal skin is difficult to repair after distortion, and at the end of about 1500 hours of service the rivets may be rather loose and affect the flying qualities. Wooden monocoque fuselages are likely to suffer from the following defect: Wherever there are concentrated loads coupled with strong vibration, as in the vicinity of the engine-mount fittings, the wood is likely to crack and split. This condition is very difficult to repair and is aggravated by the entrance of oil and water, which softens the wood and may eventually lead to structural failure. Other points where failures in the monocoque construction are likely to occur are at the landing-gear attaching points and tail skid. At these points there is little vibration, but the loads are highly concentrated and unless properly distributed may cause failure. Another trouble is the accumulation of dust behind the bulkheads, which holds moisture against the wood shell and rots it. If these failures do not occur after four or five hundred hours of service, it may be assumed that the aircraft is satisfactory for coverage against accidental damage. However, in a crash wooden monocoque fuselages break up more easily than metal; the resulting hazards to the passengers due to smaller absorption of energy by the fuselage structure and the increasing danger from splinters are evident.

Metal monocoque fuselages seem to suffer from corrosion when used in the vicinity of salt water. If, through an accident, such fuselages are totally submerged in salt water, it is almost impossible to prevent corrosion in the seams. Naturally the loss is quite large under these circumstances, and such construction is reflected in the rates unless special means are taken to prevent corrosion. The repair of some metal monocoque fuselages is very expensive, necessitating large replacements for only a small amount of damage. In other types of construction, this is not so true. It is very difficult to realign metal monocoque fuselages once out of alignment.

Baggage compartments, cargo space, lavatories, etc., should be placed in front of the fuselage rather than in the rear to protect passengers in case of crash. This eliminates the danger of a large load coming forward on to them.

For flying boats and amphibians, metal is preferred to wooden construction if for no other reason than that there is more salvage after an accident or submergence.

Fire. The front of the fuselage should be covered by metal for a short distance in back of the engine mount to reduce the fire hazard. The fabric should be made to clear the primary structure by a fairing so that in the event of a flash fire, which burns off the fabric, the main structure can be saved. An all-metal fuselage with a Diesel engine would probably receive the best consideration in rates for fire in the air and fire following crash.

Wings. The conventional braced wooden wing is preferred by underwriters because it is easy to repair and cheap to replace. Full-cantilever wings are not so well considered as braced wings, because in the event of damage to, say, a wing tip, entire wing replacement is necessary, whereas on a braced wing, repairs could be easily made. At least such was the ruling in a typical case by the Department of Commerce.

The high wing is preferred to the low wing from the point of view of damage on the ground. However, the visibility offered by the low-wing type is considered of sufficient advantage to counteract this. Furthermore, in the event of a crash, the low wing offers more protection to the passengers. For operations over forests and barren lands, the high wing is preferred to the low wing because of smaller danger of damage on bad fields and also because the wing is out of the way while working around the airplane.

The center section of the wings or the fuselage should have suitable fittings for hoisting the aircraft. This would hasten salvage operations after an accident and prevent considerable damage.

Certain types of construction are preferable for use in countries where salvage operations are difficult or where the plane is likely to be far from repair bases. For example, there is the case of an airplane forced down in a remote part of Canada by a broken engine mount. Temporary repairs were made by welding the handle of a frying pan to the engine-mount strut, and the aircraft was then flown to the nearest repair base.

Undercarriage. A husky undercarriage with oversized wheels, good brakes, good tread, and universal joints at the fuselage attaching points is preferred. The universal joints lower the damage sustained by the fuselage when the undercarriage is wiped off. Where castings are used, manganese bronze or similar tough material is preferred. Plenty of bearing area in the hinges is recommended. Retractable undercarriages should have indicators showing the position of the wheels. The idea of leaving part of the wheels exposed to prevent damage in case of landing with the undercarriage retracted is favorably regarded.

Control Surfaces. Braced tail surfaces made in independent sections, so that if one side is injured the other side remains unharmed, are favored. Fins which are built integral with the fuselage will cause more damage to the fuselage in an accident than detachable ones. Oversized hinges are desirable on all control surfaces, especially the ailerons.

Control System. The control system should have plenty of bearing areas, or have bearings that may be easily replaced. It takes almost no time to get considerable undesirable looseness in the control system. The designer should not place too great dependence on lubrication for ease of operation, because in cold weather the oil or grease will harden and make operation more difficult. It is important to be able to make quick and easy inspections of all linkages in the control system, especially where the stabilizer control mechanism attaches to the stabilizer spar. Bearings here should be extra large. Bearings, in general, should be designed for impact and wear rather than for the theoretical bearing loads.

Cabin. The cabin should be lined with materials which are fireproof. The chairs should be well anchored, fitted with safety belts, and padded on the backs. Doors should be large, and if possible so built that they cannot jam in case of an accident. Windows should be large enough to permit the exit of a normal person. Cigarette receivers should be very evident.

Cockpit. The cockpit should be roomy and comfortable. The instrument board should not be too close to the pilot, making it necessary for him to change the focus of his eyes considerably when glancing at it. With a distant instrument board the pilot will be able to take in more at one glance, and there is less danger that he will hit his head against it in a crash.

The windows should be made to open easily in all kinds of weather. They should be designed so as to eliminate reflection of lights in night flying.

Soft padding should be placed wherever the head of the pilot can come in contact with the cockpit. There should be nothing hard located above the pilot's head for a distance of about six inches to eliminate the danger of striking his head in bumpy weather.

The influence of the air-mail pilot is evident in some recent designs of single-engined passenger planes. The pilot is located in an open cockpit aft of the cabin instead of directly behind the engine. One occasionally hears an opinion that the pilot should be located in the front so that he will exercise more care in guiding his ship by virtue of his danger in event of a crash. However, it is believed that the pilot should be located in the best position to guide his craft rather than in the most dangerous position. If his location aft of the cabin gives him greater ease of mind and therefore better control of his ship, so much the better. This is analogous to marine practice. The pilot of a ship is situated in the most favorable position for guiding his craft rather than in the most dangerous position in the event of a crash.

Instruments. Underwriters like to see good instruments, easy to maintain and properly installed. Air-mail planes as a rule are well arranged in this respect, but the average commercial job is poor. One prominent transport company operating over large stretches of water supplies two compasses so that the pilot has a check on the correctness of his bearings. The installation of recording tachometers would receive very favorable consideration by the underwriters, especially in scheduled operations. Radio-beacon equipment without weather-broadcasting facilities tends to make the pilot fly in bad weather without knowledge of conditions at his terminal airport. Hence such an installation is not received favorably. However, with receiving and broadcasting equipment, the radio-beacon installation is given considerable credit. Horizon indicators are regarded with approval, but mechaviators are looked upon with suspicion.

Wiring. The wiring system should be easy to inspect and the danger of short-circuiting eliminated as far as possible. Certain sound-deadening materials used in aircraft are very inflammable and the wiring should be protected from them. This is important as it affects the hazards of fire on the ground as well as fire in the air.

Lights. On aircraft using more than one rudder, the tail light should not be placed on the fuselage in front of the fin because the outboard rudder will blanket it. Larger and more visible navigation lights are strongly recommended. Celluloid cases of tail lights are likely to burst into flames on the ground because of heat generated by the lamp. This has been proved by actual tests. Glass cases should be used wherever possible.

Flares. Flares should fall free of the aircraft; the danger of hooking on to the tail skid or tail surfaces should be entirely eliminated. Chances of coming loose on the ground or in flight should also be avoided as the fire hazard is large.

Folding Wings. Folding wings are favorably regarded for tornado and windstorm coverage. With the wings folded back, there is less chance of damage on the ground under storm conditions.

Propeller Clearance. On multi-engined aircraft the clearance between the propeller and the fuselage should be great enough to permit the pilot to swing his hand out of the window without being hit by a propeller.

Tail Skids. The tail skid proper is generally of sufficient strength, but the anchorages and bearings are not as a rule. Quite often anchorages are pulled out or bearings soon become loose and shaky.

Special Designs. Aircraft built for special services such as crop dusting, forest surveying, hauling machinery, etc., receive special consideration. Crop dusting, for example, is considered an especially dangerous undertaking because of the chance of fire due to ignition of dust particles inside the fuselage, danger of corrosion due to chemicals, and low flying. Dual-engined aircraft, capable of climbing on one engine, would be preferable for such work.

Miscellaneous Considerations. Steps and grips used by mechanics in inspecting engines or other parts of the aircraft should be built considerably stronger than is commonly the case. The walkways on wings should be skid-proof, especially in the vicinity of the propeller. For operation in cold climates, grips should be provided in the tail of high-wing full-cantilever aircraft so that skis frozen in the ground can be shaken loose. This is not necessary on braced wings because the brace struts can be used. Incidentally, after the skis are loose and the aircraft starts forward, mechanics find it difficult to run from the tail to the door of the fuselage on full-cantilever jobs. However, on braced-wind types they can cling to the brace struts and work their way to the door.

Salvage. Contrary to popular opinion, the insurance companies do not care to salvage the defective parts of an aircraft. Although they might be able to lower the amount of the claim by doing this, such defective salvage may be reemployed to the loss of the insurance company.

Structural Failures and Other Accidents. The accident report of the Department of Commerce for the year 1929 and the first six months of 1930 indicates a serious increase in the number and percentage of accidents due to structural failure during flight. From January to June, 1929, there were eight failures out of 744 accidents; from July to December, 1929, there were seventeen failures out of 924 accidents; from January to June, 1930, there were thirty-eight failures out of 930 accidents. Furthermore the fire losses in 1930 were three times those in 1929, amounting to about $2,000,000.

While the number of accidents has decreased in scheduled flying, the opposite is true of non-scheduled flying. The increase in the total number of accidents in non-scheduled operations, for the first six months of 1930, was 24 per cent over that for the same period in 1929. The increase in fatal accidents was 22 per cent. In addition to this depressing knowledge, the selection of risks is against the insurance companies; operators try to foist doubtful propositions on underwriters. These facts justify a strong degree of skepticism. It is evident that aviation underwriters, instead of being a band of greedy pessimists, are among the world's great optimists. This optimism is largely based on the continued development of better aircraft structures, engines, and accessories, for which the engineer is responsible.

Discussion

F. S. Hubbard.[2] In regard to the angle of descent, the ability of a ship to glide either at a flat or a steep angle to the horizontal is desirable. The ability to glide under control at or near maximum lift will of course depend largely in the case of a conventional airplane on the pilot's skill. In order to insure real safety some form of lateral control should be provided that will not be affected by the burbling of the wing at this angle.

In locating the center of gravity of the airplane in reference to the chord of the wing, the writer does not believe that a fixed rule can be established, as the best position will be dependent on the type of wing cellule used. For example, the best center-of-gravity position for a monoplane will be quite different from that for a highly staggered biplane wing cellule.

The writer is thoroughly in agreement with the author on his discussion of multi-engined aircraft, as he believes this type of aircraft should maintain flight with one or more engines out of commission, and unless they do so should not be approved for passenger-carrying work.

The author has covered very thoroughly the power-plant question, which includes both the reliability of the engine and the satisfactory installation of the different power-plant items.

In the discussion of general types of aircraft the statement is made that in the event of a crash the low-wing monoplane offers more protection to the passengers than the high-wing. This is not true if the ship should nose over and go over on its back, as under this condition the high-wing monoplane would be preferable, as the wing would offer some protection to the cabin or cockpit, which would not be true in the case of the low-wing monoplane.

T. P. Wright.[3] Although the author's opening statement may in general be true, the writer nevertheless feels that aeronautical engineers are becoming more and more cognizant of the necessity of creating a product which the hard-headed businessman, in which class are placed the insurance representatives, can consider safe and can therefore both use and insure on the same basis as maintains for other means of transportation. In other words, the writer admits the great need for improving the safety of airplanes under all conditions of operation before it is reasonable to expect great reductions in insurance rates.

The following notes may be of interest:

Landing Speed. The trend is more or less toward higher landing speeds at the present time, which is unfortunate, as the writer is quite convinced that landing speeds, certainly in the case of airplanes for general pilot-owner use, must be reduced rather than increased.

Multi-Engined Aircraft. The present Department of Commerce regulations take care of the performance item of maintaining reasonable altitude under full load when one power unit of the total used is out of commission. This is believed to be a proper regulation, and assuming that it is being enforced in all cases, and there is no reason to suspect it is not, it then appears that there is a very decided improvement in safety and reliability when using multi-engined aircraft.

Engine Location. The writer is pleased to note the importance which has been placed on engine location, as the removal of the engine from the fuselage is an extremely important step in the design of multi-engined aircraft toward improving safety.

Fuselage Construction. The writer believes that the criticism of the so-called monocoque fuselage on the score of maintenance is made too soon after the appearance of this type of construction in service, as certain information at hand, particularly from the military service, indicates an actual decrease in maintenance cost when using monocoque construction.

Wings. The difficulty of making definite statements on the best wing arrangement for all uses is clearly brought out by the author, as each arrangement has distinct advantages and disadvantages. Probably the best that one can do is to attempt to solve each problem on its own merits, admitting the impossibility of setting down any one arrangement of wings as representing the best for all cases.

Instruments. There might have been added the necessity for installing crash pads, which in the cases of quite minor accidents will frequently save the pilot from very painful injuries.

Structural Failures and Other Accidents. It is disappointing to note the quoted statistics on increase in structural failures when comparing 1929 and 1930. In all probability this was brought about by the inflation of the industry, with the consequent putting out on the market of a great number of types made by manufacturers of short experience, coupled with the great mass of detailed work in the Department of Commerce, because of which design errors may not have been discovered. All in all, however, the structural failures that have occurred are quite small in proportion to the total causes of accidents and will surely be greatly reduced from this point on.

Author's Closure

The author agrees with Mr. Hubbard's remarks concerning the impracticability of a fixed rule for locating the center of gravity. Probably the statement should have been qualified by saying that the suggested location at 28 per cent of the chord was found satisfactory on an unstaggered biplane with a Clark Y airfoil. This airplane was very successful in the United States Air Mail Service and subsequent private air-mail operations.

Low-wing airplanes are more dangerous than high-wing ones in the event of nosing over completely, but this does not always occur in accidents. Furthermore, it is believed the Department of Commerce insists on designing for this condition.

Mr. Wright's comments on high landing speeds are in agreement with the underwriters. There are indications abroad that the slot and flap will soon play a more prominent part in the reduction of landing speeds.

Regarding the performance of multi-engined aircraft, the Department of Commerce makes no distinction as to the altitude of the terrain over which the airplane is to operate. The performance data are generally measured at above sea level, not the operating terrain. Furthermore, gradual increases in weight by reinforcement of cowling, landing gear, etc. often make serious changes in the performance of aircraft which are not often considered.

Regarding monocoque construction, the author's original comments have been reinforced by a gear of additional experience (this is written Jan. 17, 1932). However, he believes that some one will evolve a type of construction far superior to the present.

AER-54-16

Stresses in Rigid Airships: The Effect of Indeterminateness on Their True Value

By W. WATTERS PAGON,[1] BALTIMORE, MD.

Part I of the paper discusses statical determination as applied to a rigid airship and cites the difficulty of computing the actual stresses in a redundant structure of high degree. Part II treats the subject of statical stresses in an unbraced shell of varying longitudinal profile, advancing from a simple prismatic tube, through such a tube with a conical nose, to a symmetrical form of elliptical profile. Part III deals, in the way of a progress report, of the effect of introducing internal bracing, beginning with a single wire in a complete shell, prismatic or curved, and leading up to a more complex system in two prismatic bays.

The conclusions tentatively show that unless there is a considerable degree of rigidity in the bracing systems the shell stresses cannot be determined with even fair accuracy; that the change to loose wired ring frames requires careful attention to stresses induced in the shell by reason of the lowered rigidity of the ring frames as compared with tight wired frames; that there should be local reinforcement of members near concentrations of load; that keels and corridors have a marked influence on the stress distribution in the shell and that their effect on these stresses is as yet undetermined; that ships of curved profile differ so from those of prismatic form, heretofore studied, that the approach to St. Venant's Principle is different and probably less certain; that there is some similarity to the stresses in a semi-rigid; that redundancy of the crossed diagonals in the facets of the shell is of rather localized effect; that even joint rigidity causes a secondary effect that is of importance; that some points are deserving of further study, such as the "keel effect" adjacent to loaded longitudinals; and the rigidity of the longitudinals between main frames; that there is evidence of a stress system underrunning the systems calculated by the common theories; that as the number of sides of the ship increases, from triangular to rectangular (square), hexagonal and octagonal, the stresses agree less and less well with the common theories, progressively, and since the trend is large, the effect should be studied further; that further study is needed to determine if, and how much, additional braced frames reduce the discrepancy just noted; finally, attention is called to the fact that the discrepancies discussed apply only to part of the stress in any one member, and that the discrepancy from the total stress will be a lesser percentage.

FOREWORD

MUCH effort has been devoted to this subject in the United States, England, and Germany; many able minds have considered it from many angles; but no one has found successfully a solution on that basis which is the only one used in the structural design of bridges and buildings. (See R. & M. 1057, p. 22, also R. & M. 800.) The author determined as a matter of pure research to see how far he could carry this tried method, i.e., the method of finding the determinate stresses—which are unique—and adding to them by some reasonable device the effects of redundancies. As a complete answer the results attained thus far fall very short of a complete solution; hence this paper must be treated somewhat as a progress report, submitted at this time in order that some one may make ground tests in order to check the mathematical conclusions. It is believed that the investigation of stresses is justified by the marked increase in size of ships now building, and the radical alteration of the bracing system and the longitudinal curvature. The topic has long been in the author's mind, but was emphasized by the discovery of excessive flexibility in the rings of a design prepared by him as the basis for a competitive bid in the 1928 Competition for U. S. ships *ZR-4* and *ZR-5*.

The structure of lighter-than-air ships still offers a field for extensive study. Only the rigid type will be considered.[2]

---

[1] Consulting Engineer. His degrees are: A.B., 1905, Johns Hopkins University, in mathematics and physical course; S.B. in C.E., 1907, Massachusetts Institute of Technology; M.C.E., 1910, Harvard University. His experience includes the following: 1907–1909, Baltimore Bridge Company (now Baltimore Warehouse, Carnegie Steel Company), as detailer, checker, estimator, field superintendent, on bridges and buildings; 1910–1917, with J. E. Greiner, later member of J. E. Greiner & Co., consulting engineers, in charge of design and construction of bridges, coal piers, etc.; 1913–1914, resident engineer, Washington Street Bridge, Norwalk, Conn.; 1918, in private practice on structural design and as Civilian First Assistant to Construction Quartermaster, Camp Meade, Md., then Captain, Construction Division of the Army, First Assistant to Construction Quartermaster (later Construction Quartermaster), Curtis Bay Ordnance Depot, Anne Arundel County, Md.; 1919 to date, consulting engineer in charge of design and construction of bridges, factories, etc. Consultant to U. S. Navy on U.S.S. *Shenandoah*, and to U. S. Army on semi-rigid *RS-1*. Co-author of "Pressure Airships," Ronald Press Co. Won $5000 prize on new type of rigid airship in 1928 Navy competition. Submitted competitive design for Navy ships *ZR-4* and *ZR-5* in 1929 competition, as chief engineer, Rigid Airship Division, American Brown Boveri Electric Co., and vice-president and chief engineer, Dirigible Engineering Co., Camden.

[2] A semi-rigid comprises a fabric envelope (but cv. metalclad) stiffened below by a metal keel, which has generally been of triangular cross-section, statically determinate as regards its internal forces, but indeterminate as to the percentage of the total bending moment and shear which it carries. The design basis has assumed full bending carried by the keel, but theory and experiment show that this assumption is not realized, that the envelope may carry nearly one-half, and that there may even be interaction between envelope and keel due to variations of pressure ("breathing") that have no origin in the external loads.

See "Pressure Airships," by Blakemore and Pagon, also "Adjustment of the Elastic Properties of a Model Keel, U. S. Army Airship *RS-1*," Wm. Hovgaard, *Journal of Mathematics and Physics*, vol. V, no. 1, Dec., 1925.

Presented at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

A rigid is in principle a full structural frame, which carries all loads and, ultimately, all gas-lift forces, wind pressure, and reactions from the control surfaces. The gas and air forces are seldom applied at the joints alone, but usually act more or less uniformly as local bending loads on the frame members. C. P. Burgess has well covered the computation of these loads in "Airship Design," and for the purpose of this paper they will be assumed as accurately known in direction, position, and amount. Reference should also be made to R. V. Southwell's paper R. & M. 1057. Numerous expedients have been ingeniously devised to minimize the local bending stresses, and the author will assume that these forces are applied at the joints and that by superposition the total stresses can be found in each member.

Even with these assumptions it will be found that the rigid is a highly indeterminate structure, and the author proposes in this paper to address himself to the effect of indeterminateness on the true value of the stresses. A review is in order of the meaning of "indeterminateness," and will be found in Appendix No. 1.

I—A SHIP AS A DETERMINATE STRUCTURE

A determinate structure may be:

1 A plane truss formed only of triangular areas
2 A three-dimensional truss formed only of tetrahedrons
3 A "space framework" consisting of a closed surface that is formed of triangular areas (facets), without, however, any internal members crossing the enclosed space.

A ship of small size might be so framed as to conform to the third type, but ships as built previously have had tight-wire bracing at intervals, serving as bulkheads for the gas cells; and now there is a trend in large ships toward the use of rigid ring bracing instead, completely unwired. See Appendix No. 6.

It is clear that many degrees of indeterminancy are produced by even only one transverse frame. For instance, *each* such frame in an 8-, 16-, or 32-sided ship will cause the following degrees:

a Transverse wiring, in one plane, and statically determinate in itself in that
plane, $n - 3$ = 5 deg. for 8 sides
(or counting symmetry = $^1/_2 n - 1$, or less) = 13 deg. for 16 sides
= 29 deg. for 32 sides
(N.B. As usually built the number is two or more times these figures)
b Rigid ring, of triangular cross-section, $2n$ = 16 deg. for 8 sides
(or counting symmetry = $n + 3$, or less) = 32 deg. for 16 sides
= 64 deg. for 32 sides

A ship with (say) 13 cells would have 12 times these numbers; hence clearly the effect of redundancy in common practice is large.

COMPUTATION OF INDETERMINATE STRUCTURES

Structures that are indeterminate can be solved only by (1) a composite method, or (2) semi-empirical methods.

(1) By eliminating all redundancy, in any desired manner, the statically determinate stresses can be computed, and then by invoking the laws of elastic deformation the redundant members can be considered and their effect superposed. This method is exceedingly laborious in many cases, and impossible in fact when 6 to 10 or more redundancies occur; hence it is customary in airship practice to design on semi-empirical methods.

(2) Semi-empirical methods comprise:

a Method of moments
b Method of shears
c Method of inverse ratio.

These methods are well described by Burgess in the book quoted, and reference should also be made to R. & M. 1057. Many writers have shown that by studying the deflection of a frame, based on the assumptions that the transverse frames do not distort from a plane, and that in that plane the radial and tangential positions of the joints do not change; based on uniformity of size of the longitudinals, of the diagonals, and of the ring members, respectively, the methods *a* and *b* give identical results. Burgess has shown (Trans. A.S.M.E., 1929) that each is accordant with the principle of least work. But any variation of size destroys the agreement, as does the introduction of any variant, such as a keel or corridor; hence one or the other (or both) must in general be incorrect. In N.A.C.A. TN 140, the author has shown (pp. 19–21) that for the frames to remain plane the counter wires must all be acting, in addition to the above requirement of uniformity of size.

COMMENTS ON PREVIOUS WORK

Method *a* has been considered of late to be closer to the truth than the others, but discrepancies between the theoretical stresses and those found in model tests have not been explained. Southwell (R. & M. 737, 790, 791, 819, 1057) has shown that for the assumption of plane bending to hold, the loads applied to any transverse must be placed in one, singular conformation. He and Pippard make frequent reference to the reservations which St. Venant himself held regarding the accuracy of the theory when applied to cross-sections that are proportionately near to the loaded section. Pippard has shown (R. & M. 977) by tests that for an unbraced, prismatic tube the assumption of plane bending is an impossible one, and this point the author discusses theoretically in the present paper; he also shows (R. & M. 948) that unless the bracing is highly rigid as compared with the rest of the structure, there are wide discrepancies in those frame spaces near the loaded frame. See Appendix No. 5.

But substantially all work that has been done theoretically has been based on parallel body alone, and Pippard has shown (R. & M. 948) by experiment that even the introduction of a nose cone at the end of a prismatic model has a marked effect on the stresses. Tests by the Bureau of Aeronautics, U. S. Navy, of a model of the *Shenandoah*, see Appendix No. 3, showed also the effect of applying a nose cone, in that the secondary longitudinals became stressed to approximately the full value that they would have on the plane-bending assumption, although there were no shear wires attached to them whatsoever, and their entire stress came from the nose cone. Redundancies in this model, however, largely obscured the external load stresses. Recorded strains in the *Los Angeles* during flight cannot be correlated with any of the theories with reasonable accuracy, though perhaps they are concordant with the moment theory to some degree. (N.A.C.A. TR 325.)

Prof. Wm. Hovgaard in two papers, *Journal of Mathematics and Physics*, Vol. II, No. 4, December, 1923, "A New Proof of the Theory of Ordinary Bending and Its Extension to Beams of Non-Homogeneous Materials," and Vol. IV, No. 2, April, 1925, "Determination of the Stresses in a Beam by Means of the Principle of Least Work," discusses interestingly the stresses in a beam. A few quotations follow:

"If then we accept this principle" [i.e., Least Work], "it follows that a beam in bending will have an inherent tendency to conform to the law expressed in Equation [1]." [I.e., $M/I = p/y$.] "The question arises: to what extent is this result achieved in practice? Saint-Venant has shown that when the length of a beam is large in comparison with its transverse dimensions, the state of stress and strain created by terminal couples is practically independent of the mode in which these couples are applied, and conforms to the above-stated law, except quite locally near the ends. This applies probably also to non-homogeneous girders with the qualification that here the adjustment of strains and stresses will extend to a greater distance from the ends before an ideal régime is established. Practical experience, as well as large- and small-scale experiments, has shown that the law holds with great accuracy even close to the points of application of the terminal forces, and this is true not only of homogeneous but also of non-homogeneous girders such as beams of reinforced concrete. It is not here asserted that the ideal condition will be attained in any beam under all circumstances, but by means of the Principle of Least Work it is shown that the tendency to do so must always exist..." And, again:

"It is not asserted that the ideal state of stress and strain defined by Equation [16]" [i.e., a modified form of the beam formula, for non-homogeneous beams] "actually exists in any ordinary girder, but it is believed to be shown that in accordance with the Principle of Least Work there will be a tendency for the stresses and strains to so adjust themselves as to approach to this condition. This tendency agrees with and confirms the Principle of Saint-Venant." He then applies the modified formula to find the stresses in a semi-rigid, and shows that the envelope would carry "more than one-third of the entire bending moment," the remainder being carried by the keel.

In the second paper he states that the solution "gives assurance that the state of stresses to which it leads is one to which the beam must tend, even although it may not in practice conform to it near the points of application of the external forces." He works from certain assumptions, such as: "All the external forces as well as their distribution over the end sections are assumed to be known..." "No external forces act on the lateral bounding surfaces..." "It is assumed that the distribution of the external forces over the terminal section at A" [i.e., the free-end section] "is such as to conform to the yet unknown stress distribution required by the Principle of Least Work. The same assumption is made for the reactions over the section at the fixed end." "As in the solutions given by Saint-Venant and Clebsch it is further assumed that there are no normal transverse stresses, that is, the longitudinal fibers, of which we may imagine the body to be made up, do not exert on each other any pressures or tensions normal to their direction." Finally, "we have assumed that the forces at the free end and the reactions at the fixed end[3] are distributed over the terminal sections in accordance with the stress distribution subsequently determined by the Principle of Least Work. In practice these conditions are never fulfilled, but as there is an inherent tendency of the stresses to conform to that principle, we are justified in asserting that at a certain distance from the terminals the stresses will adjust themselves in accordance therewith. Saint-Venant has shown that this adjustment actually takes place very close to the terminals (Saint-Venant's Principle)."

In "The Mathematical Theory of Elasticity," by Love, second edition, Par. 89, is the following: "In the problem of Article 87, the tractions, of which the bending moment EI/R is the statical equivalent, are distributed over the terminal sections in the manner of tensions and pressures on the elements of area, these tensions and pressures being proportional to the distance from the neutral plane. But the practical utility of the solution is not confined to the case where this distribution of terminal traction is exactly realized. The extension to other cases is made by means of a principle, first definitely enunciated by Saint-Venant, and known as 'the principle of the elastic equivalence of statically equipollent systems of load.' According to this principle, the strains that are produced in a body by the application, to a small part of its surface, of a system of forces statically equivalent to zero force and zero couple, are of negligible magnitude at distances which are large compared with the linear dimensions of the part. In the problem in hand, we infer that, when the length of the bar is large compared with any diameter of its cross-section, the state of stress and strain set up in its interior by the terminal couple is practically independent of the distribution of the tractions, of which the couple is the resultant, in all the portions of the bar except comparatively small portions near its end."

In Par. 95, for the bending of a narrow rectangular beam, of width $2h$ and depth $2c$, by a terminal load, he shows that the "terminal tractions, of which W is the resultant, are distributed over the end so as to be proportional to $c^2 - y^2$. As in Art. 89, the distribution of the load is important near the ends only, if the length of the beam is great in comparison with its depth."

In Par. 245 he shows that the deflection of a beam due to a central load of W is increased by the local stress at the load. "Either part, AC or AB, of the beam might be treated as a cantilever, fixed at A and bent by terminal load $^1/_2W$ acting upward at the other end; but Saint-Venant's solution would not be strictly applicable to the parts AB or AC, for the cross-sections are distorted into curved surfaces which would not fit together at A.[4] In Saint-Venant's solution of the cantilever problem the central part of the cross-section at A is vertical, and the tangent to the central-line at A makes with the horizontal a certain small angle S_0.... The correction of the central deflection which would be obtained in this way would be equivalent, in the case of a narrow rectangular beam, to increasing it by the fraction $45d^2/16L^2$ of itself, where L is the length of the span, and d is the depth of the beam. The correction is therefore not very important in a long beam." However, if the length/depth ratio be small, for instance, 5, this fraction amounts to one-ninth, and for a ratio of 4, to three-seventeenths.

Reference should also be made to R. & M. 821, "On Castigliano's Theorem of Least Work, and the Principle of St. Venant," R. V. Southwell. See also Appendix No. 3.

In Trans. A.S.M.E., 1929, Burgess determines the stresses in a cantilever, parallel-sided space frame of 8 sides, with keel, upon the methods of moments, shear, inverse ratio, least work, etc. Underlying the computation of stresses is an assumption, expressed as, "....all longitudinals and diagonals are pin-connected to an absolutely rigid wall," and, again, "The frame at the right-hand end is rigidly cross-braced," and, again, "The internal work in all transverse members, including the cross-bracing of the right-hand end frame, is negligible. This is equivalent to assuming that EA is infinite for these members in the least-work and inverse ratio calculations."

The excellent report of the Airship Stressing Panel (R. & M. 800) gives methods for computation of stress. Certain assumptions and qualifications are of note:

1 The shear in any facet is assumed to be equally divided between the two diagonals.

2 Appendix IV clearly states (p. 33), in the discussion of the assumption that the frames remain plane, "It should be emphasized that the alternative solutions will be neither more nor less exact than the solutions found previously: their differences corresponding to a difference in the implied distribution of the external loads and it must be left for subsequent investigation to decide which are the more representative of actual conditions."

3 The loaded frames are radially wired, and it is shown in Appendix XI that such a system has greater rigidity than other types, hence the frames are considered to be truly rigid.

---

[3] Cv. Appendix No. 3, stresses at Frame No. 70, upper and lower longitudinals.

[4] Cv. Appendix No. 3, Frame No. 70, longitudinals D, E, F, G, and H.

4 Appendix VIII shows that when all members are considered flexible there is a considerable difference in the stresses as computed by least work from those that result by considering the frames rigid. It also shows marked variation of stresses in all shell members for different systems of loading of a given radially wired frame.

5 There is a basic assumption that the supplementary load system will be resisted entirely by the frame itself. The following statements are made on p. 60: "Since there is no practicable method of allowing for these local stress effects due to the bulkhead elasticity, *it is important to design the bulkheads as rigid as possible in order to eliminate them*" (italics the author's), also, "The effect of the elasticity of the bulkheads is therefore a local disturbance, the amount of the disturbance depending on the exact method of application of the load. After the second bulkhead, the stresses in the longitudinals as we pass from bay to bay, are practically the same as those for a tube in which the loads are applied through a rigid bulkhead. The difference between the stresses in the longitudinal members in the two cases does not increase after the second bulkhead, but is in the nature of a constant initial difference, and the percentage difference decreases from bay to bay in geometrical progression."

6 Another effect, which the author will not consider in this paper, is the reduction in modulus of elasticity, mentioned in Appendix X.

FIG. 1a, CASE Oa

FIGS. 1 AND 1a

7 And the ineffectiveness of the shell diagonals in stiffening the longitudinals, given in Appendix XII.

8 Attention is called, however, to studies in Appendix XIII of the rigidifying effect of the shell caused by initial tensioning of the diagonal wires.

In the other R. & M. reports mentioned will be found much excellent and intensive work on the degree of accuracy to be expected of computations based on the assumption of plane bending, or upon the assumption of planar transverse frames. Southwell shows (R. & M. 819, 790, etc.) that a given loading can be divided into one which will carry along the structure in St. Venant's fashion, and one which ("supplementary") will be self-equilibrating in the loaded region. The theory implies an inextensible frame, i.e., infinite rigidity. But Pippard shows that unless this frame be in fact inextensible, i.e., unless its rigidity be in fact very large compared with that of the shell, the stresses found in the shell do not compare well with "St. Venant stresses."

All bases for the presupposition that St. Venant's methods will give acceptable results have involved the assumptions of parallel body, great elongation ratio, and great rigidity of the loaded frames. The authors quoted repeatedly stress this fact. Until recently the facts did not differ widely from these assumptions, in that the main frames were cross-wired rigidly and in an indeterminate (and hence rigid) fashion, and considerable parallel body was used. But the introduction of ring frames, the reduction of the elongation ratio, and the elimination of parallel body so alter the facts that the author believes that the assumption of plane bending, *without further proof*, is unjustified. It is of course certainly true that the range over which any local stress extends is limited, but every loaded frame is a group of focal centers for such stresses. Or, speaking in terms of Southwell's analysis, correction stresses must be considered for every loaded frame. Every keel, or corridor, is also an irregularity.

St. Venant considered conditions that appear in a long prismatic beam, at sections well removed from the point of loading. Local stresses at such point inherently prohibit local deformation according to planar distribution. An airship of variable diameter throughout, having an elongation ratio in modern designs of 4 to 6, having flexible bracing so that the initial positions in their plane of the joints are not closely maintained, must vary quite a little from the fundamental assumptions.

II—TENTATIVE RESULTS

Determinate Structures. Tacitly, the previous work quoted begs the question, from the standpoint of this paper. The manner of application of the load to these frames, and their rigidity, influences the stresses throughout the ship, as evidenced by the papers of Southwell and Pippard. For instance, consider a structure, similar to the ones already studied, but without keel, and with statically determinate end frames. See Fig. 1. The determinate stresses shown, which must be true—unless the joints are not frictionless—differ widely from all of the theories, as shown in Table 3, Appendix No. 4. This table has been computed according to the recognized formulas and by determinate methods.

The first reaction to this table may probably be expressed: "But Fig. 1 does not even approximate to an actual ship, having no nose and no internal bracing." At most it states that this is one of an infinite variety of designs of a given contour; that it differs widely from the common theories; that therefore the theories cannot be universally true. That the determinate stresses listed are not erroneous may easily be confirmed by reference to Table 4, in Appendix No. 5, which gives comparison of theoretical stresses and of stresses actually found by experiment for a similar case. (Cv. R. & M. 977.) There is a marked agreement with the statical stresses, and a marked disagreement with the stresses as computed by other methods.

FIG. 4 CASE 5—NO INTERNAL BRACING

In Fig. 2 will be found a somewhat closer approximation to an actual ship, in that there is now a blunt nose similar to that used in all rigids built in the early part of this century—but still no internal bracing. Here again the stresses do not resemble in any way those determined by the common theories. The effect of the nose, however, is marked.

Figs. 3 and 4 all differ from the common theories, though they show an interesting trend that is a function of the longitudinal curvature.

One fact is clearly expressed by these designs, all of which are determinate, namely, that a load applied at a joint will cause high stress in those gores (a "gore" meaning a longitudinal group of facets) whose common edge passes through the loaded joint, provided there is no internal bracing. This is also equally true even if redundant wires are present in every facet. How far the internal bracing modifies this statement remains to be proved.

Another fact expressed is that at joints where "kinks" occur in the longitudinal profile, stress in any gore is partially transferred to the neighbor gore; and only at such joints can transfer take place unless there is internal bracing. The designs shown are all for an 8-sided ship, in which, therefore, all gores become stressed in some part of their length after 4 kinks have been passed, even without a nose cone. The stress, in other words, spreads spirally around the shell. Note, however, that in a 32-sided ship 16 kinks would be required, meaning that a load on a central frame could only just encircle the ship if a total of 31 frame spaces are provided, and no nose cone.

Again, the amount of stress transmitted to the neighbor gores is a function of the number of sides. For instance, comparing 32 sides with 8 sides, the stress transfer will be 3.9 times as much. Also it is a function of the kink angle in the longitudinal profile, a sharp kink giving greater transmission.

Discussion of Statical Stresses. Let us see what may be learned from this statical sequence by further study.

First, in Fig. 1, Case 0, which has no kinks but is all parallel body, with a determinate frame at each end, the whole being symmetrical, it will be noted that a load, say 1 lb., applied at any joint, can stress only the two adjacent gores—as already stated. All members above the *D* longitudinals have no stress for the load indicated, and it makes no difference where the end reactions are placed except in so far as the stresses in the end frames themselves are concerned. Two gores carry all moments and shears, and because they are of shallow depth the stresses are high.

The figure also shows the stresses in a 32-sided ship. These are more excessive.

These cases and all which follow involve of course the ratio, L/r, or (length of frame space)/(radius of circumscribing circle), which for convenience has been assumed as unity. Any change of this value will alter only the numerical values of the stresses, proportional to the changes of length. Each facet shown can be subdivided into any number of shorter ones, still maintaining determinateness, without any change except in numerical stress value. Moreover, all diagonal members can be doubled, or increased n times, so that each facet will become indeterminate *in its own plane*, and there will be no transfer of stress to any members outside of the two gores.

In Fig. 2, Case 1, having one kink, we see an immediate change. The end reaction of $^1/_2$ lb. is now carried by two systems. There is, first, the system of the two gores that adjoin the load of 1 lb., whose stresses are now much reduced; also, second, there is a system that resembles, somewhat, a reinforced concrete girder, or more nearly a semi-rigid airship (see footnote 2). This latter consists of a "top flange," located at the ship's axis and having an area equal to that of *all* eight longitudinals, and a "bottom flange" which consists of the one bottom longitudinal (where frequently the ship has been reinforced with an actual keel). The first system carries all shears in the parallel body; in the nose no diagonals have any stress, all shear being carried by the longitudinals. Sub-facets may be inserted here as before, if desired, without change except in numerical stress values. Any facet may be made indeterminate, as before, except those which are contiguous to the kink.

In Fig. 3, Case 3, having 3 kinks, the stress from the two gores has been still further reduced and distributed to the other gores, so that now the whole stress system has changed materially. The bottom longitudinal has less stress than before, but it still is affected to a much larger degree than any of the others. The stresses increase downward as the two gores are approached.

In Fig. 4, Case 5, having 5 kinks, the process has gone further but there is not much change (in percentage) from Fig. 3. The profile is now almost elliptical, with two parallel bays amidships. In a rough way, Cases 3 and 5 are almost identical in stress, and even Cases 1 and 3 do not differ as greatly as any one case differs from any of the common theories.

There has not been sufficient time to compute the statical stresses for designs of more than 8 sides, because although simple methods have been devised, there is still considerable work involved. But for the purpose of this paper it is shown that the transverse bracing that is always used is called upon to perform—on the assumptions that underlie the common theories—a multifold duty. Every one of the stress systems shown differs from every other, and from the common theories, hence the transverse bracing must be able to convert any one of an infinite number of stress systems into a system of just one single type, i.e., a system where the stresses in the longitudinals are linear functions of the distance from the neutral axis and the stresses in the shear wires are functions of the angle of inclination of the facet planes.

The next step to be taken is the determination of the effect of a single intermediate transverse frame, determinate within itself, but of necessity causing indeterminateness in the aggregation of transverse frame and shell. Once the effect of a single frame is determined, there comes then the determination of additional frames. The redundancies caused by only one frame are somewhat formidable, even for an 8-sided prismatic shell, and the author must content himself with these in this paper.

III—INTERNAL BRACING

Effect of a Single, Self-Determinate, Transverse Frame

The high order of redundancy of an actual ship precludes the possibility of an exact solution, as has already been said. To find the best solution, even though approximate, there must be extensive study of various methods. Even then the result can only be obtained by slow steps and painstaking care. The following discussion outlines the steps which the author has taken thus far.

One Single-Wire Bracing Member, in a Complete Shell. Let us apply to Figs. 1, 1a, and 4 a single wire on the vertical axis of the plane of symmetry, with loads of 1 lb. at the top and bottom joints. Let the area of all longitudinals and all transverse struts of the shell be equal; and the area of all wire diagonals and of the single bracing member be equal to one-tenth of the area of the longitudinals. The variation of each case for other sizes of the bracing wire may be given by formula. Let the wires be steel, the other members duralumin, and the ratio of moduli of elasticity 3.

The most direct path for the stress is through the wire, but its elastic stretch will cause strain in the shell, hence the portions carried by the two systems will be inversely proportional to their relative rigidities. The hull stresses due to either load are given in the figures, and those for the mate will be symmetrical. The elongation ratio of these figures is 5.5, but other ratios are tabulated below.

Division of Load Between Bracing Wire and Shell

		Parallel Body, 8 Sides		
Elongation ratio	=	5.5	4.5	3.5
Per cent in wire	=	99.4	99.0	98.2
Per cent in shell	=	0.6	1.0	1.8
		Parallel Body, 32 Sides		
Elongation ratio	=	5.5	4.5	3.5
Per cent in wire	=	99.997	99.994	99.988
Per cent in shell	=	0.003	0.006	0.012
		Curved Body, 8 Sides		
Elongation ratio	=	5.5	4.5	......
Per cent in wire	=	97.0	93.1	......
Per cent in shell	=	3.0	6.9	......

Note that in the curved body the shell receives a much larger proportion of the force, because of greater rigidity relatively, also that 32 sides cause lowered rigidity relatively.

One Single-Wire Bracing Member, in a Length of Two Bays. Let us consider the effect of the single wire and the same load system on the shell in a length of two main bays between braced end frames consisting also of a single, vertical wire. In effect the structure has an elongation ratio of 2.

		Parallel Body, 2 Main Bays Long 8 Sides	 32 Sides
Elongation ratio	=	2.0	2.0
Per cent in wire	=	88.3	99.6
Per cent in shell	=	11.7	0.4

Note that the shorter shell is much more rigid, but the 32 sides again cause lowered rigidity.

Self-Determinate Braced Frames in a Length of Two Main Bays

Parallel Body. Let us consider an octagonal structure such as is shown in Fig. 5, having a central and two end frames, but for the moment let the bracing of these frames consist only of a single vertical wire. Let there be a single load of 1 lb. at the central frame resisted by loads of $^1/_2$ lb. at the end frames. This simulates a case where the frame loading exceeds the gas lift at that frame, which may actually occur at heavy concentrations, and which has some resemblance to certain aerodynamic systems. The moduli are the same as before, also the areas, but the ratio of Ea for the wires of the transverses divided by EA for the longitudinals is denoted by k.

Then the stresses in the shear wires of the shell will be as follows:

Member	Statical stress, no intermediate frame	Least-work stress for various values of k 0.03	 0.30	 0.60	 3.0	 ∞	Stress by method of shears	Stress by method of moments
A-B	0	+0.455	+0.480	+0.482	+0.484	+0.484	+0.079	+0.079
B-C, C-D	0	0	0	0	0	0	+0.190	+0.190
D-E	1.07	+0.615	+0.590	+0.588	+0.586	+0.586	+0.079	+0.079

Let us now consider the structure as shown in Fig. 5, with the self-determinate frames shown. To avoid the complexity of a crossed diagonal, consider that the members may resist compression as well as tension.

There are 5 redundant members, but symmetry reduces this number to 3, and these have been chosen as the shear wires *A-B*, *B-C*, and *C-D* in any panel of the ship. The work, or deflection, computations are too voluminous to give here, but the results are tabulated in Table 1.

In Fig. 8 is a graph showing the variation given in Table 1. It should be noted that a different type of bracing would produce stresses of differing values, but the trends would be similar with change of rigidity. It is evident that when k is less than $^1/_4$ the stresses vary considerably from the common theories. If $k = 0.10$ be considered to represent a customary ratio in ships as built, then the discrepancy is roughly 33 per cent as an average, and increases very rapidly for lower values.

A difficulty arises in applying the methods of moments and shears to a structure with only a single system of wiring in the facets, which cannot be symmetrical above and below the axis. For instance, E_1E_2 cannot have a stress in the octagonal design, although by these methods it should have a stress equal to that in A_1A_2. Similarly in every panel of the cases shown in the figures the upper longitudinals will have one more increment of stress than the respective lower ones.

---

[1] For formulas used, see Appendix No. 4, also note at end of appendix.

The method of shears is based upon the relative deflection of two parallel frames of infinite rigidity, hence as the rigidity of the frames approaches infinity the tabulated stresses would approach those by the common methods as a limit, if there were crossed diagonals in the facets. Actually they do show a close approximation, though there are slight variations. It is of great interest to note that on either side of the value, $k = 0.10$, there is a change of sign in some longitudinals. For very small values of k the stresses should approach the statical stresses as a limit, and longitudinals *D* and *E* do so. But *A*, *B*, and *C* do not, because of the fact that the wire-bracing size in the end bulkheads was changed as well as in the central bulkhead, as would be the case in an actual ship, and therefore for $k = 0$ the structure would be unstable unless the $^1/_2$-lb. reactions had been applied at the joints E_1. These three members, therefore, become large, as should be true. In order to find the trend with number of sides, a hexagonal but similar case has been computed. See Fig. 6. It might be noted, in passing, that the methods used give results agreeing within 1 per cent with Professor Pippard's computed stresses for a hexagon with a keel and with rigid frames. The shear-wire stresses are tabulated herewith, and the longitudinals may easily be computed from the increments of stress due to the shear wires.

STRESSES IN SHELL OF LENGTH EQUAL TO 2 MAIN BAYS, FOR VARIATION OF RIGIDITY OF INTERNAL BRACING OF A GIVEN TYPE (SEE FIG. 6)

HEXAGONAL CASE

Member	Statical stress, no intermediate frame	Least-work stresses for various values of k					Stress by method of shears[1]	Stress by method of moments[1]
		0.03	0.30	0.60	3.0	∞

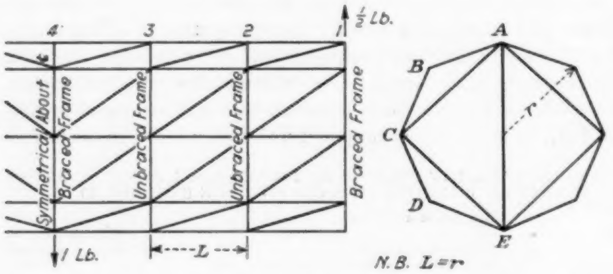

FIG. 5 OCTAGON

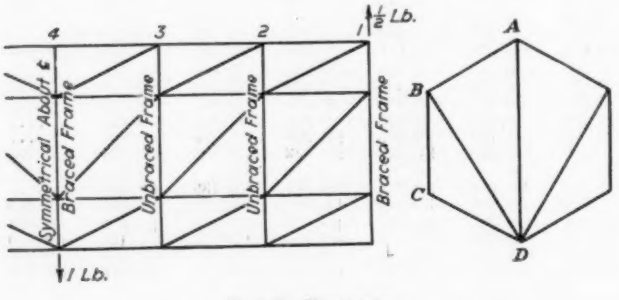

FIG. 6 HEXAGON

The two cases just cited are extreme ones in respect of the distance between main frames as compared with the diameter of the shell. To show the trends more broadly the following case deals with a hexagonal shell in which the distance between main frames has been reduced to a length equal to the radius of the shell.

STRESSES IN SHELL SIMILAR TO PRECEDING, WITH SPACING OF MAIN FRAMES REDUCED BY ONE-THIRD (SEE FIG. 7)

HEXAGONAL CASE

Member	Statical stress, no intermediate frame	Least-work stresses for various values of k					Stress by method of shears[1]	Stress by method of moments[1]

C-D	0.707	+0.374	+0.201	+0.173	+0.147	+0.139	+0.118	+0.118

---

[1] For formulas used, see Appendix No. 4.

Fig. 8 shows graphically the results of the tabulations. It will be noted that the ratio of the tabular stresses to those computed by the common theories is plotted against the value of k. Clearly the discrepancy between the two is far greater in the case of the octagon than in the case of the hexagon.

Curved Body. Amidships the curved body will approximate to parallel body and the previous discussion applies. Fore and aft there will be a difference. This effect has not yet been studied. It is true that most of the heavy concentrations of load, where the lift is less than the local loading, lie near midlength. At any frame the lift is, of course, distributed over the top and sides of the frame, and the modern tendency is to concentrate the loads near the 45-deg. points of the lower portion of the frames.

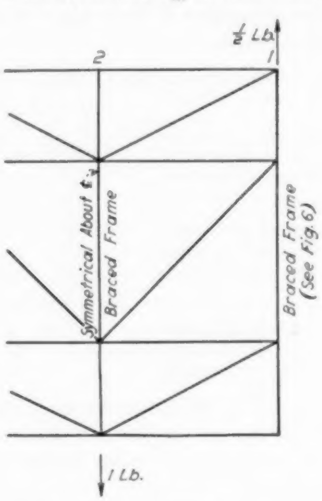

FIG. 7 HEXAGON

Unwired Ring Frames. In Appendix No. 6 is a rough computation of the relative rigidity of unwired and tight-wired frames, indicating the approximate value of $k = 0.142$ which is marked *A* on Fig. 8. The degree of redundancy of the unwired frame is such that at present the effect on the shell can only be approximated. Within the accuracy of this computation, it is apparent that frames having a depth of one-eighth of the radius, or less, will cause serious discrepancy; and that even for deeper rings great care should be paid to the stresses induced in the shell. Much further study is needed.

ALL MAIN FRAMES BRACED, WHETHER SELF-DETERMINATE OR HIGHLY REDUNDANT

The only information at hand at present is that afforded by the brief study made by Burgess in Trans. A.S.M.E., 1929, and by the experiments of Pippard. See Appendix No. 5. It is evident that even a multiplicity of frames are not locally effective, unless the loaded frames are themselves *very* rigid. The *Shenandoah* model seemingly points to the same conclusion. It should be noted that Pippard's frames, especially those with $^5/_8$-in. rods, were very rigid. See point *C*, Fig. 8.

SUMMARY

The foregoing discussion in reality deals with two effects; the local "supplementary" load system, and the general bending of the hull. These can never, in the author's belief, be considered singly because of the limited elongation ratio and of the multiplicity of supplementary systems. Some system of stresses as shown by a series of influence lines seems to be the solution of this general design problem, the influence lines, for instance, being drawn for loads at each longitudinal. Each influence line will show the full effect of a load at any point, i.e., will cover the general stress condition as well as the local stress system. The author has found no general argument which will even approximately describe the effect of a change in any one of the many variables which enter this problem, because the interrelation of the variables is too complex. The shear and moment theories seemingly give rough approximations, and may be satisfactory for general design purposes; but for determining the actual size of members, or the actual stress in any given member they seem, at this writing, to be too uncertain.

The curves of Fig. 8 are the nearest approach to a statement that can at present be made as to the effect of the number of sides; but some small part of the effect shown is a function of the angle, ϕ, the angle between the longitudinals and the facet diagonals, and for a given length of panel the tan ϕ is a function of the number of sides. Of course as ships have grown larger and larger in diameter, the spacing of main frames has increased so that now there may be 3 intermediate, unbraced frames in a bay where before there were 2 or only 1, necessitated by the increasing number of longitudinals and the need for an optimum value of the angle, ϕ. The stresses for Fig. 7 show the effect of reducing the spacing of main frames, and have been computed for two reasons: (1) to show the stresses for main bays of length approximating to that of actual ships, and (2) to show, in part, the effect of the angle, ϕ, since the shortening of a panel to increase the angle, ϕ, will increase the rigidity of the shell and therefore produce a curve lying higher on the chart than before, i.e., with greater discrepancies.

The author has attempted to find and apply all checks that were available on the arguments and results of this paper. Only by extended study can it be determined whether the arguments will be borne out in fact in the actual ship. The paper points toward certain tentative conclusions, that must be confirmed or denied before they are accepted. The most serious bending and shear stresses in a ship result from (1) running into a gust and (2) operation of the controls. The latter applies force to a rigid frame, which creates inertia "forces" that are pretty uniformly distributed, except as regards the concentrated loads near the bottom of the shell. The former applies forces that probably are quite concentrated on the windward side of the nose, which produce the same kind of inertia "forces." Such a force system is far from being applied as St. Venant requires, and much more closely according to the forces discussed in Fig. 5, for instance. Perhaps this paper contains a germ for a theory of the cause which resulted in the breaking away of the control car of the U.S.S. *Shenandoah*, with heavy loss of life. For some years past the author has had this belief.

The following conclusions, therefore, are offered tentatively and in the hope that opportunity will arise for checking and amplifying them, or disproving them.

TENTATIVE CONCLUSIONS

All evidence points to the facts:

1 That unless there is great rigidity in the transverse bracing, especially at points of loading, the shell stresses cannot be determined with even fair accuracy by the common methods.

2 The change to loose-wired frames requires careful attention to stresses induced in the shell by reason of the lowered rigidity of the ring frames as compared with highly redundant, tight-wired frames.

3 The arguments of this paper and the results of experiments point to the conclusion that with curved profile the approach to the theoretical stresses of St. Venant's principle is very different and probably less certain, than in parallel body.

4 That there should be local reinforcement of members near concentrations of load.

5 That keels and corridors have a marked influence on the stress distribution in the shell, and that their effect on these stresses is as yet undetermined.

6 That the stresses in a rigid have some similarity to those in a semi-rigid

7 That redundancy of the crossed diagonals in the facets of the shell is of rather localized effect.

8 That joint rigidity causes a secondary effect that is of importance.

9 That there is evidence of a stress system underrunning the systems calculated by the common theories.

10 That some points are deserving of further study, such as the "keel effect," or increased stressing near load points, and such as the rigidity of the longitudinals between main frames and the effect of altered modulus of elasticity in curved members on conditions of bending.

11 That the stresses in an octagonal prismatic body compare much less favorably with those stresses computed by the common theories than do those in a hexagonal prismatic body; and that seemingly this shows as a trend that there will be increased differences as the number of sides increases; that this point deserves further study, especially in curved body, to establish the trend further; and that the order of difference is sufficiently large to be of importance in the design of ships.

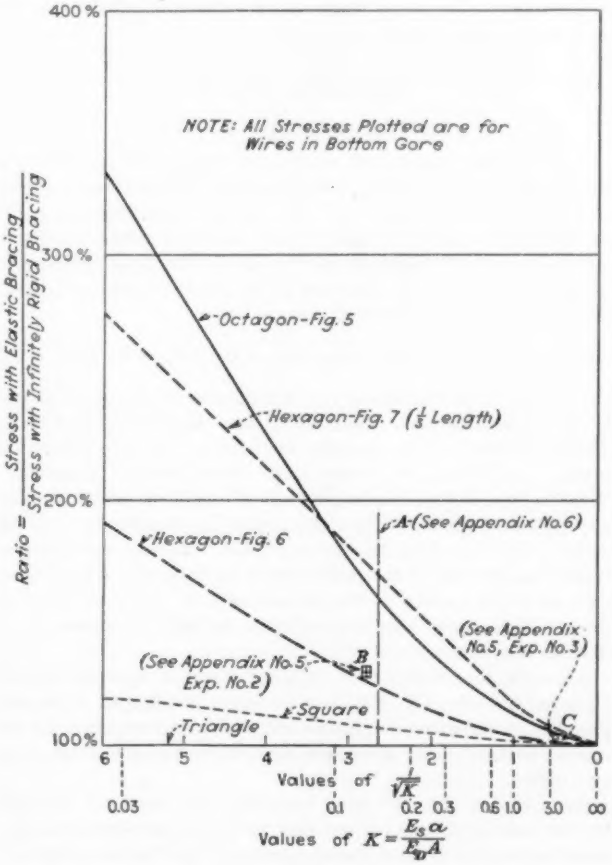

FIG. 8

12 That further study is required to determine how far the presence of additional braced frames may diminish the effect of the preceding conclusions, although there is already experimental evidence that for sizes of bracing used in current practice there is little diminution.

13 It should be noted that this discussion deals with that portion of the stress in any member that results from each localized group of loads; that other portions of the stress in such a member that are caused by loads more distant from it may show less discrepancy; that therefore the discrepancy in

the total stress may be a smaller percentage of the total stress; but that for such load systems as that caused by a sudden large gust, all localized groups of loads are of the same character, probably causing considerable discrepancy even in the total stress.

Acknowledgment

The author wishes to acknowledge the helpful assistance of his associate, Mr. Willard W. Troxell, who has contributed many valuable suggestions and criticisms, and who has carried out much of the extremely tedious computations on which the paper is based; to the Bureau of Aeronautics, United States Navy, for the use of data obtained from the photoelastic model of the U.S.S. *Shenandoah;* to the writers quoted for the masterly studies which they have made and for the full presentation of their experimental data.

Appendix No. 1

STATICAL DETERMINATION

A (statically) determinate structure is one in whose members the stresses due to known joint loads can be found by the laws of statics alone. These laws tell us that a stationary body (or one moving with balanced forces) can have neither resultant force nor resultant moment on it in any of the three component directions. As usually expressed, if the forces X are longitudinal, forces Y lateral, and forces Z vertical, then

$$\Sigma X = 0;\ \Sigma Y = 0;\ \Sigma Z = 0;\ \Sigma M_x = 0;\ \Sigma M_y = 0;\ \Sigma M_z = 0$$

the summations expressing the component forces or moments in the three directions. Be it noted here, in passing, that these directions need not be mutally rectangular, but they must be mutally exclusive, i.e., must have some relative angularity. What is true of the structure as a whole is of necessity true for any portion segregated from the rest by an imaginary dividing surface, and therefore true for any joint. In such portions the truss members cut by the surface must be replaced by their total internal stress applied at the cut end as if in reality an external force. These equations are sufficient to find all stresses in a determinate frame.

Maxwell determined that in a structure of n members and j joints, $3j - 6 - n = 0$, is a necessary condition. It is not, however, a sufficient condition, and the members must be arranged so that there is neither superfluity nor insufficiency at any point.

An *indeterminate structure* (omitting the word "statically" for the sake of brevity) is one that has more members than can be solved by the laws of statics alone, and the degree of indeterminacy is measured directly by the number of surplus, or "redundant," bars. In other words, $3j - 6 - n$ is positive.

An *unstable structure* is one which is deficient in the number of its members, and the degree of instability is likewise measured by the deficiency of members. In other words, $3j - 6 - n$ is negative. Such structures may or may not be generally unstable according as the deficiency is general or localized.

The term *quasi-determinate* has been applied to such instances as that of the facet with two diagonals, each capable of withstanding tension only, because one such member (unless initially tensioned) must become slack and therefore, in principle, disappear. ("Facet" is used to mean any plane, exterior surface bounded by members.) Pippard (R. & M. 1057, Par. 36) has emphasized that when a ship is stressed near to its point of failure, most of such wires, even if initially tensioned, must have become inactive, so that at such time the ship may have become in fact determinate. A little study will show that *one* such redundant wire causes indeterminancy only in its own facet, in a determinate ship, so that if half of the redundant wires in a ship, arranged in checkerboard fashion, become inactive, the ship has become determinate in general, though there will still be local indeterminancy in each still-redundant facet. Pippard has shown by experiment (R. & M. 977) that in a rough way the shear in a facet is divided equally between the two wires, if initially stressed, of course. Southwell suggested (R. & M. 1057) the "device of the separate panel" as a means of avoiding the difficulties caused by such quasi-determinancy. Pippard has also shown that as compared with the effect of bulkhead bracing the effect of these redundancies is small. In any event this paper will exclude all such wires for the present. The Airship Stressing Panel in R. & M. 800 consider that the shear in a facet is divided equally. This is common practice in bridge design.

Appendix No. 2

OVALING

When an externally loaded closed tube, a tubular column, or a tubular beam has an excessive length-diameter ratio, collapse may occur by "ovaling" of the section at some point in the length. In boiler tubes collapse rings, similar to transverse bracing, have been used to prevent collapse. This effect will not enter into consideration in this paper. It has been studied by Bryan, Southwell, and Frazier (R. & M. 1081). The theory has not been extended, however, to cover a frame structure to the author's knowledge. Reference is also made to Appendix XII of R. & M. 800.

Of collateral interest is an excellent study of pipe bends in "The Elastic Deformation of Pipe Bends," by Wm. Hovgaard, *Journal of Mathematics and Physics*, Vol. VI, No. 2, November, 1926. This paper stresses the fact that the assumption that the distance from the neutral axis to any fiber remains constant does not in fact always hold true, may lead to serious discrepancy. After allowance is made in the paper for variation of this distance, the theoretical results agree very closely with experiment, but differ from the "St. Venant stresses" by from 100 per cent to 400 per cent, and similarly for deflections.

Reference may be made also to R. & M. 800, Appendix I, p. 67, and R. &. M. 792, "The Reduction of the Effective Value of Young's Modulus in Flexible Compression Members," by A. J. S. Pippard.

Appendix No. 3

NOTES ON DESIGN MEMORANDUM NO. 57, BUREAU OF AERONAUTICS, U. S. NAVY, BY C. P. BURGESS

Photoelastic Experiments on Lengthened Model of U.S.S. "Shenandoah"

"Design Memorandum No. 28 was devoted to the analysis and interpretation of the photoelastic experiments upon a celluloid model representing seven main frame bays of the *Shenandoah.* It was shown that the distribution of stresses was much more in acccord with the shear theory than with the bending theory. On the other hand, strain-gage experiments on the actual ship in flight showed the stress to be in accordance with the bending theory rather than with the shear theory. It was thought that the great discrepancy between the model and the full-scale experiments was due to the difference in end conditions. These conditions were very different because both ends of the model were open, allowing considerable distortion of the end frames out of their planes; whereas the closed bow and stern structures of the airship hull very much restricted such distortions."

The model was therefore lengthened by five additional bays,

[1] Stresses in *F*, *G*, and *H* are too small to be of value.

"the longitudinals of which were curved to a radius of about eleven feet and terminate in a celluloid cone or cap." "The lengthened model was secured to a wall as a cantilever, with the new closed end outward; and was tested in two loading conditions." First an upward load of 43 lb. was applied at the rear of the end cap, i.e., at Frame 185, and then this was replaced by a downward load of 26 lb., making a reversal of 69 lb. Stresses in the celluloid members were taken photoelastically and those in the wires by a small Larsen tensiometer. The actual stresses were of little use, "because of the rather erratic initial stresses which appear to be unavoidable in such a model. The important data are the changes of stress in passing from one load condition to the other."

"The secondary longitudinals had no shear wires secured to them, and hence should have no load according to the method of shears." In applying the inverse-ratio method, "it is assumed that the counter shear wires are slack. In panels having both main and secondary shear wires, the load is divided between the two systems of wiring according to the inverse ratio of the internal work in the two systems of wires."

Under the head of Conclusions: "The photoelastic investigation shows actual stresses much more closely in accord with the simple bending theory than with any of the other theories. The principal discrepancy is in the keel where the top (*N*) girder had usually the sign of stress called for by the theory, but of much less magnitude, and there was a corresponding increase in the load carried by the *M*-girders. It was remarkable that the secondary longitudinals which were entirely unconnected to the shear wires, and therefore should have had no load, according to the shear and inverse ratio theories, were actually stressed to almost the full intensity called for by the bending theory."

"The result indicates that for future design work the simple bending theory should give satisfactory results if the shear wires are reasonably proportioned to the loads to be transmitted. In the primary strength calculation, the internal members of the keel should not be counted as contributing to the resistance of the hull against bending; but in designing these internal keel members, allowance should be made for their possibly receiving end loads up to 25 per cent or even 50 per cent of the load calculated for them on the assumption that they are fully effective in the primary bending of the hull."

The numerous tables given have been collected into Table 2. In a few cases there were small discrepancies between corresponding longitudinals on opposite sides of the model, such as *B* and *B′*, etc., and the table eliminates these discrepancies by averaging all such members, from *B* to *M*. Longitudinal *A* is the top member, and *M*, *M′*, and *N* form the keel, with box girder *P* inserted in the keel to carry concentrated loads. Only in frame space 70–80 are all stresses given, hence this bay is the only one listed fully in Fig. 9.

It will first be noted that taking all results into consideration the observed results agree much more closely with the theory of moments than with the other theories; but even so there are considerable discrepancies. Of these discrepancies, the most notable characteristic is that whereas in frame space 70–80 their percentage value is small,[5] still as the successive frame spaces are studied their percentage value increases steadily as the load is approached. The accompanying diagram, Fig. 9, shows a plotting of a ratio expressing the discrepancy for each individual longitudinal. This ratio is the quotient obtained by dividing the stress obtained by use of the method of moments by the actual observed stress, using the values listed in Table 2. For instance, for longitudinal *A*, the top member, the theoretical stress is always greater than the actual, and from frame 120 to frame 160 it is nearly twice. If the member were designed for the theoretical stress in this region it would be nearly 100 per cent too heavy in cross-section. Other members show a similar trend, so that roughly speaking there is a discrepancy which increases in a linear fashion to 100 per cent at frame 120 and continues to increase to frame 160. The members that form the keel differ considerably from the others. The apex member, *N*, shows a stress of opposite sign at frame 70, so that between 70 and 80 the ratio is infinite, the box girder, *P*, has a ratio of 6 at frame 70; then both decline rapidly to about frames 110 and 120, after which they agree somewhat well with the top longitudinals. Members *L* and *M* agree with the top longitudinals at first, but then—probably because of the change in *N* and *P*—show a declining tendency that is contrary to the top longitudinals.

At frame 70 the assumption of a rigid transverse was clearly realized, and the actual stresses agree closely with the moment theory.[5] As the load is approached the error increases progressively. The order of variation of the discrepancy is somewhat remarkable, when consideration is given to the fact that every main transverse was rigidly wired in the style that was standard when the *Shenandoah* was built. All theoretical considerations that are quoted in this paper, and the experimental results obtained by Pippard, point to a rapid diminution of the discrepancy after the first main frame from the load has been passed.

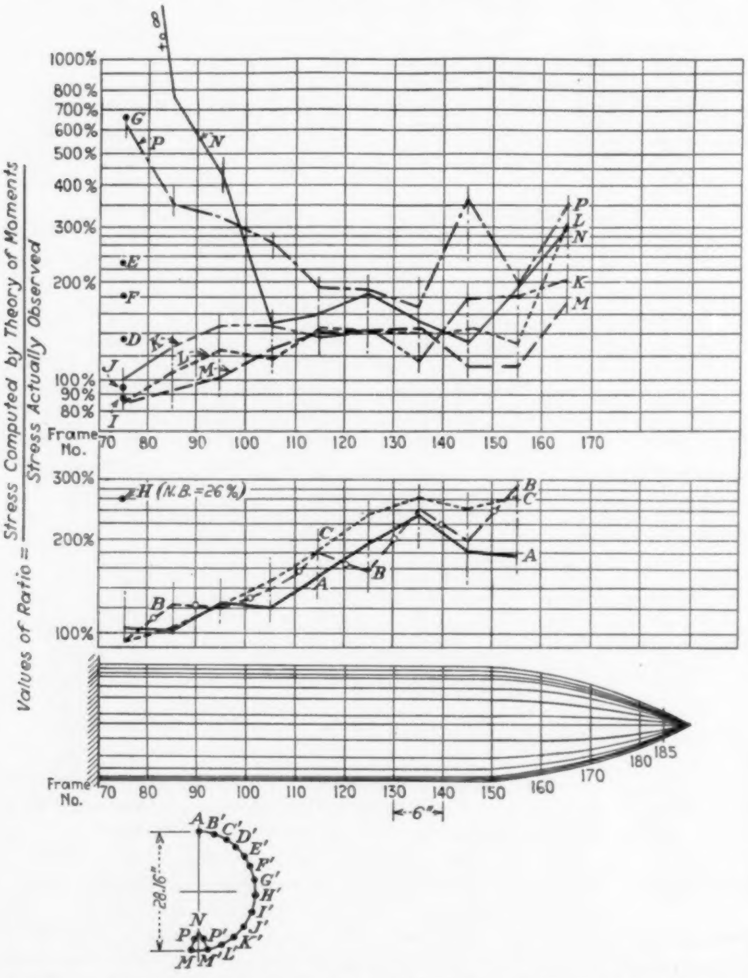

FIG. 9 RATIO OF STRESS COMPUTED BY THEORY OF MOMENTS TO STRESS ACTUALLY OBSERVED IN "SHENANDOAH" MODEL

The point at which the trend in the ratio alters is somewhat near the point at which the parallel body changes to curved body, and this point is frame 140, where the extension was joined to the original model.

That the discrepancy persists for so many bays, and does not become zero until the very rigid supporting wall was reached, is remarkable, when it is recalled that this model had in it all of the double diagonals of the primary shear wiring; the double diagonal system of secondary wiring; the rigidity of the joints that results from the very thick celluloid truss members that had of course, to be used; the highly redundant wiring of the main transverses, which occurred at every second frame; every one of which conditions is essential for the obtaining of correct results from the theory of moments. But in spite of all these favorable elements, the discrepancy is large, and it extends through 12 bays.

A point of interest is that the nose cap[6] produced marked stresses in the secondary longitudinals, which could otherwise get no stress because of the absence of any shear wire connections. This paper explains why stresses developed; it has not yet gone sufficiently far for the author to be able to compute, in so complex a structure, just what the stresses should be. Moreover, the stresses in the longitudinals of the model are a function of the reactions at each of the pin joints at the wall, because frame 70 was a wired frame and probably caused, therefore, shearing stresses on some of the joints. Unless these reactions were known it would not be possible to compute the stress.

It is evident that *N* and *P* have composite stresses; first, a stress of the same sign and proportionally about the same value as *L* and *M;* second, a stress of opposite sign resulting from cantilever action of the keel from its connections to the rigid wall support. Since the keel is much more flexible than the shell, this effect disappears in about four frame spaces, beyond which the members *N* and *P* act very much like the adjacent longitudinals.

Little can be said about members *D, E, F, G, H, I,* and *J* because they were recorded only for frame space 70–80. Their values are plotted in Fig. 9 in the same manner as the others, but of course only as single points. All that can be said of them is that passing around the perimeter of the section from *A* to *M* the ratio increases progressively (excepting that *E* and *F* are reversed) until *G*[7] is reached, i.e., to about mid height, and then there is an abrupt change to a very small value for *H*, after which the ratio again increases steadily to about unity at the bottom longitudinals. In a general way the ratio has a value that approximates to the cotangent of the central angle between the longitudinal in question and the horizontal, transverse axis of the cross-section.

[5] For top and bottom longitudinals, but not for side longitudinals and keel members.

[6] There were also such stresses without the nose cap.

[7] The ratio is negative at *G*.

area. Length of bay equal to radius of circumscribing circle. The methods of moments and shear assume infinitely rigid bulkheads at the loaded frames. These methods give identical results. The stresses have been computed from the customary formulas,

$$S = \frac{F}{\sin\phi}\,\frac{\sin\theta}{\Sigma\sin^2\theta}$$

$$S = \frac{Fl\,\Sigma y}{2\Sigma y^2}$$

where ϕ = angle between diagonal and longitudinal
θ = angle of facet to horizontal
F = $^1/_2$ lb.
l = length of diagonal
y = distance from any longitudinal to neutral axis (which is the center line)

The summation of y applies to all longitudinals above (outside of) the diagonal in question.

Note that the stresses in the longitudinals do not prove to be planar, but that on a zig-zag section they are planar (i.e., on a section, for instance, through A_0A_1, B_1B_2, C_0C_1, D_1D_2, E_0E_1). In other words, the total horizontal stress at the joints of any frame is planar. This is true regardless of the direction of the diagonals.

Appendix No. 5

NOTES FROM R. & M. 948, 971, AND 977, BY PROF. A. J. SUTTON PIPPARD

In these papers Professor Pippard has given an excellent series of experiments on a hexagonal, parallel-body tube, with and without crossed diagonals, with and without transverse bracing, and with and without a conical nose piece. The study was made to determine the accuracy of the design methods advocated by the Airship Stressing Panel, R. & M. 800, of which he and R. V. Southwell were members.

		Final average	128		Final average	128	

These papers afford an excellent basis for studying the effect of variations in redundancy. Only in two respects are the experiments disappointing: that they deal only with a hexagon, and that they are confined entirely to parallel body, with a conical nose piece, from which must be drawn conclusions as to ships of 32, 36, or more sides, and of continuously curved profile. In spite of these shortcomings, they are a valuable contribution.

Let us study Table 4, which is based on his set No. 1, R. & M. 977, Load Systems Nos. 6 and 7. In the calculated stresses the crossed-wire redundancy has been met by *assuming equal division of shear between the wires*, although this is inconsistent with the actual observed distribution. See Fig. 10 for diagram of members.

In this table several interesting points appear. There are actually stresses in the side gores (2–3) where statically none can develop; clearly therefore there was considerable rigidity in the joints of the transverse frames, due to the use of screwed studs of small diameter (p. 4). As an average, for bay *CD*, the statical stresses are 116 per cent of the observed, indicating that approximately 14 per cent of the load has been lost from the upper and lower gores; for bay *BC*, 131 per cent and 23 per cent; for bay *AB*, 137 per cent and 27 per cent, respectively; and these figures hold very closely for both load systems. There is wide variation between the wires of each diagonal pair, and since in the quasi-statical computation the redundancy was met by assuming equal division of stress, the ratios show equally erratic values. It is interesting to note that the variation from equality increases progressively from bay to bay, and, perhaps strange to say, in the same manner for both load systems in almost every case. In R. & M. 800, Appendix V, it is stated that the fictitious bar effect must produce such a variation, which is not the same in successive bays; but the fictitious bars cannot act in a single parallel gore because they lie at the center line of the gore, and therefore can have an effect only on that part of the load that is carried by a secondary stress system.

The longitudinals do not all differ from the computed stresses by a constant percentage, but if the diagonals, instead of being assumed equal in stress, are altered to the same ratio as that of the experimental results, the longitudinals are found to be somewhat more consistent (i.e., about 5 per cent better in bay *BC* and 10 per cent in *AB*).

Comparison of the two load systems, Nos. 6 and 7, shows that doubling of the load at D_4 causes a doubling of the stresses in the two top gores within an error of 3 per cent (except A_3B_3 which is about 7 per cent). The secondary effect (to be discussed later) is evidently also doubled, as might be expected.

On the other hand, the lower gores for system No. 7 should agree closely with the upper gores of system No. 6, because they are caused by identical loads. But in fact, this agreement is not close, and moreover, a change takes place between the end bay and the other two. For instance a rearrangement of Table 4, as given in Table 5, brings out the condition more clearly.

TABLE 5

Member	System No. 6	Member	System No. 7	Ratio, per cent	Averages	
C_3D_3	102.6	C_2D_2	85.6	83.4

B_3C_3	263.4	B_2C_2	300.0	114		
B_4C_4	—633.2	B_1C_1	—578.4	91.5	102.7	
B_3C_4	130.0	B_2C_1	102.4	78.8		
B_4C_3	—104.6	B_1C_2	—128.0	122.5	100.6	101.6
A_3B_3	378.8	A_2B_2	481.2	127		
A_4B_4	—1001.2	A_1B_1	—918.8	91.5	109.2	
A_3B_4	134.6	A_2B_1	93.6	69.7		
A_4B_3	—89.8	A_1B_2	—132.6	147	108.3	108.8

It is evident that the first and fourth lines of each group are fairly consistent in themselves, and the second and third lines, in themselves. These pairs consist of a longitudinal and the diagonal of its facet that causes its stress increment, showing that the source of variation lies in the division of stress between the crossed diagonals. The average of the four ratios of each group is approximately 100 per cent, but increases slightly toward the wall support, and the averages of the pairs of ratios in each group of four are almost equal.

For both load systems, Nos. 6 and 7, there is a resultant net shear on the whole cross-section (upward on the right) of 200 lb., hence that portion of the observed stresses that results from rigidity of the joints has a common element of the same sign. This seems to be a sufficient explanation of the lack of agreement noted in the second paragraph above.

It may be concluded from the experimental results that the load is carried by two means; first, a statical system that agrees well with the statical conditions, and, second, a secondary system that carries an increasing percentage of the load as the rigidity of the joints of each successive frame has opportunity to act. (But see later discussion of R. & M. 971, in which the shear carried by each gore remains almost constant.)

The method of support on the wall at the left end is undoubtedly influential in the inducing of secondary stresses (which can perhaps be said to have a trend toward St. Venant's principle), and if a symmetrical structure were tested, having a reaction at A_1 and another at A_4, similar to Fig. 1, the secondary effect might be greatly different.

Professor Pippard clearly sets forth the limitations of his apparatus, citing the "substitution of partially fixed joints for pin joints," the "elastic bulkhead in the plane of the transverse frame at which the load is applied, instead of applying the load in a special manner in order to prevent collapse." He found that "initial tensioning plays an important part in stress distribution." In his first experiment he found it necessary to apply corrections of from 2 per cent to 12 per cent in order to show equilibrium at the joints, and all of the correction was applied to the longitudinals because of their relatively large size.

Experiments Nos. 2 and 3 are similar to No. 1, except that "great care was exercised in getting the cross-bracing wires and the bulkhead bracing very tight," and that in No. 3 "the radial members in the end bulkhead, which had previously been 4 B. A. swaged rods, were replaced with $^5/_8$-in.-diameter steel rods." In Experiment No. 2 "there are appreciable differences between the measured and theoretical loads in the members, the characteristic being that the loads in the wires of the top panels, that is, C_4D_5, C_5D_4, etc., are larger than calculated, while the loads in the remaining wires are smaller." In Experiment No. 3 "it is clear that the elasticity of the end bulkhead is an appreciable factor in the distribution of loads in the structure, and care is needed to insure that such bulkhead bracing is effective if the theoretical results are to be applied to the calculation of strength." In this experiment the maximum discrepancy is about 3 per cent, as compared with 31 per cent in experiment No. 2.[8] Clearly the very rigid $^5/_8$-in. bars can be considered almost infinitely rigid,[9] so that the results should check the theory for such a condition; but the wires of Experiment No. 2 are such as to give a considerable degree of rigidity, and yet there are discrepancies of 12, 13, 14, 29, and 31 per cent in C_4D_5, B_6C_1, B_4C_5, C_5D_4, and A_5B_4. It is of interest to note that the last of this list is in the wall bay, furthest from the load.[8]

In Experiment No. 4 all bulkheads were braced with 4 B. A. swaged rods but there was no other change. "It will be seen that in the bay between bulkheads *C* and *D* there is a serious difference in all members between the actual and calculated loads, the panel $C_4D_4C_5D_5$ carrying much more than is indicated by theory and the other panels correspondingly less. Once the bulkhead *C* is passed, however, the measured and calculated loads agree well."

In Experiment No. 5 the end bulkhead was braced with $^5/_8$-in.-diameter rods and the others as in Experiment No. 4. The maximum discrepancy here, in member A_4B_5, is about 4 per cent.

In Experiments Nos. 7, 8, and 9 a conical nose piece was applied and the stresses measured. The top longitudinal was also a $^7/_8$-in. solid "keel" bar. In No. 7 there was bracing in the end frame only; in No. 8 all frames were braced with 4 B. A. rods; in No. 9 there was bracing in the end frame only, using $^5/_8$-in. rods. A comparison of No. 7 (with nose) with No. 6 (without nose), and with the calculated stresses for No. 6, shows that in 14 cases out of 18 the measured stresses of No. 6 agree more closely than those of No. 7. This indicates that the addition of the nose piece causes a wider discrepancy from the calculated stresses. A comparison of the ratios of calculated stress to measured stress in No. 8 and 7 shows that there is better agreement in some members in the latter case. Even in No. 9, with its heavy bracing in the end frame, combined with the nose piece, there are discrepancies of 23, 25, 27, and 32 per cent. It is clear that the nose structure serves only to disturb the approach toward agreement with the planar stresses. The addition of radial bracing in the intermediate frames of No. 8 only serves to magnify the error in some of the members. Professor Pippard himself states, referring to the experiments with the nose piece, "the redistribution of stresses requires a long tube in which to become operative" (p. 18); "when the transverse was approximately rigid in its own plane, the loads induced in the members of the nose piece were sufficient to cause some of them to bow" (p. 20); "for effective restraint a very stiff nose structure is necessary, as well as a very nearly rigid transverse frame" (p. 20); and, finally, under the head of Conclusions:

---

[8] See point *B*, Fig. 8.

[9] See point *C*, Fig. 8.

"It appears essential, however, that both the transverse frames and the nose structure must be very stiff if anything approaching a close approximation is to be obtained.[9] Even under these conditions, the stresses in the members appear to require a considerable length of structure to adjust themselves to the theoretical values. This may be well appreciated when it is realized that the nose members introduced alternate tensile and compressive axial forces to the joints of the transverse frame to which they were attached, and although the system gives zero resultant axial force, this distribution of load is one which clearly requires some length of tube before the high local stresses imposed can be equalized."

FIG. 11 (SEE R. & M. 977)

In Experiments Nos. 10, 11, and 12 he shows that torsional stresses of a braced tube agree well with theory, but in Experiment No. 13 where all bracing was omitted, the gores adjacent to the two applied forces of the couple, i.e., 2–3 and 5–6, carry almost the entire shear, in accordance with statics.

In R. &. M. 977 he concludes (p. 12): "it is evident that redundant bracing when in the plane of the bulkhead is far more efficient than when placed in the panels, in conducing to an equalization of stresses;" "unless efficient bracing is provided in the plane of loading to act as an initial distributor of the external load, even if the tube exhibits a high degree of redundancy in other planes, the process of equalization is a very slow one and the stresses, even at a distance from the plane of loading, are dependent to a considerable extent upon the arrangement of the load system;" "it is important that effective bracing should be provided in the plane of the load system. Unless this is done there is a very serious liability of error."

In R. & M. 971, Table 2, are given the measured loads in the structure when the end frame is wired with 4 B. A. wires, but all wires acting downward to the right are omitted. It can be seen that the bracing system serves to distribute the load of 100 lb. at D_4 to the lower gores, which carry their shearing force almost constant to the wall, with little apparent change due to the secondary system. The general conclusion reached is that the "device of the separate panel" is a good approximation, i.e., that in effect, each redundancy of the crossed wires is largely confined to the members of the facet containing the redundant member.

* * * * * * * *

It may be concluded from Pippard's experimental results that the crossed-wire redundancies are of somewhat local nature; that very rigid bracing is required at all loads; that after a second braced frame is passed St. Venant's principle may be effective in *parallel body if the bracing is very rigid*, but that in curved body (i.e., when there is a conical nose) there is still a serious discrepancy even after 3 braced frames have been passed.

Appendix No. 6

RELATIVE RIGIDITY OF TIGHT-WIRED AND UNWIRED FRAMES

The modern type of ring frame is in general formed of three polygonal rings braced by a Warren system in three planes to form a complete ring of triangular section. For the purpose of this paper it is sufficient to reduce such a structure to a planar ring having an outer and an inner chord, braced together by a single system. The relative sections of the chords may differ, but it is assumed herein that they are of equal area.

It is simpler to treat them also as being circular instead of polygonal. Professor Pippard, in R. & M. 913, and previous papers, has derived formulas for their change of shape under load. The formulas are complex, but fortunately the author has found that they may be reduced to simple approximate terms. Applying a correction, then, to the formula for the deflection of a circular ring due to two axial loads of P,

$$\Delta_d = \frac{2PR^3}{EI}\left(\frac{\pi}{8} - \frac{1}{\pi}\right)\left(\frac{\sin\theta}{\theta}\right)^3 \cos^2 \tfrac{1}{2}\theta$$

where Δ_d = the axial elongation of the polygonal ring of $2N$ sides
N = one-half the number of sides
θ = one half the central angle subtended by one side
R = radius of center line of the ring
E,I = modulus and moment of inertia of the ring.
Let r = outside radius of the ring
qr = radial depth of the ring
A = sectional area of either chord
a = area of section of the bracing wire of previous studies

Then $\Delta_d = \dfrac{2Pr}{aE_s} = \dfrac{0.15P(r - \frac{1}{2}qr)^3}{\frac{1}{2}E_A q^2 r^2}\left(\dfrac{\sin\theta}{\theta}\right)^3 \cos^2 \tfrac{1}{2}\theta,$

and since $\dfrac{aE_s}{AE_A} = k,$

$$k = 6.65\,\frac{q^2}{(1 - \frac{1}{2}q)^3}\left(\frac{\theta}{\sin\theta}\right)^3 \sec.^2 \tfrac{1}{2}\theta$$

If $q = {}^1/_8$, in an 8-sided ship
then $k = 0.142$, which is the value marked A in Fig. 8.

This approximation is correct with 1 per cent, in so far as the formula is concerned. The assumption, however, that the deflection of an unwired ring is the same in its effect on the shell stresses as the stretch of a single vertical wire, cannot be correct, because in the former case the ring members in part belong to both systems, shell and ring, and do work in both. Or to look at the problem in a different light, the change of shape of the transverse frame (unbraced) of the shell will not be the same as the change of shape of this frame when acting as a ring, hence there will be reactions not only at the two joints where the loads P act, but reactions also at *every joint* of the frame.

To determine roughly whether the discrepancy of these two deflection shapes would be great, the shape of the two is shown in Fig. 10. They do not agree, showing that a more accurate result must still be obtained for the effect of the unbraced ring.

The self-determinate frame with vertical central wire if loaded alone would transmit all stress through the central wire, and would be similar to the single wire, hence this computation is a rough approximation to such a frame.

Discussion

Karl Arnstein.[10] The paper is a very interesting outline of strength calculation as applied to rigid-airship design. The data used in this analysis have been obtained from existing publications dealing with stress analysis and from some of the author's calculations on assumed structures.

Although the method of approach is of interest, the conclusions cannot be considered as sufficiently applicable to warrant the passing of judgment upon the airship art, particularly in view of the fact that the papers published summarize only a portion of the work which has been done in the study of stress analysis for airships.

It also is to be regretted that the assumed airship structures have been so "simplified" that they are considerably removed from the types of structure being employed and that the concentrated-load condition considered in this study has such a small bearing on the basic-load distributions experienced in airship design that the results of such an investigation should not be used for the comparison of airship types.

Even in the early Zeppelins attempts were made to avoid concentrated loadings. In those cases where concentrated loads were unavoidable, special provisions were made for getting these loads into the frames. In the case of the bottom keel, which may well serve as an example, the lower section of the frames was considerably stiffened by framing in order to distribute the load over a larger portion of the frame.

On these early ships it also was the practice to use auxiliary framing at those points on the hull where inward radial loads could be expected. In the U. S. Navy airship *Akron* the distribution of both types of loading to the frames is efficiently carried out by means of (*a*) the two lower longitudinal keels and (*b*) the use of inherently stiff main frames.

It should be remembered that with the increase in size of airships the resistance to static loads is becoming a smaller factor in the overall strength of the ship, while the aerodynamic loads are becoming more severe.

Fortunately these aerodynamic loads are far from concentrated, their effect being felt over large portions of the ship's surface. Most of these loads are experienced near the bow and the stern of the ship, where the structure is extremely rigid, due to the small diameter of the frames and the domelike character of the structure.

It also should be recalled that since the bending moments may be practically the same all around the cross-section, a linear stress distribution (St. Venant) is by no means ideal. In fact, a distribution giving a somewhat reduced maximum fiber stress is more economical, even though the stresses nearer the neutral axis may depart considerably from a straight-line distribution.

Comparative calculations, using the method of least work, have demonstrated that the character of the stress distribution cannot be wholly charged to the rigidity of the main frames. The character of the distribution is primarily dependent upon the relative rigidity of the main frames and shell.

Charles P. Burgess.[11] The author has presented an interesting paper on the interaction of longitudinal and transverse stresses in rigid airships. The bulk of the paper is presented as a progress report, and criticism is forestalled as it is not clear whither the progress is leading.

It has long been known that the shear in the neighborhood of large local keel loads is not distributed in accordance with the usual fairly simple theories used in the calculation of airship stresses. In modern rigid airships this departure of local stress distribution from theory is of small importance because the static loads are so distributed that they do not cause large shear forces or bending moments. The aerodynamic forces are responsible for the greater part of the shearing stress, and these forces are so distributed around the cross-section that they do not cause enough transverse distortion to have more than negligible influence upon the longitudinal stress distribution. Large local aerodynamic forces occur only upon the tail surfaces, and extremely strong transverse frames are used to transmit these loads into the hull of the ship.

Observations with strain gages on the U. S. Navy's airships *Shenandoah* and *Los Angeles* in flight have shown that the stress distribution approximates to the bending theory and that the departures from theory are on the safe side. In other words, the stresses in the longitudinals vary somewhat less than as their distances from the neutral axis, so that the maximum stresses are smaller than calculated by the bending theory. The longitudinals near the neutral axis take a considerably larger percentage of the total bending moment than calculated; but since the stresses in these members are small, the departure from theory is of no practical importance.

It is to be hoped that the author will continue his researches and give airship designers the benefit of his conclusions regarding the exact distribution of local stresses. Here, again, a reservation must be made in regard to the use of the word "exact" in airship stress calculations. Such calculations may be mathematically exact, but practically they never can be so, because the real distribution of stress from any given set of forces is locally very much influenced by unpredictable conditions involved in the construction of the ship and the initial tensioning of the vast maze of wires which take the shear and gas-pressure forces.

A. J. S. Pippard.[12] The problem of stress determination in such a complex structure as that of a rigid airship is so difficult that any work bearing upon its solution is to be welcomed, perhaps more especially when such work is of an arithmetical nature. It is comparatively easy to suggest possible methods of attack, but without the check of arithmetic these will not make a very forcible appeal to the engineer responsible for the design of such a structure.

The author indicates that he is endeavoring to find a solution by reducing his structure to a statically determinate frame, the stresses in which will then be corrected for the effects of redundancies.

The typical airship structure has such a large number of redundancies that treatment by exact methods is impossible on account of the labor involved, and while the author's proposal is, theoretically at least, one method of attack, one feels that treatments which in the first place assume the structure to be completely redundant and then apply corrections on the results obtained are much more hopeful.

[10] Vice-President, in charge of engineering, Goodyear-Zeppelin Corporation, Akron, Ohio. Mem. A.S.M.E.

[11] Bureau of Aeronautics, Navy Department, Washington, D. C.

[12] Professor of Civil Engineering, University of Bristol, England.

Stress analysis of a statically determinate structure is a simple matter, since the elasticity of the members does not affect the result. The introduction of even a single redundancy, however, changes the character of the problem, since the elasticity of the members then enters into the calculations. As the number of redundancies increases, the stress distribution will usually depart further from that of the simple frame. The two problems are different, and on this account the writer is doubtful whether the author will obtain a general method of analysis of sufficient accuracy for airship work by the method which he is suggesting.

Coming to the tentative conclusions of the paper, the writer agrees with a number of the points in principle.

It is essential that the transverse bracing shall have a considerable degree of rigidity if the standard methods which the author quotes are to give a high degree of accuracy, but the writer thinks the error in the total stress at any point will not be considerable with the degree of rigidity obtainable in a modern airship. Possibly the author is overanxious as to the loss of rigidity of ring frames when these are loose-wired, since experience of the British airships showed that such frames can be made remarkably rigid.

It was pointed out in the report of the Airship Stressing Panel (R. & M. 800) that any local variation in the section of a ship such as that introduced by a keel or a corridor would cause departure from the stresses calculated by the methods set out in that report, and the writer agrees with conclusions No. 4 and 5. He also agrees with conclusion No. 7, that redundancy due to crossed diagonals in the facets has a rather localized effect, and the successful "device of the separate panel" suggested by Professor Southwell for dealing with such redundancies is based on this fact.

With regard to conclusion No. 8, it is clear that joint rigidity may in some cases be of importance; continuous or rigid joints do in effect introduce extra redundancies of a sort which apply secondary stresses to the longitudinal members. The magnitude of such secondary stresses is a problem which requires considerably more analysis, but it is a difficult one and peculiar to each design.

In conclusion the writer would like to thank the author for the kind references to his experimental work and to say that he regrets that circumstances did not allow him to continue the work upon structures more nearly approximating the shape of a modern airship.

Author's Closure

Since the paper was printed, an attempt has been made to evaluate the effect of providing bracing in *all* frames, instead of only those frames where loads were concentrated. This computation was carried out for the case of a ship six bays long and of square cross-section. The results are shown in Fig. 12 by the curved marked "Square—all frames braced." Comparison of this curve with the one marked "Square," which is for a ship similar in all respects, except that only those frames where loads occur are braced, shows that with all frames braced the stresses deviate even more markedly from the infinitely rigid case.

The very able discussions by Dr. Arnstein, Mr. Burgess, and Professor Pippard bring out clearly the complexity of the problem confronting an airship designer. It is so complex that, as Mr. Burgess points out, "exact solutions are practically unobtainable." After a large number of ships have been built, of different sizes, there will, it is hoped, be developed satisfactory empirical or semi-empirical rules for design. But until such rules are developed, and proved to be satisfactory in successful ships, the art must depend upon such analyses and tests which those interested can perform, even upon simplified structures. While such analyses and tests may not give a complete answer, they are nevertheless necessary to point the way and to set up warning signs at pitfalls that may beset it. It was from this point of view that the author started his investigations.

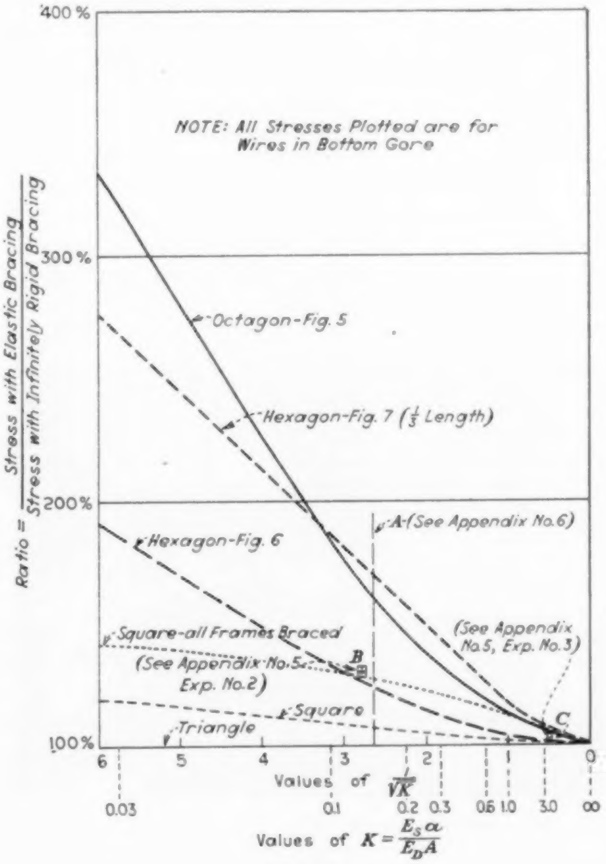

FIG. 12

(This is Fig. 8 of the paper, with a curve added for "Square—all frames braced.")

The author wishes to express his thanks to those who have so interestingly discussed the paper and also to acknowledge his indebtedness to the National Advisory Committee for Aeronautics for a large mass of data made available to him in this research.

Special Methods of Testing Aircraft Materials

By DAVID M. WARNER,[1] DAYTON, OHIO

This paper presents a study of special methods employed at Wright Field in the mechanical testing of characteristic aircraft materials and construction, together with a practical exposition of the special equipment developed. The testing of welded joints, riveted joints and fittings, and of parts such as axles, wheels, and brakes has been discussed, together with the combined loading of struts, columns, and beams. The proportional loading of wing ribs, the elimination of low-strength steel tubes, the reverse bending of streamline wires, the superiority of preformed cable, the determination of an economic pulley-cable diameter ratio, and the fatigue testing of streamline wires and of extra-flexible control cable are taken up in detail. The advisability of testing aircraft-engine materials over the temperature ranges to which they are subject in service is emphasized by the tension and Brinell results obtained on typical light piston alloys. The importance of simulating service conditions, especially in all tests involving endurance in any form, is heavily stressed.

THE mechanical testing of aircraft structural materials for the purpose of determining their physical properties and characteristics is done in accordance with standard practice and methods of procedure as recognized by the American Society for Testing Materials and other engineering societies. However, a relatively high percentage of the testing done in the aircraft laboratory is on fabricated parts, accessories, and assemblies of great variety whose strength and other characteristics depend quite as much upon design and fabrication as upon the qualities of the materials of which they are constructed. The variety of shapes, forms, and combinations which find their way to the Air Corps laboratory constitute a representative cross-section of the whole field of aircraft design and construction, both commercial and military. The methods of procedure and the equipment required for doing the work are governed by the data to be derived. For making most of the simpler tests it is usually possible to get along with improvised set-ups in the universal standard testing machines, but for those involving special conditions, such as elevated temperatures, combined loading, friction, fatigue, or endurance, it is necessary to provide special jigs and set-ups, and for some tests special machines must be developed.

In these tests the specific conditions of service are simulated in such manner as to make it possible to derive empirical data in a relatively short time, which otherwise could be obtained only from actual service, with the attendant loss of time and with the added uncertainty of the influence of accidental factors.

After a brief review of some of the more characteristic tests, a few special methods and developments will be presented in detail.

Special Tests With Jigs

The general use of gas and electric welding as a method of joining steel tubes in the construction of fuselage, landing gears, and similar parts makes it necessary to test samples of the various types of joints from time to time in order to insure the maintenance of a high standard of workmanship. The cluster joint is cut out of the fuselage, with the various members left long enough for holding in the tension machine. The joint is then jigged up for support in such position as will insure a direct loading on the member under test. The efficiency of the joint in each case is reported as a percentage of the original full strength of the member. The values obtained in all tests requiring improvised jigs and set-ups are largely dependent upon the experience and judgment of the testing engineer.

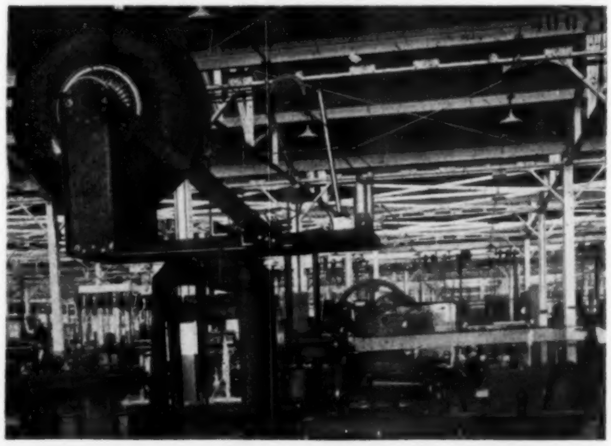

Fig. 1 Brake Test Set-Up on Universal Testing Machine for Friction and Proof Loading Tests

Riveted joints are tested in the same manner. The size, number, and locations of rivets will be reported with the materials data, and in the case of welded bases the quality and appearance of the welds also will be noted.

Fittings and parts are tested in accordance with their assembly requirements as to supports and direction of loading. Fittings are usually secured to an appropriate jig or mock-up to simulate service conditions, and mounted in the testing machine in such manner as will insure direct loading on the part under test, a new set-up being required for each lug or other member. Cantilever axles are mounted on a base beam, on which they are supported by means of their regular lugs, while the loads are

applied perpendicular to the wheel bearing at its middle point in a universal testing machine. Deflections for curves may be taken from a projecting arm attached to the spindle and extending parallel to its axis.

Struts and columns are usually given only axial loading, but occasionally combined column and bending data are desired, in which case the member is mounted in a suitable jig and tested in a standard compression machine. When tested for independent loading, the transverse load is usually applied by means of a dynamometer, but when proportional loading is desired, one end of the column is supported by a lever which converts a percentage of the column load into transverse load, which is applied to the side of the column by means of cable and pulley or other mechanical arrangement. In either case the column is given lateral support to prevent displacement by the transverse load. Deflection data are taken by means of either scales or dial indicators as desired.

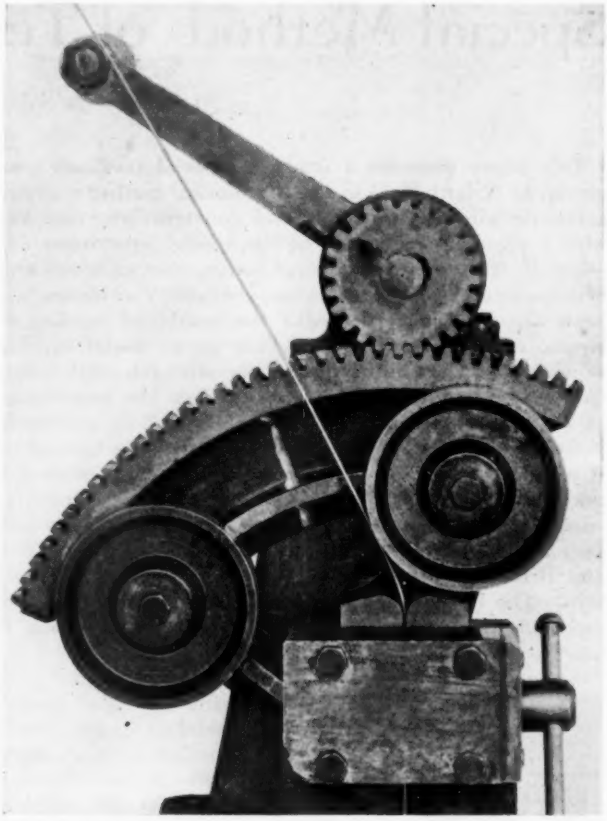

Fig. 5 Reverse Bending Machine for Testing Wire, Especially Streamline Wire (D. M. Warner)

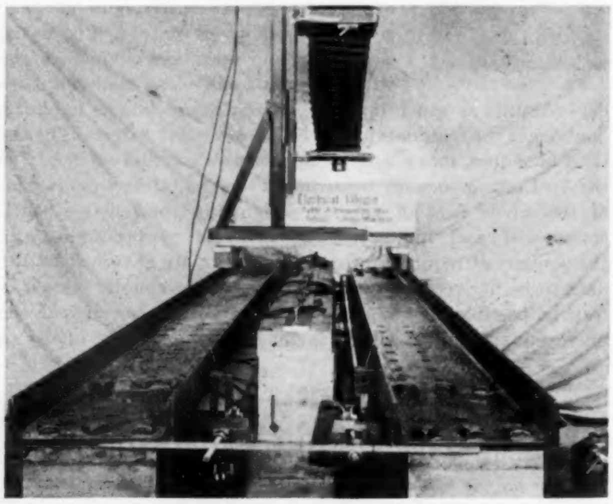

Fig. 6 Fatigue Machine for Vibrating Streamline Wire Under Tension, With Camera Set-Up for Measurements (D. M. Warner)

A series of experimental wing beams of different designs and constructions was tested in combined torsion and bending for the purpose of comparison. A special ring was built in connection with an Olsen 50,000-lb. testing machine for the work (Fig. 2).

It consists of two end-anchor or fulcrum units, a central torque unit, and a connection unit through which the torque moment is applied and weighed by the tension-testing machine. The ends of the beam were secured in the end units, which are fitted with roller-mounted knife edges to resist rotation and to prevent longitudinal binding. The torque moment was applied by means of a large disk at the center, through which the beam was passed and carefully centered. Two tension cables passing off in opposite directions from the top and bottom of the disk establish a couple tending to rotate the beam. The two cables were brought together through the connecting unit overhead and passed down through the weighing head of the machine to the power head. The transverse loads were suspended from a ball bearing which rides in a concentric slot in the lower quadrant of the disk. The deformation data were taken at regular intervals along the beam by means of Wisler dial indicators operated by fine wires from quadrant arms. The results obtained with this set-up were quite satisfactory.

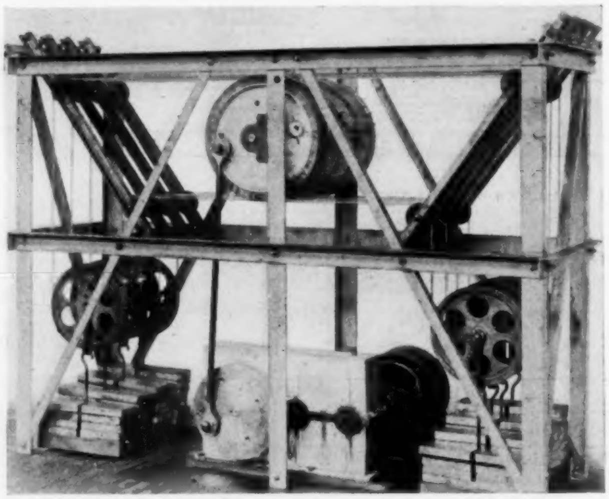

FIG. 10 CABLE AND PULLEY FATIGUE MACHINE FOR TESTING CONTROL CABLES, PULLEYS, AND ANTI-FRICTION PULLEY BEARINGS (D. W. WARNER)

Airplane wheels are usually tested with tires assembled. For direct radial loading the wheel stands on a sand bed in a box mounted on top of an Olsen 100,000-lb. universal testing machine, while the loads are applied through a pair of slings dropped from either end of the spindle shaft to a crossbar under the power head. Radial deflections are taken both vertically and laterally by means of special extensometers. For side-load testing a wheel is assembled horizontally on a vertical shaft in a strong base jig which is mounted on a universal testing machine. The side load is applied through a system of straps glued to the upper half of the tire, which collect and pass over its edge to a cable leading down to the power head. By this method the wheel is given cantilever loading at its assembled radius limit with the effect of the roll of the tire included.

Brakes are tested while the wheel is assembled in a vertical position free to rotate on a shaft in a cantilever jig, which is mounted on top of a large universal testing machine (Fig. 1). The brake is applied by means of a spring dynamometer attached to the hand lever, while torque is delivered to the wheel through a strap passing over the periphery of the inflated tire and down through to the power head. The brake friction moment is read from the machine, while the corresponding hand force for its application is indicated by the dynamometer. Although this method is not true to service conditions, the parts are tested for strength, and the friction data serve for comparison with other brakes.

SPECIAL METHODS AND EQUIPMENT

Wing ribs are tested as beams supported by spar sections and loaded proportionally over practically the full length of the chord. A special machine was built to accommodate the various sizes and shapes of ribs (Fig. 3). It consists of a table

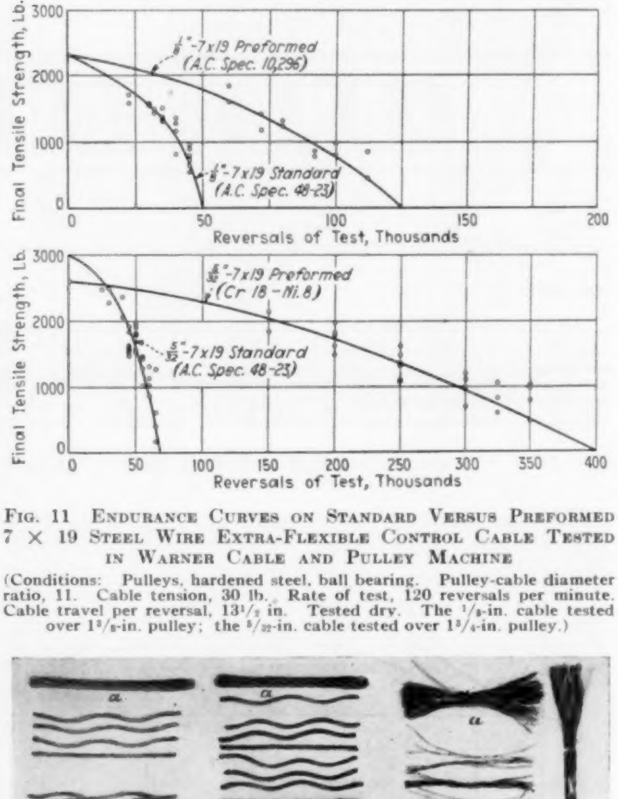

FIG. 11 ENDURANCE CURVES ON STANDARD VERSUS PREFORMED 7 × 19 STEEL WIRE EXTRA-FLEXIBLE CONTROL CABLE TESTED IN WARNER CABLE AND PULLEY MACHINE

(Conditions: Pulleys, hardened steel, ball bearing. Pulley-cable diameter ratio, 11. Cable tension, 30 lb. Rate of test, 120 reversals per minute. Cable travel per reversal, $13^1/_2$ in. Tested dry. The $^1/_8$-in. cable tested over $1^3/_8$-in. pulley; the $^5/_{32}$-in. cable tested over $1^3/_4$-in. pulley.)

bearing a frame for mounting the rib, an adjustable proportional loading-lever system, and a dynamometer and hand screw for applying the loads. The rib is held by means of cross-section blocks fitted into the spar ports, with center holes to fit the two anchor posts, which are adjustable for incidence. The loads are applied along the chord by means of a series of drawbars with adjustable lugs to engage the rib profile. These drawbars lead to the compound levers which distribute the load in accordance with the loading schedule. Wisler dials are mounted at convenient points for taking deflections.

Since tubes are important structural elements in an airplane and the presence of a single low-strength tube might cause disaster, a non-destructive bend test has been devised for the routine inspection of each individual tube. The testing machine consists of a stand bearing a long base on which is mounted a support at either end equipped with balanced knife-edge V-bearings to receive the tube as a beam, and a loading unit at the center with a dynamometer attached (Fig. 4). The tube is mounted as a beam over a constant span and loaded at the middle to produce a stress and deflection representative of the specified minimum yield limit for the grade of material in question. The required loads for the different cross-sectional dimensions are obtained from tables previously calculated for

the various grades of tubing. While this test does not determine the actual strength of the material, it serves to eliminate the tube with low yield point or low modulus of elasticity.

Ductility is an essential requirement of tension members manufactured from wire, since most of them are subjected to vibration. The measurement of percentage elongation in the tension test has not proved to be satisfactory; hence, the reverse bend test has been substituted. One end of the wire is gripped in a vise with jaws rounded to specified radii, while the other is bent back and forth through an angle of 180 deg. to failure. Under these conditions the wire is required to withstand a specified number of 90-deg. bends. When made by hand in a bench vise with rounded jaws, the number of bends not only increase with wire diameter, but the results obtained by different operators often vary by as much as 50 per cent, especially on the larger wires. To eliminate these variables, a reverse bending machine was developed (Fig. 5). It consists of a vise with a pair of radius adapters to accommodate each standard size of wire, a quadrant lever unit which bends the wire back and forth over the adapters through 180 deg., and a crank and pinion for driving the quadrant.

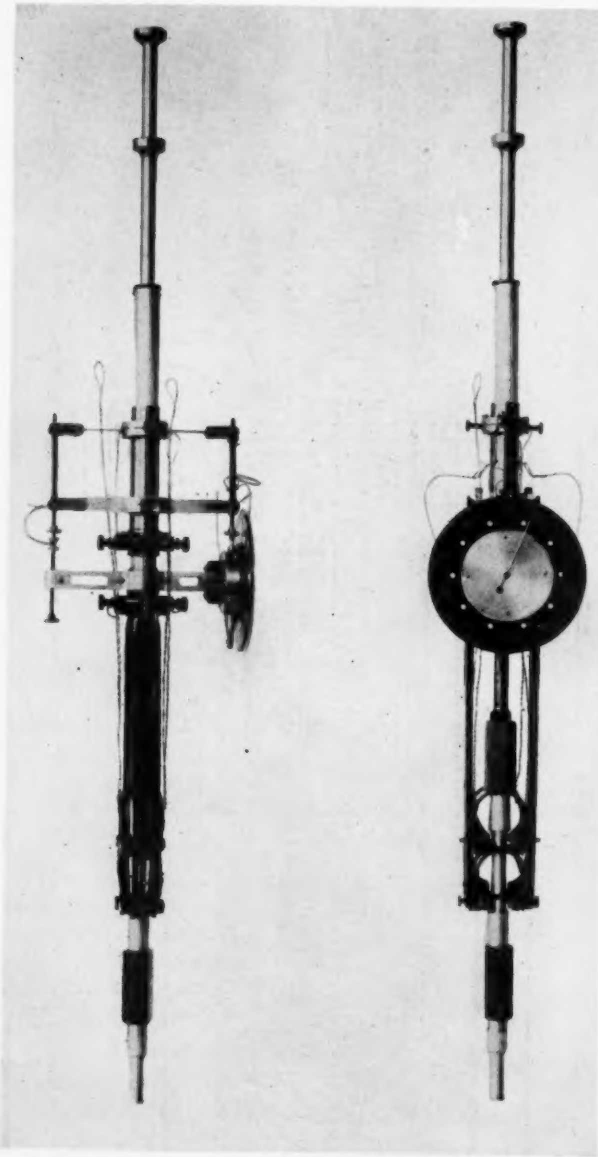

FIG. 16 EXTENSOMETER AND SPECIMEN ASSEMBLY FOR TENSION TESTS AT ELEVATED TEMPERATURES (D. M. WARNER)

While the wire is gripped in the vise one of the two 4-in. rollers on the lever unit bends it across and forces it down over the one adapter, then the other brings it back in the same manner to conform to the other side, and so on to failure. The jaw adapters automatically center the different sizes of wires and regulate the clearance under the rollers, thus making conditions constant for all operators. When the tests were made by hand, the Army requirements on streamline wire ranged from 7 bends on the No. 1 size to 13 on No. 8, but since the machine gives the same number on all wires of like quality, regardless of size, Army specifications now call for 9 bends for all sizes. Streamline wires are bent over radii of three times the thickness, while round wires are usually bent over a radius of $^{3}/_{16}$ in.

For the purpose of determining the cause of failures of streamline wires in service, a series of fatigue tests were made in which the wires were vibrated under tension, until failures occurred, in a special machine (Fig. 6). It consisted essentially of two heavy tension units, each holding three wires under the desired tensions, and a central power unit consisting of a battery of twelve electromagnets to vibrate them. Provision was made for the independent adjustment of each wire for tension and for spacing to or from the magnets at either end, as well as for individual test (Fig. 7).

It was found that failures were due to fatigue from reverse bending induced by the refusal of the terminal fitting to respond to the vibration of the wire. Accordingly, a special fitting with a knife-edge bearing was designed which permitted free vibration and stopped the failures. Check tests were then run on four new No. 5 wires, three assembled with service terminals at one end and the new fittings at the other, while the fourth had knife-edge fittings at both ends. When tested under identical conditions and vibrated to the greatest amplitude that could be maintained, which produced angles of from 4 to $4^{1}/_{2}$ deg. at the knife-edge terminals, the first three wires failed after $5^{1}/_{2}$, $2^{1}/_{2}$, and $6^{1}/_{2}$ hours, respectively, while the fourth, with knife-edge fittings at both ends, continued for over two months without failure. The tests were run under loads of between 500 and 600 lb., representing only about 10 per cent of their rated strength.

A panoramic photograph was taken over the full length of the vibrating wires by means of a camera mounted on a sliding frame, as shown in Fig. 6. From the resulting mosaic, data were obtained for the curves plotted in Fig. 8, which show the behavior of the whole wire, including the damping at the service terminal which caused the failures. The behavior of the two types of terminals is contrasted in Fig. 9. Considerable longitudinal vibration is shown by the concave crosslines.

Steel-wire control cables which operate over pulleys through angles of 90 deg. or less under loads probably rarely exceeding 10 per cent of their tensile strength, fail by fraying in the short sections that pass back and forth over pulleys or guides, with the result that they are replaced when a few broken wires are noticed.

In order to determine the cause and importance of this fraying in service and to determine the relative merits of cables of different materials, construction, and manufacture, it was necessary to make endurance tests on specimens under tension over the standard pulleys and to make a study of the cable and pulley relationship.

Accordingly, a fatigue machine was developed for testing both cables and pulleys (Fig. 10). This machine consists of a rigid steel frame having these features:

(a) A drum located in mid-section for driving the cables
(b) A set of standard control pulleys for the cable to pass over
(c) A set of suspension loading pulleys
(d) A power unit with crank and connecting rod to oscillate the drum through the desired angle.

(Y-alloy; composition: 4 Cu, 2 Ni, 1.5 Mg, remainder, Al. Heat treatment, none. Specimens, A. S. TB1. Skin on as cast. Threaded. Size, 1/2 in. diameter by 2 in. gage length.)

Average Test Results

Temperature, deg. fahr.	Proportional limit	Ultimate strength	Modulus of elasticity
Room	14,460	26,620	10,554,000
300	15,700	26,940	9,332,000
350	13,140	27,570	9,342,000
400	9,310	25,200	9,485,000
450	12,040	26,680	8,018,000
500	12,250	22,090	7,819,000
550	7,490	19,940	8,084,000
600	5,300	15,080	8,011,000

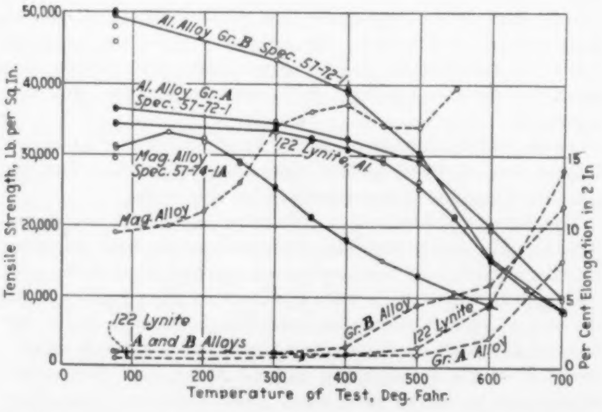

FIG. 18 TENSION AND ELONGATION RESULTS ON FOUR PISTON ALLOYS AT ELEVATED TEMPERATURES

(Tensile results on cast alloys. Specimens, A. C. TB1; gage, 1/2 in. by 2 in.; cast in size. Tested in oil bath after 30 min. at temperature. Olsen 20,000-lb. machine used.)

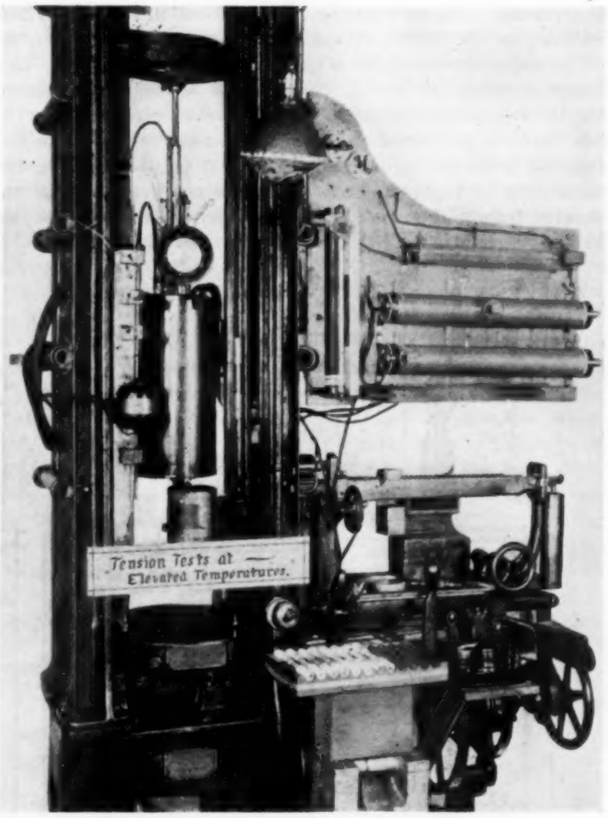

FIG. 19 FURNACE AND EXTENSOMETER SET-UP IN UNIVERSAL TESTING MACHINE FOR TENSION TESTS AT ELEVATED TEMPERATURES (D. M. WARNER)

It has a capacity of eight cable specimens, four at one end and four at the other, and sixteen control pulleys. The pulleys are mounted in pairs, one up and one down, in members set at an angle, to adjust for different diameters.

The cable specimens, made up to standard lengths with eyes at either end, hook on the back of the drum and pass over the top horizontally to the first test pulley, then over through an angle of 90 deg. and down under the loading pulley and up again through 90 deg. over the second test pulley, to return under the drum and up to the hook on the back. The drum eliminates the constant jerking of the load which is inevitable when cables are driven direct from cranks. It drives the cable back and forth over the two test pulleys under a tension of half the suspended load, including the weight of pulley and pan. Any desired cable tension may be applied. A counter on the crankshaft records the revolutions of the test run, or half the reversals. Two independent endurance tests are made on each cable at points several feet apart where it operates over the pulleys. At the conclusion of the endurance run the cable is tested for final strength at both worn sections. These results are recorded, together with the conditions and the number of reversals of test. The original tensile strength is obtained on an undamaged section of the cable. When removed from the machine, the cable is dipped into a solder bath at points several inches back on either side of each worn section to make tension-test lengths of approximately 30 in. The solder prevents the worn strands from shifting and makes it possible to hold the cable in V-grips to make the tension tests.

When a curve is desired, it is made from the endurance results obtained on a series of cable specimens run to regular intervals of reversals. The results are plotted as shown in Fig. 11. These curves show the preformed cable, Air Corps specification 10,296, to be quite superior to the standard cable conforming to Air Corps specification 48-23. Still greater superiority is shown by the preformed cable made of stainless-steel wire. Due to the fact that the preformed and the standard cables look alike and that the latter shows the higher original tensile strength, the superiority of the preformed cable was not evident until endurance tests were made. The chief difference between the two kinds of cable is in their construction, as shown in Fig. 12.

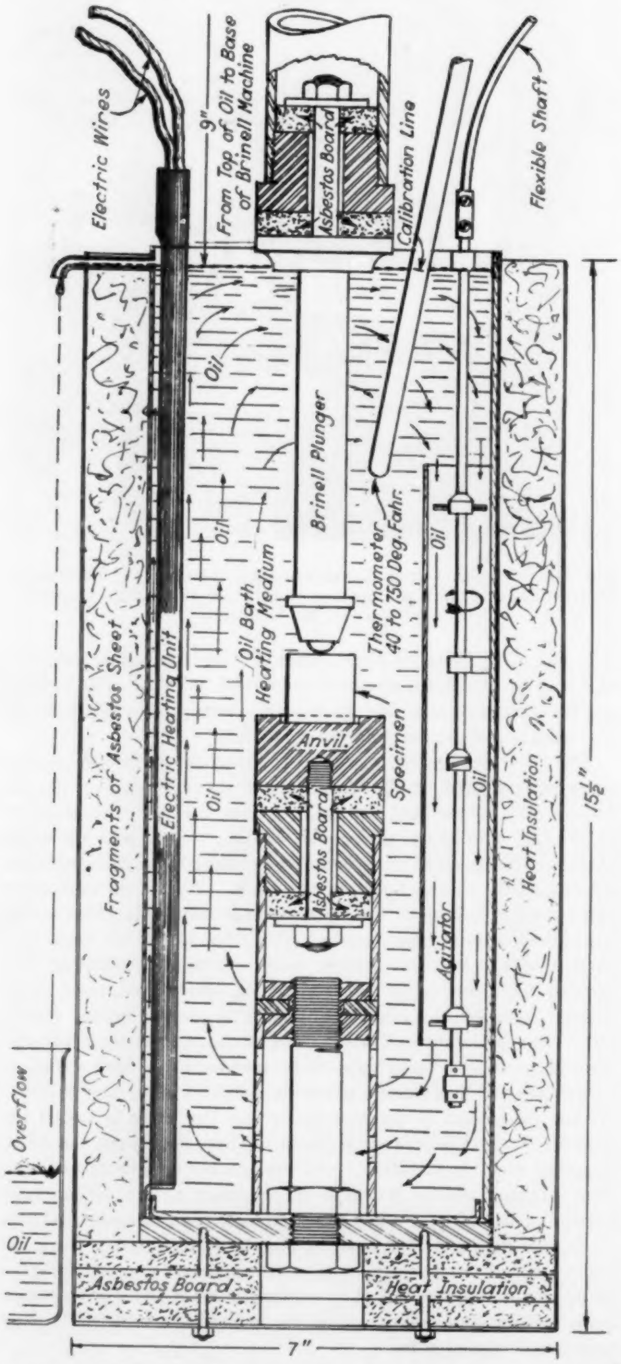

FIG. 20 DIAGRAM FOR FURNACE AND BRINELL SET-UP FOR HARDNESS TEST AT ELEVATED TEMPERATURES (D. M. WARNER)

In addition to the usual tests for materials and assembly strength, it is necessary to resort to the endurance test on control pulleys to determine these factors:

(a) The least practical diameter ratio of pulley to cable
(b) The most desirable type of sheave
(c) The ability of the sheave to resist cable wear
(d) The effect of the sheave on the cable
(e) The relative merits of different types and makes of bearings.

Since control cables and pulleys are always tested together, the same fatigue machine is used for making endurance tests on both, the data being taken in accordance with the purpose of the test. A series of tests was made, on an earlier machine, to determine the least practical ratio of pulley diameter to cable.

Standard $^5/_{32}$-in. 7 × 19 steel-wire cable (Air Corps specification 10 281-A) was run over a series of pulleys machined from cast brass with diameters ranging from 21 down to 9 times that of the cable. The specimens were run over the pulleys through an angle of 90 deg. under a tension of 51 lb. at the rate of 92 reversals per minute. At fairly regular intervals of run the machine was stopped while the broken wires in each cable were counted as closely as possible without removing the specimen, as a measure of the rate of breakdown. The averages of the progressive counts on several cables over each diameter of pulley were plotted against the corresponding average of reversals of test in Fig. 13, to show the rate of cable failure over the different diameters of pulleys.

The final tensile results were plotted against the total count of broken wires in each in Fig. 14. Although the curves would be different under different conditions of test, and especially for the better preformed cable, it is probable that the general relationship between the several diameter ratios would be practically the same.

Endurance tests under constant conditions are run on control pulleys fitted with anti-friction bearings of different types and manufacture to determine their relative merits. At present the size AN-210-4 pulleys so equipped are required to satisfy specified endurance tests under a cable tension of 500 lb.

TESTS AT ELEVATED TEMPERATURE

Because of the high temperatures at which aircraft engines operate it is necessary to test materials to be used in pistons and similar parts for hardness and tensile properties over the entire range of elevated temperatures to which the parts are subject in service, in order to determine their suitability for this purpose and also to determine the relative merits of different materials and treatments. To make such tests the specimens had to be heated to the desired temperature, held constant long enough to reach equilibrium, and then tested at the same temperature.

An electrically heated oil-bath furnace, with mechanical circulator, and electrical heating unit, a special extensometer, and a Brinell adaptation were developed for this work.

The furnace consists of a cylindrical steel tank for the oil, with a light outer jacket filled with asbestos for heat insulation. For the tension tests the furnace is assembled around the lower pulling bolt where, as a unit, it is free to align itself with the upper pulling bolt when the specimen is coupled in for test. The oil is heated by the electrical unit which extends down in one side of the furnace and is kept at an even temperature throughout by forced circulation. The heated oil rises around the heating unit and is driven back down on the opposite side of the tank by the mechanical circulator through a well extending to within 3 in. of the bottom, while the specimen is located midway where the temperature averages practically constant

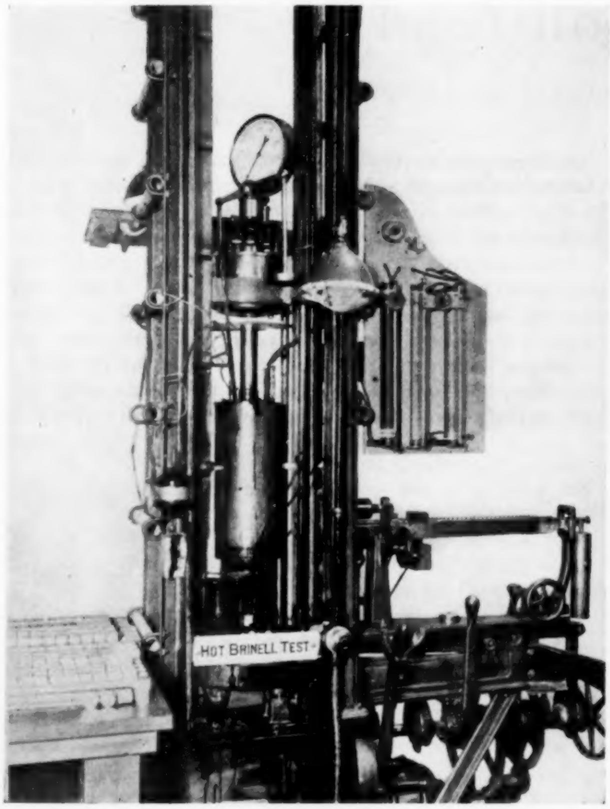

Fig. 21 Furnace and Brinell Set-Up in Universal Testing Machine for Hardness Tests at Elevated Temperatures
(D. M. Warner)

(Fig. 15). The tank is kept full to the overflow pipe by adding a little oil from time to time. The temperature of the bath is indicated by a thermometer (2-deg. graduations) which hangs suspended to an even depth throughout the test.

By preliminary experimentation with thermocouples placed on the outside of the specimen at the end and middle point of the half-inch gage section and in the center of the shoulder a half-inch from the gage section, it was found that the temperature of the specimen came to within 3 deg. fahr. of that of the bath, as indicated by the thermometer, after a maximum of from 15 minutes at 300 deg. fahr. to 8 minutes at 500 deg. fahr. for aluminum alloy. In the tests reported all specimens were held in the furnace for a period of 30 minutes.

By adjusting the thermostats the temperature was held constant at any desired point within the limits of the oil used. Standard threaded specimens with 2-in. gage length were used in these tests. The strain data were taken over the 2-in. gage length by means of the specially developed extensometer consisting of a telescoping unit on the upper pulling bolt with extension bars running down into the bath, where they were secured to the specimen by means of C-springs which were removed before breaking the specimen. The indicator reads direct to 0.00025 in. on large graduations on a 5-in. dial (Fig. 16).

From the tension tests the proportional limit, ultimate strength, per cent elongation, and modulus of elasticity were determined at regular intervals from room temperature up to 700 deg. fahr. A set of representative stress-strain curves obtained on grade A aluminum alloy, Air Corps specification 57-72-1, are given in Fig. 17, and tension and elongation results obtained on this and three other alloys are shown in Fig. 18. These will suffice to show the advisability of testing materials at the temperatures required of them in service. The tests were made in an Olsen 20,000-lb. universal testing machine, as shown in Fig. 19. In order to make all results comparable, the tests at room temperature were made with the same set-up but without the oil bath.

The Brinell tests at elevated temperatures were made in the same furnace, as described, with the pulling bolt replaced by an anvil post for supporting the specimen midway in the center of the bath, as shown in Fig. 20. In this case the furnace was firmly supported on the weighing table of the 20,000-lb. Olsen testing machine, while an Alpha Brinell testing machine unit was assembled in the movable head, which served as a vehicle for rough adjustment only (Fig. 21). A special head was cast and bored to accommodate the Brinell unit. By substituting a long insulated plunger, the ball was extended down into the oil to the specimen, where it remained throughout the tests, being slightly withdrawn to permit the exchange of specimens, which were handled by means of tongs. An asbestos baffle plate on the plunger prevented the oil in the Brinell cylinder from being heated by the fumes from the furnace. The test load was applied by the Brinell unit, as in standard practice, thus insuring true Brinell loading conditions.

These tests were made on a series of specimens 1 in. in diameter by 1 in. high. First, they were all tested on one end at room temperature (in the same set-up without the oil), and then one or more were tested on the other end at each of the regular intervals of temperature over the desired range. After cooling they were all tested again at room temperature to determine the permanent effect of the heating. All Brinell impressions were measured at room temperature by means of a specially mounted microscope with lateral travel graduated to 0.01 mm. A comparison of the tensile strength and Brinell hardness results obtained on a representative aluminum alloy at temperatures up to 700 deg. fahr. is shown graphically in Fig. 22.

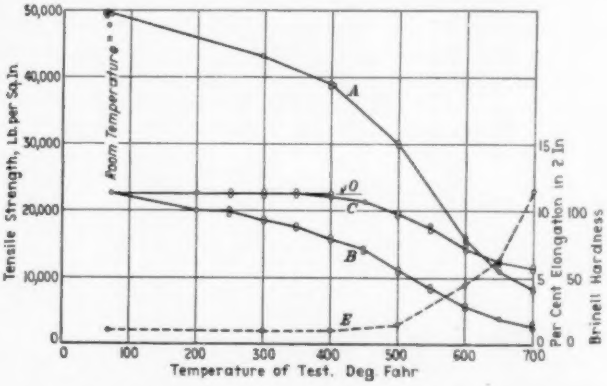

Fig. 22 Tensile and Brinell Results on a Representative Piston Alloy at Elevated Temperatures

(Aluminum alloy, grade B, A. C. specification 57-72-1. *A*, tensile strength over temperature range; *B*, Brinell hardness over temperature range; *C*, final Brinell hardness at room temperature; *O*, original Brinell hardness at room temperature; *E*, per cent elongation in 2 in. at elevated temperatures. Composition: Cu, 3.0; Ni, 0.5; Fe, 1.5; Si, 0.5; Mg, 0.5; Al, difference. Note on *C*: After finishing the Brinell tests at elevated temperatures, the same specimens were again tested at room temperature to determine the permanent effects of the 30-minute heating. The results are shown in curve *C*. Thus each specimen was tested first at room temperature, then at elevated temperature, then again at room temperature. Different specimens were used at each station.)

At elevated temperatures the Brinell test is more economical than the tensile test, since the specimens are easier to prepare and the testing conditions are more readily controlled; hence since the Brinell results practically parallel those of tensile strength, the Brinell test is preferred for exploratory work.

The Autogiro Rotor

By HERACLIO ALFARO,[1] PHILADELPHIA, PA.

The rotor of the Autogiro is described, as some authorities have considered that this revolving feature has added much in the way of increased safety and utility to the heavier-than-air craft. In the latest designs the Pitcairn Aircraft blade spars have been made of chrome-molybdenum steel. The necessity of attaining rigidity in torsion has determined in some designs the size of the blade main tubular spar. Research during the year has been devoted to mastering this structural requirement. The chief features are flexibility in the plane of lift, rigidity in the plane of rotation, and rigidity in torsion.

THE Autogiro has been presented to this Society in a general way on various occasions in the past. Mr. Cierva himself, inventor of this novel aircraft, read a paper in Cleveland introducing his invention and describing it. Later papers by Mr. Agnew Larsen and Mr. Laurence LePage have very well covered practically all of its general aspects. I therefore decided to discuss to a greater extent in this paper one of its component units only.

Of all parts in the Autogiro the most striking one is undoubtedly the rotor. This odd revolving affair of "flimsy looking" blades is taken by many aeronautical authorities as the outstanding development in the art of flying and is considered as bringing increased safety and utility to the heavier-than-air aircraft industry of today.

It looks odd because of its marked departure in appearance from natural fliers, and it seems flimsy because of its hinged and flexible blades, which feature is nevertheless established as one of the greatest assets of the Autogiro.

Much as is the case with the wheel, which did not follow the example of nature for ground transportation, the Autogiro rotor departs entirely from nature's flying models—the flapping-wing and soaring birds. This does not keep the Autogiro from approaching nearer to accomplishing what birds do than does the stationary-wing aircraft, and I dare say it goes farther than nature would go itself, should it decide to raise flapping and soaring birds of very large sizes.

For reasons of structural strength only, nature could not produce satisfactory flapping or soaring birds of the size of the present-day airplane without evolving the use of substances of greater structural efficiency than those of which birds of today are made.

Not a Windmill

Can the rotor of an Autogiro be called a windmill? Qualitatively the forces and behavior of both are the same. Quantitatively they are so different that they are well worthy of a different name.

In a windmill practically the only thing wanted is a great torque. In the Autogiro rotor the torque is zero, and the blades should be allowed to revolve as freely as possible, with the double purpose of obtaining great parachute effect when in vertical descent and great lift-over-drag ratio when in horizontal flight.

An Autogiro rotor can be distinguished from a regular windmill by its longer and narrower blades, fewer in number, more flexible, and set at slight positive angles to their plane of rotation. Also, for most purposes, Autogiro rotors are likely to have hinged blades—a feature that seldom, if ever, will be justified in a windmill.

Autorotation

"What makes the rotor spin?" This is a popular question, not only of the average non-technical man but also of many engineers. Explanations of autorotation have been given often, but they have failed at times to satisfy a great many people; so that a further attempt at an explanation appears needful.

The Autogiro rotor spins for the same reason that a windmill spins. The apparent difference is in that the Autogiro rotor has a positive angle of pitch in the blades, which would indicate that it could not rotate the way it does when in operation. A windmill has its blades set at a negative angle. This difference is due, as said before, to the different requirements of the Autogiro rotor and the windmill. The rotor is not expected to furnish any torque, but it is intended to give a high lift.

To further explain autorotation, Fig. 1 must be considered, which represents a symmetrical airfoil (similar to those used in the Autogiro) placed at 90 deg to an air stream such as would meet the blades of a rotor in vertical descent, before starting rotation. The flow will probably behave as shown. Due to the streamlined shape of the airfoil, the flow will go around the leading edge easier than around the trailing edge, and produces[2] a forward force sufficient to start rotation. As the rotational speed increases, the accelerating rotational moment increases; later, however, when rotation is fast, it decreases again, to become zero as soon as the rotor reaches its normal rotational speed.

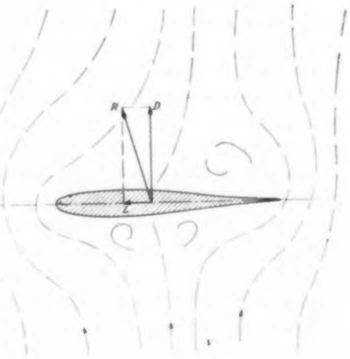

Fig. 1

The N.A.C.A. M-1 symmetrical airfoil of 6.16 per cent of chord thickness, placed at 90 deg to the air stream, gives a lift coefficient $C_L = 0.05$, which in the present case applies to the forward component L, shown in Fig. 1. If the air velocity V is of 20 mph and the area of the airfoil 10 sq ft, the forward component becomes $L = 0.05 \times 0.00256 \times 10 \times 20^2 = 0.512$ lb, which is sufficient to start rotation. In this airfoil the forward component L becomes zero when the angle of attack is 93 deg. It is estimated that with airfoils of 12 per cent of chord

---

Presented at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] N.A.C.A. Tech. Report No. 317, "Wind Tunnel Tests on a Series of Wing Models Through a Large Angle of Attack Range, Part 1."

thickness $L > O$ at all angles below 95 deg. The Clark-Y has a zero value of L at about $95^1/_2$ deg. The Göttingen 429 at 90 deg would have approximately an L component = 0.83 lb if the area was, as before, 10 sq ft and the wind velocity 20 mph.

Once the velocity of rotation reaches a certain value, conditions become such as are shown in Fig. 2, where the velocity V_1 is the resultant of adding rotational speed V_2 to the previous velocity V. The usual resultant R of the air forces can be resolved into the lift L and drag D when referred to the direction of motion p-p and its perpendicular z-z. However, when referred to the plane of rotation x-x and the axis y-y, the same resultant R is resolved into T, which is sensibly equal to L, and into F, which is opposite to D and promotes rotation.

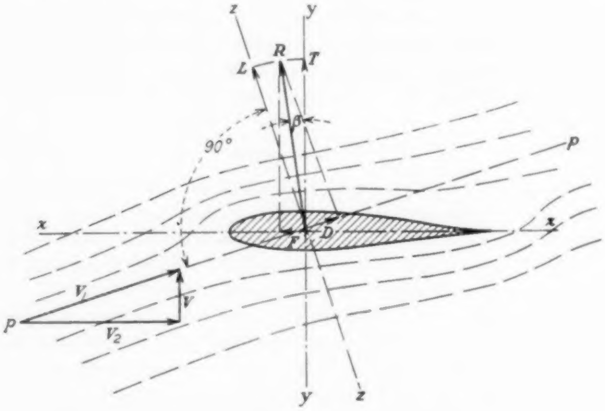

FIG. 2

As the rotational velocity increases, the angle β between the resultant R and the y-axis diminishes. V_2 becomes constant when β equals zero.

It has been found that the best lift is obtained when the blades have a slight positive angle of pitch. In this case, the rotor may have difficulty in getting started since the L-component with the blades at rest would be very small. There is a critical angle of pitch which is the best for a high lift, and beyond it, in a matter of a few degrees, autorotation is altogether impossible even with an initial start.

So far, the Göttingen 429 section has been used for the blades almost exclusively, due primarily to its stationary center of pressure, which is a very desirable feature. There are other sections that are likely to give better results. The matter is now under careful investigation and may result in some improvement.

SELECTION OF AIRFOIL[3]

From an aerodynamical viewpoint, the best airfoil for Autogiro blades can be selected from a group about which the characteristics of each individual airfoil are known.

Consider an element ΔS of a blade of the rotor of an Autogiro in a steady vertical descent, Fig. 3. The axis of rotation is parallel to the y-axis, and therefore rotation may occur in the plane of the x-axis. The air under the compound velocities of descent V and of rotation V_2 will meet the blade element with a resultant velocity V_1 at an angle β with the plane of rotation. These velocities are vectorially represented in the figure. Steady velocity of descent implies a steady rotational velocity. Steady velocity of rotation can only occur if the resultant R of all air reactions in the blade is parallel to the y-axis. Deviation of R fore and aft from the perpendicular to the plane of rotation would result in an acceleration or a deceleration of the rotational speed.

From the foregoing, the following relations can be written:

$$R_1 = L\cos\beta + D\sin\beta$$

$$R_{c1} = L_c\cos\beta + D_c\sin\beta$$

These coefficients refer to the component true velocity V_1 of the blade element.

$$V_1 = \frac{V}{\sin\beta} = V\csc\beta$$

also

$$R = R_c\,(\Delta S)V_1^2 = (L_c\cos\beta + D_c\sin\beta)\,(\Delta S)V^2\csc^2\beta$$

and

$$R_c = \frac{R}{(\Delta S)V^2} = (L_c\cos\beta + D_c\sin\beta)\csc^2\beta$$

and also

$$\frac{L}{D} = \frac{\cos\beta}{\sin\beta} = \cot\beta$$

In practice, the values of β are always very small, and therefore $\cos\beta$ is nearly equal to 1 and $D_c\sin\beta$ is negligible. It therefore can be written:

$$R_c\text{ approx.} = L_c\csc^2\beta = L_c + L_c\cot^2\beta$$

$$(\csc^2\beta = 1 + \cot^2\beta)$$

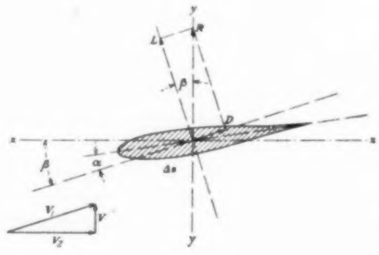

FIG. 3

The first term of this expression is also very small, and can also be neglected finally, so that it may be written:

$$R_c\text{ approx.} = L_c\cot^2\beta = L_c\left(\frac{L}{D}\right)^2 \quad\text{[1]}$$

The rotational-path speed is:

$$V_2 = \frac{V}{\tan\beta} = V\frac{L}{D} \quad\text{[2]}$$

Fig. 4 is a chart where the values of $L_c(L/D)^2$ for a number of airfoil sections have been plotted. The Sloane 105 section seems to be the best from the point of view of parachute effect in an Autogiro. It must be remembered that structural or other considerations may advise a different selection. Equations [1] and [2], however, furnish good guidance and point out the advantage of airfoils of high L-over-D ratio.

COEFFICIENT OF RESISTANCE

Mr. Cierva in his theory shows that the parachute effect or resistance of an Autogiro rotor in vertical descent is several times greater than that of a parachute of the same diameter. At first, it seems that, since a parachute or round disk of equal size obstructs the flow entirely, any other device which would let part of the flow go through would produce a smaller resistance. On second thought, however, it can be seen that the velocity imparted to the column of air handled by the Autogiro rotor in its descent may be much greater than that imparted by a disk or parachute of the same diameter under similar conditions.

---

[3] From notes on the Autogiro at Massachusetts Institute of Technology in 1925, by H. Alfaro, reproduced in part later in a thesis by Weihmiller and Hosch.

This can be better understood by comparing the proposed type of flow pattern shown in Fig. 5, which refers to an Autogiro descending vertically, and the flow pattern around a flat disk under similar conditions, as shown in Fig. 6. In the latter the flow builds some sort of an invisible dome in front of the plate and a streamlined cap behind it. These bodies are composed of eddies and dead or stationary (relatively so) air and go with the plate. The rest of the flow therefore goes around with relative smoothness, which results in a somewhat low resistance.

The flow pattern of an Autogiro rotor, however, does not give a chance to the air to go around to the same extent. The intermittent action of the blades avoids the formation of the dead-air caps mentioned, with the result of greater interference of the flow and greater resistance.

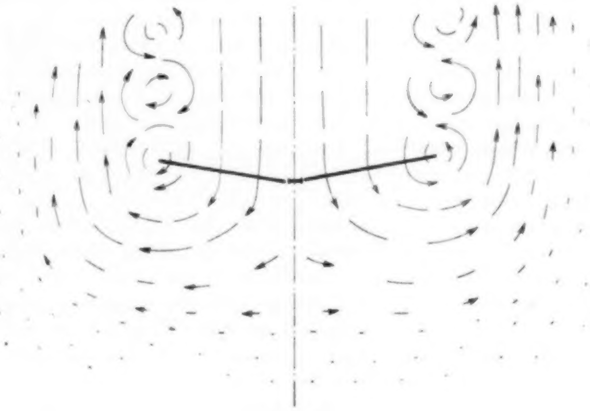

Fig. 5

Control

The ailerons are not strictly necessary, but in practice they must be used because they increase maneuverability to an enormous extent. An aircraft cannot turn any faster than it can roll. If a turn is attempted by applying the rudder alone, the first result is a side slip, resulting in a bank and then in a turn. Coming out of it with the rudder action alone is achieved also through a side slip inside the turn. The ailerons enable the pilot to make a more perfect turn, and therefore a quicker and tighter turn.

A peculiar faculty of the rotor and wing arrangement as used in the Autogiro is the effectiveness of the ailerons at high angles. This does not mean that the Autogiro has as snappy a lateral control at low speeds as at high ones. At low speeds the ailerons respond slowly but effectively and without the characteristic feeling of stalled control of airplanes at high angles.

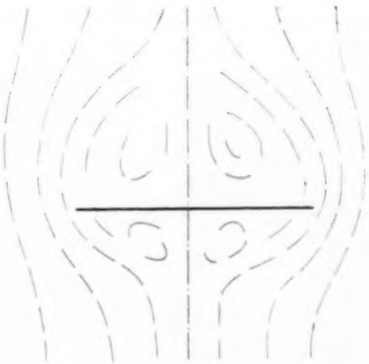

Fig. 6

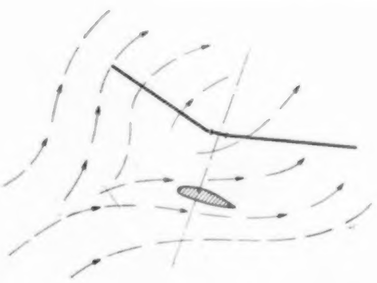

Fig. 7

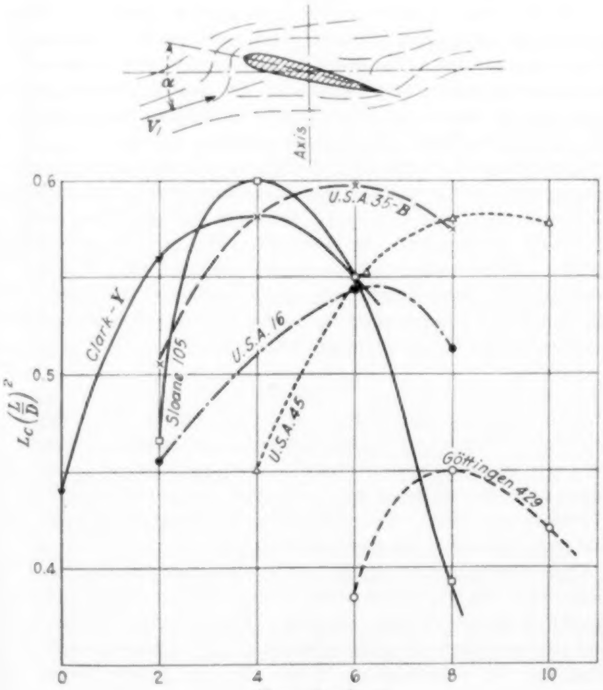

Fig. 4

This can be better understood through Fig. 7, where the flow of air is shown around a rotor and fixed-wing combination at large angles. The direction of the flow where the wing is located is such that no stalling occurs for the fixed wings. This is again one of the many fortunate findings of the Autogiro, which one is prompted to attribute to the extreme ingenuity of its inventor rather than to mere chance.

There are so many solutions like this one in the conception of the Autogiro that it is difficult to believe that any man could deliberately study and find out and then combine all these things harmoniously.

Articulation of the Blades

Autogiro experts claim that the most striking feature of this invention lies in the articulated connection of the blades to their hub. It serves so many purposes that engineers consider it as one of its greatest assets, since it simplifies many problems entering its design.

These hinges allow the blades to move freely up and down in the plane of lift, and also they provide freedom in the plane of rotation. The last is restricted by rubber blocks at the root of the blade to about ±5 deg either side from normal, while in the plane of lift the blades can move some 35 deg above horizontal and about 7 to 9 deg below it. Shock absorbers and "interbracing cables" are provided between the blades to give additional restriction to the freedom of the blades in the plane of rotation. The blades as they rotate change from driver to driven once in each revolution, which tends to produce a sort of pendular action and to start roughness. The shock absorbers used at present are of the hydraulic type and allow slow self-centering of the blades, while they restrain them from sudden jerks.

The rubber blocks not only help the self-centering of the blades, but they resist the load due to the mechanical starter torque transmitted to the rotor.

The advantages in connection with the articulation of the blades are numerous. It eliminates the gyroscopic effect of the rotor; without it the controlling ability of this aircraft would be practically impossible. As it now is, when the machine is nosed up, the blades in the fore-and-aft position will remain momentarily in their original plane of rotation. The blades have a total freedom in every direction except in torsion, and consequently the blades on the port and starboard sides will have increased or decreased their angle of attack (according to the direction of rotation of the rotor) in the same amount as the alteration produced by the nosing up of the machine. These blades, therefore, will climb or dive out of their original plane of rotation in order to maintain their original position relative to the axis of rotation. This self-aligning of the blades happens so quickly that the naked eye cannot detect any lag of the blades in following the maneuvers of the aircraft. Furthermore, since the power required for the blades to follow into a new attitude is taken from the surrounding air (at the expense of a little added drag), no damping or sluggishness in the response to the controls is observed. This is of the utmost importance for the practical side of flying.

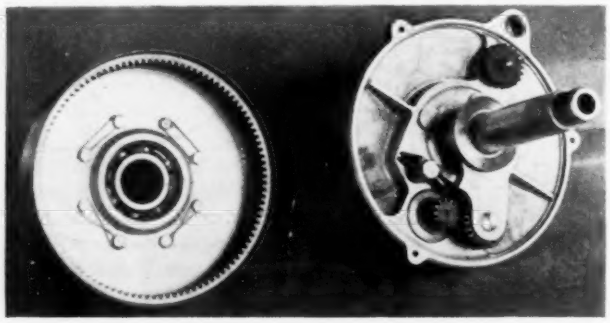

FIG. 8

Another advantage attributable to the hinged blades is the stability of the Autogiro in bumpy air. The blades give up and down slightly in the presence of gusts or pockets. The added smoothness has been observed time and again during flight and is valuable from the point of view of the airline operator in carrying passengers.

Stability in vertical descent is also much improved by the articulated arrangement.

Structurally, the hinge has at least two distinct advantages. One is the elimination of any bending moment at the root of the blade, which cuts down the structural weight to enormous extent; and the other is the reduction of the maximum possible overloads to a small figure. Mr. Cierva proves in his theory that, in a bad dive recovery, under conditions seldom if ever possible to find in practice, the maximum overload in the blades is 4.4 times the normal. This applies to a rotor of the normal proportions as used today.

But the main advantage of the articulated blade is that it makes the Autogiro possible. It is rather an essential instead of merely an advantage, since it makes workable the use of a single rotor, and it was with this in view that Mr. Cierva evolved this hinged arrangement.

ROTOR STARTER

Again, a usual question of many is, "Are the blades driven by the motor at any time?" No, is the answer, although it is not perhaps legally a correct answer. There is a power transmission that is sometimes connected with the rotor, but never during flight. It is used only to simplify and shorten the take-off. Taxying takes too long to give sufficient speed to the blades for a take-off. Many devices have been studied to take care of this. Only two have been used with any success. The first one was the "deflector tail"—a sort of box-kite tail that could be arranged to deflect up into the rotor the slipstream from the propeller when on the ground. By so doing the blades could be given quite an amount of initial rotation on the ground, and the take-off could then be much shortened. The structure of this tail, however, presented additional parasite drag, which handicapped performance in other lines. A mechanical connection with the motor had been studied in England, but was thought to be too heavy. A lighter design had been worked out on paper in this country by Mr. Joseph S. Pecker, of the Pitcairn engineering group. The general thought was to get rid of that clumsy-looking tail. At that time I had on my hands the problem of designing and building an Autogiro for Pitcairn Aircraft in Cleveland, and I had my own ideas regarding a starter. I thought that to play safe I had to arrange a limiting torque device between the engine and the transmission of power to the rotor. I figured that only 15 hp was needed to transmit ample rotation to the rotor, while the engine had over 100 available. Part of this was required to spin the front propeller on the ground, but I felt that if I were to make a foolproof device I either had to design the transmission for the worst condition of load or to use my torque-limiting device. I remained conservative, and used it, but it was thought later by Mr. Pecker that this precaution was not necessary, because some care in the application of the clutch could be expected on the part of the pilot. I went through with my idea, however. This was the first Autogiro mechanical starter ever made. Figs. 8 and 9 show this starter. The present mechanical starter is not a development resulting from this one. It was developed independently by Mr. Pecker, and is used as standard by the Autogiro Specialties Corporation in various sizes.

In all rotors a brake is installed for at least two reasons: One is to stop the blades from revolving when taxying with strong winds, that, if allowed to meet the revolving rotor, might lift or overturn the machine. The other is to avoid approaching groundcrew people from being hit by the blades.

Suggestions have been made as to folding blades that will reduce the space required to store an Autogiro, and it is thought of as a probable future development.

STRESSES

The blades are subject to a very high tensile stress due to centrifugal force, which naturally depends on the rate of rotation. This rate increases with altitude in the proportion of $\sqrt{(\rho_0/\rho_h)}$, where ρ_0 is the density of air at sea level and ρ_h that of altitude. Therefore the critical design condition to investigate should be that at the ceiling of the particular machine.

These blades also are subject to bending, and the more so the higher their rigidity in the plane of lift. That is why the blades should be flexible in that direction. It can be well understood that the centrifugal-force distribution along the blade is different from the lift distribution. While the one follows nearly a straight line of almost constant slope, the other follows a curve whose maximum is nearer the tip than the root of the blade.

much as in regular propellers. When in horizontal flight, this lift curve changes also according to the momentary position of the blade in its circular path. This may cause fatigue unless, as is the case, the bending stresses are rather low. If the blade was sufficiently flexible, it would acquire by itself a shape following the rate of change of the combination of tension and bending, and the bending stresses would be zero. But since it is to some extent rigid, some bending actually must be faced. Mr. Cierva has evolved a relatively simple method of figuring the bending for various blade-plan forms. He also has shown in his work that for almost any of the plan forms used the maximum stresses were met in the middle of the blade—that is, at a point one-half of the radius away from the center.

As mentioned before, there is also shearing due to torsion. This is the smallest of all stresses.

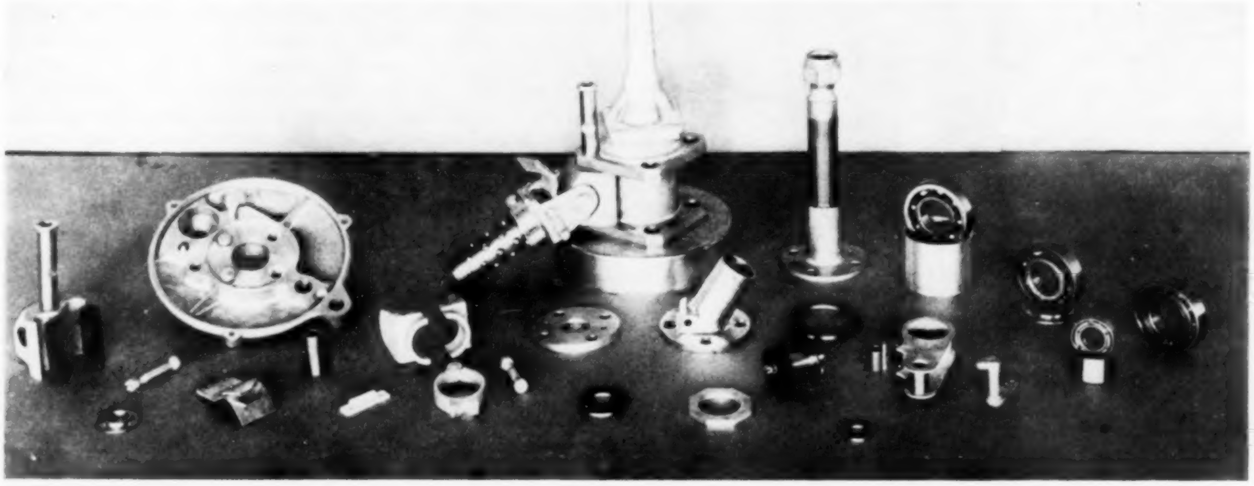

FIG. 9

The three fiber stresses should be computed for the worst condition of operation and then combined. A conservative margin of safety should be found. Mr. Cierva advises as a typical maximum-load condition the recovery from a dive where the velocity would have reached $1^{1}/_{4}$ times its horizontal-flight maximum. He assumes this to be done at the ceiling, where the rotational speed is the highest, and he considers it possible to bring the plane of the rotor instantly into a position normal to the direction of motion.

It has been found by Autogiro pilots that this assumed condition is really an ideal maximum. The computed fiber stresses under these conditions correspond to the rotor furnishing a normal force 4.4 times greater than the weight of the aircraft for a rotor of the proportions normally used. Mr. Cierva recommends a load factor of 6, so that the margin is really higher than that provided for in the regular airplane. This is due, as said before, to the hinge arrangement of the blades.

As a typical example, some figures corresponding to an Autogiro built in Cleveland by the author for the Pitcairn Aircraft, Inc., are given in Table 1.

Many practical tests and theoretical studies have been conducted, and the results indicate that this procedure is conservative and safe.

Various other points along the blades are investigated for stresses, as for instance at the root, where a suitable connection must be designed, and also at the attachment of the ribs to the main blade spar. This member in the latest designs has been made of chrome-molybdenum steel, heat treated to about 150,000 lb per sq in. Fatigue tests of spars also have been conducted under severe conditions with gratifying results, confirming the present procedure of Autogiro engineers.

TABLE 1 CHARACTERISTICS OF TYPICAL AUTOGIRO

Diameter of rotor, ft	38
Maximum chord, in	18
Weight of each blade complete, lb	58
Maximum bending moment at 0.5 R, in-lb	1,313
Share of the bending taken by the bakelite covering of the blades (found empirically), per cent	30
Fiber stress due to bending, lb per sq in	8,750
Centrifugal tension at 0.5 R, lb	2,950
Fiber stress due to tension, lb per sq in	14,730
Torsional moment at 0.5 R, in-lb	806
Shearing stress due to torsion, lb per sq in	4,465
Combined tensile stress, lb per sq in	25,240
Combined shearing stress, lb per sq in	13,000
Maximum design stresses in tension, lb per sq in	151,700
Yield point of poorest blade-tube specimen, lb per sq in	170,000
Margin of safety	1.12

The necessity of attaining rigidity in torsion had determined in some designs the size of the blade main tubular spar. It is believed that blades insufficiently rigid in this respect originate oscillations that may become dangerous and that at least are very unpleasant. Much of the research work conducted last year by Autogiro engineers was devoted to mastering this important structural requirement, which now is well under control.

To close this subject, it may be said that the three major structural requirements for the design of a blade are:

1 Flexibility in the plane of lift
2 Rigidity in the plane of rotation
3 Rigidity in torsion.

The second is easy to obtain, but the first and third are difficult to combine and demand the exercising of considerable engineering ingenuity.

The Autogiro is no mystery; it is just another engineering development. It is appealing because it deals with flying. It is doubly fascinating because it comes to solve a long-sought problem by adding substantial elements of safety, utility, and comfort to the engineering knowledge gathered in the aeronautical field.

AER-54-19

Design Problems of Controllable-Pitch Propellers

By W. B. HEINZ,[1] SCHENECTADY, N. Y.

This paper presents analytical studies of the most common problems that are encountered in the design of mechanisms to rotate airplane propeller blades about their axes. It includes (1) a brief discussion of centrifugal thrust-bearing loads, (2) an analysis of the torque created by centrifugal force, (3) an analysis of lateral bearing loads from which their frictional torques can be determined, and (4) an investigation of the centrifugal torque of multiple masses by means of which a counterbalance can be designed to neutralize to any desired extent, at all settings, the centrifugal blade torque. The analyses are carried further than in previous published work, and results are reached by which quantitative design data can be obtained with minimum numerical and graphical labor.

THE problem of controlling the pitch of airplane propellers while in flight has been studied for years.[2] The need of some reliable mechanism for this purpose is widely recognized as the result of expansion in military and commercial aeronautics. Practically all serious attempts to design and construct controllable-pitch hub mechanisms have been confined to devices by which the blades can be rotated in the hub about their axes. It can be demonstrated by aerodynamic considerations that a reasonable approach to ideal pitch control is accomplished by this means and that major improvements in economy and performance are to be expected in airplanes equipped with successful propellers of this type. A number of separate designs have been constructed and tested. Several have received extensive flight tests and have justified those sanguine hopes aroused by model and flight tests of propellers with blades adjustable at standstill.

Since pitch control is receiving widespread attention at this time, it is believed that the publication of several analytical solutions of certain design problems may prove of value to the industry. Hence there are presented in this paper analytical studies of the most common problems encountered in the design of mechanisms to rotate the blades about their axes. Each blade must be held in place in the hub by some means which will allow rotation about its axis, and there must be provided some arrangement by which the necessary torques can be applied about the blade axes to cause this rotation.

There are here considered (1) the centrifugal loads upon the blade thrust bearings and (2) the operating torques involved.

Design Problem

The design of a controllable-pitch hub mechanism centers about two broad problems: First, means of retaining the blades in the hub structure, which will be capable of resisting the high centrifugal forces exerted and which will readily allow each blade to be turned about its own axis and, second, a mechanism by which the blades can be turned about their axes in the manner desired.

Means which have been conceived to accomplish the first result include flexible supports, which allow limited blade rotation through flexure; hydraulic cylinders; mercury float arrangements; paraffin-saturated fiber bearings; and especially designed ball and roller thrust bearings. Because of recent developments it now seems safe to assume that a bearing of the latter type can be obtained which will stand up satisfactorily under the extremely high loads encountered.

As an example, the method of support which is used must restrain the blades of a 525-hp. propeller against a centrifugal force which may rise to 100,000 lb. or more per blade. The centrifugal force on a hollow steel propeller blade, which is lighter than a corresponding one of aluminum alloy, has been calculated by well-known processes of graphical integration. For this propeller of 9 ft. 5 in. diameter the centrifugal force per blade amounts to 70,300 lb. at 2500 r.p.m. This force increases as the square of the r.p.m., which may reach 3000 in a power dive.

Once the centrifugal loading of the thrust bearing has been calculated and a bearing has been obtained which can be expected to satisfactorily meet the necessary requirements, there must be determined the operating forces exerted by a hub mechanism.

The problem is primarily that of determining the torque required to turn each blade in its socket under the most extreme operating conditions. The most important components are the following:

(*a*) The aerodynamic torque created in the blade
(*b*) The torque created by centrifugal force
(*c*) The frictional torque in the thrust bearing
(*d*) The frictional torque in the lateral blade bearings
(*e*) Miscellaneous frictional torques in the operating mechanism itself.

Aerodynamic Torque

In a well-designed propeller blade the sections are all arranged so that their centers of gravity lie on a straight line, which is generally radial. The sections are not symmetrical about their centers of gravity, however, and the pressure distribution

The author was graduated from the University of Washington in 1926 with the degree B.S. in E.E., after minoring in aeronautics. He spent the first year and a half as electrician on power-plant construction for the Washington Water Power Company at Spokane. On entering the employ of the General Electric Company in December, 1927, he studied for three years in their advanced course in engineering. The last two years have been spent largely in the study of propulsion problems.

[2] "The Value of Controllable Pitch Propellers to the Aeronautics Industry," by W. B. Heinz, A.S.M.E. Annual Aeronautical Meeting, Baltimore, Md., May 12 to 15, 1931 (with bibliography).

Contributed by the Aeronautic Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

over each one is such that there is exerted an aerodynamic moment tending to increase its angle. Analysis of this torsion has been performed, based upon assumed ideal flow conditions. This assumption in itself is so far in error that the results are not quantitatively accurate, but they are nevertheless sufficiently representative of the true values that one important conclusion can be drawn. That is, the aerodynamic torsion is so small in relation to the centrifugal and frictional moments that it need not be given quantitative consideration.

Centrifugal Torsion

Fig. 1 shows a propeller blade section, rotating with constant velocity about the *Y*-axis parallel to the *X*-*Z* plane. The forces to be considered are analyzed at a certain instant of time, when the section is passing through the position in which it is shown. As indicated, the radius from the axis of rotation to the center of gravity of the section is z. The distances x and y locate an elemental mass dm in the section, which has acting on it the centrifugal force

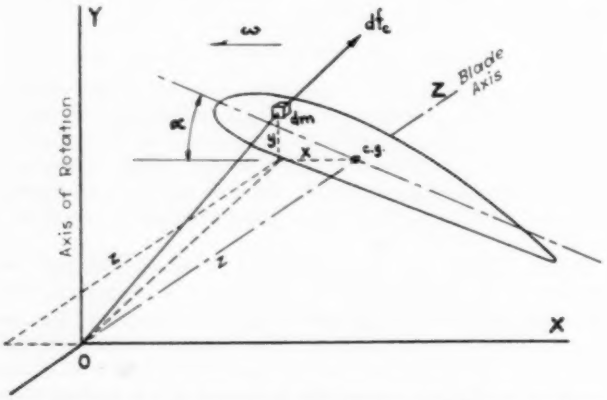

Fig. 1 Creation of Torsion in a Propeller Blade by Centrifugal Force

$$df_c = \omega^2 dm\sqrt{x^2 + z^2} \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

This analysis is based upon the assumption that all forces are carried from a point at the intersection of the blade and engine axes. On this assumption it is apparent that the force df_c tends to swing dm on the extremity of the line *O*-dm downward into the *X*-*Z* plane of rotation. All other elements are similarly urged toward this plane, but are prevented from going there by the internal resisting moment of the blade structure. The blade is thus placed in a state of torsional stress by centrifugal force.

The elemental force expressed by Equation [1] acts at the lever arm y to swing dm downward at the extremity of its radius $\sqrt{(x^2 + z^2)}$. The resisting structure must apply an upward force to balance this moment by its action about the lever arm $\sqrt{(x^2 + z^2)}$. If we term this equivalent force f_e, we can equate moments as follows:

$$y\omega^2 dm\sqrt{(x^2 + z^2)} = f_e\sqrt{(x^2 + z^2)} \ldots\ldots\ldots\ldots [2]$$

The torsion created in the blade by its exertion of the force f_e is

$$dQ_c = xf_e$$

from which

$$f_e = \frac{dQc}{x} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Equation [2] now becomes

$$y\omega^2 dm = \frac{dQ_c}{x} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [4]$$

From Equation [4] we obtain for the elemental centrifugal torsion created by the mass dm, the expression

$$\underline{dQ_c = xy\omega^2 dm} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [5]$$

The torsion thus created by any complete blade section is obtained by integrating Equation [5] over the section area:

$$Q_c = \rho\omega^2 \sum_{\text{area}} xy\, dx\, dy \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

In Equation [6] there has been substituted for the mass dm its equivalent $\rho dxdy$. The section is taken as of unit thickness along the *Z*-axis, and ρ represents the mass density of the material.

It is interesting to note from Equation [6] that the centrifugal torsion created by any section is independent of its distance z from the axis of rotation.

It is well known that the product of inertia (U) of any section is

$$U = \sum_{\text{area}} xy\, dx\, dy \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

We can thus write for Equation [6] the following:

$$Q_c = \rho U\omega^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [8]$$

In terms of moments of inertia,

$$\begin{aligned} U &= (J_{\text{maj.}} - J_{\text{min.}}) \sin\alpha\cos\alpha \\ &= {}^1/_2(J_{\text{maj.}} - J_{\text{min.}}) \sin 2\alpha \ldots\ldots\ldots\ldots [9] \end{aligned}$$

where α is the angle between the major and minor axes of the section, respectively, and the coordinate axes about which U is taken.

Equation [8] now becomes:

$$Q_c = \frac{\rho\omega^2}{2}(J_{\text{maj.}} - J_{\text{min.}}) \sin 2\alpha \ldots\ldots\ldots\ldots [10]$$

To obtain the centrifugal torque created by an entire blade we must sum up all the individual section torques of Equation [10] from the blade root to its tip. This summation may be written

$$Q_c(\theta) = \frac{\rho\omega^2}{2} \sum_0^{\text{tip}} J(z) \sin 2\alpha(z, \theta) \ldots\ldots\ldots [11]$$

In Equation [11] we have written $J(z)$ instead of $(J_{\text{maj.}} - J_{\text{min.}})$, the letter z in parentheses calling attention to the fact that J varies along the blade radius. Similarly, $Q_c(\theta)$ implies that the total torque varies with the blade setting angle θ; and $\alpha(z, \theta)$ means that α is a function of both z and θ.

Equation [11] now represents the summation of torques for all sections along the blade as it varies with changes in the setting angle θ. The term for each section (Equation [10]) if written as a function of θ becomes

$$Q_c(\theta) = \frac{\rho\omega^2}{2} J(z) \sin 2\alpha(z, \theta) \ldots\ldots\ldots\ldots [12]$$

Inspection of Equation [12] discloses the fact that it represents any one of a group of sine waves of equal double frequency, whose coordinates are Q_c and α and whose amplitude and phase both change along z. Their summation (Equation [11]) is then another sine wave:

$$Q_c(\theta) = Q_m \sin 2(\theta + \lambda) \ldots\ldots\ldots\ldots [13]$$

In Equation [13] there are two new symbols. Q_m is the amplitude of this new sine wave, it being physically the maximum total torque which can be obtained in a given blade by changing its setting. The symbol λ represents the "phase angle" of the wave, which in reality is that negative angle at which the blade must be set for the total centrifugal torque to be zero.

We can now readily obtain the entire curve of $Q_c(\theta)$ for any blade by (*a*) graphically solving Equation [11] for any two values of θ, and then by (*b*) solving Equation [13] for Q_m and λ.

After we have performed step (*a*) for any two angles θ_1 and θ_2, we can place in Equation [13] the two torques obtained for $Q_c(\theta)$. Designating them Σ_1 and Σ_2, there result

$$\begin{aligned} \Sigma_1 &= Q_m \sin 2(\theta_1 + \lambda) \\ \Sigma_2 &= Q_m \sin 2(\theta_2 + \lambda) \ldots\ldots\ldots\ldots [14] \end{aligned}$$

Solution of Equation [14] gives for the phase angle:

$$\tan 2\lambda = \frac{\Sigma_1 \sin 2\theta_2 - \Sigma_2 \sin 2\theta_1}{\Sigma_2 \cos 2\theta_1 - \Sigma_1 \cos 2\theta_2} \ldots\ldots\ldots [15]$$

NUMERICAL EXAMPLE

The solution of Equation [13] has been worked out by this method for a hollow steel blade, whose characteristics are given in Fig. 2, rotating at 2000 r.p.m. For simplicity the values 0 deg. and 45 deg. were chosen for θ_1 and θ_2, respectively, when Equation [15] became

$$\tan 2\lambda = \frac{\Sigma_1}{\Sigma_2} \ldots\ldots\ldots\ldots [16]$$

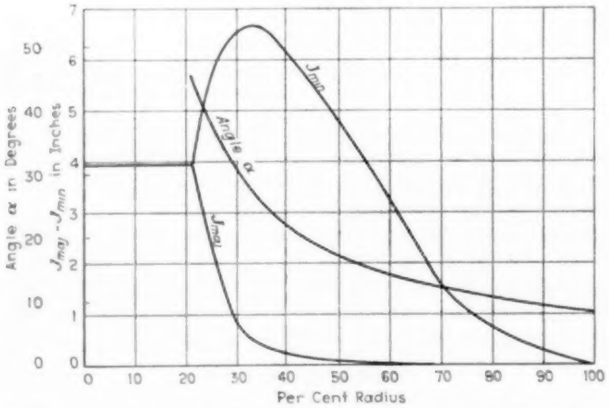

FIG. 2 MOMENTS OF INERTIA AND SECTION ANGLES OF PROPELLER BLADE

Thus by graphical integration for only two points we obtain the complete centrifugal torque-curve equation:

$$Q_c(\theta) = 1953 \sin 2(\theta + 9.875 \text{ deg.}) \text{ pound-inches} \ldots [17]$$

The curve is readily plotted, as shown in Fig. 3.

This fundamental Equation [13] or [17] represents the total centrifugal torque created in a blade of a rotating propeller. The coefficient Q_m is the maximum value of this torque which could be obtained at any one speed by varying the setting angle θ. The angle λ is that negative setting at which the total torque would be zero. Both of these terms can be determined for any particular case by graphical solution of Equation [11] for any two values of θ, followed by simultaneous solution of the two equations obtained from [13], when these two sets of values are substituted therein.

We have now a simple method by which the centrifugal torque created in any propeller blade can be determined for all angular settings. Such information is valuable in the design of a counterbalance to free the operating mechanism from all or part of this centrifugal component. It points out the way to so proportion a counterbalance and its angular position that the blade torque will be exactly neutralized at all settings, or that any desired net torque in either direction can be obtained.[3]

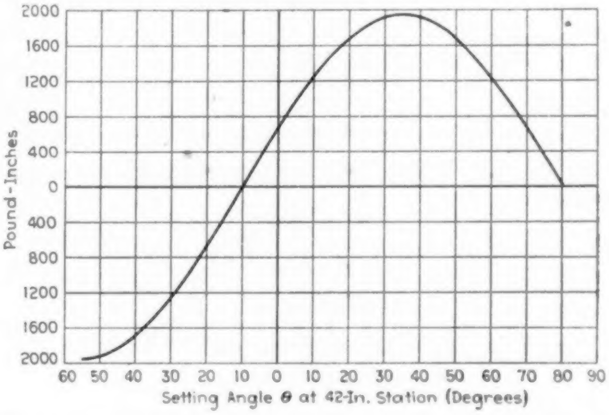

FIG. 3 TOTAL CENTRIFUGAL BLADE TORQUE VERSUS SETTING ANGLE

(For blade of 525-hp. propeller at 2000 r.p.m.)

THRUST-BEARING FRICTION

Thrust bearings of several different types are being developed for use in controllable-pitch propellers. Their characteristics are all different, and the manufacturer of any particular type should supply load friction data. Then by the application of known centrifugal loadings the required turning moments can be calculated.

LATERAL BEARING FRICTION

The fourth component of operating torque is that occasioned by friction in the lateral blade bearings. Friction coefficient data will be obtained from the bearing manufacturers, but in order to make intelligent use of it the bearing loads must be known.

In this analysis only the following three forces are considered as affecting the lateral bearing loads:

1 Blade thrust, which propels the airplane
2 Blade drag, which resists the engine torque
3 Centrifugal force acting on every blade section.

It is assumed that the first two forces can be added as vectors at 90 deg., and that the resultant always acts in the direction of least blade stiffness. The deflection produced is assumed to be perpendicular to the plane of rotation. All vibratory stresses are neglected.

The method of analysis here outlined is not rigorously correct, but it seems to be the best available, and the assumptions upon which it is based are close enough for all practical purposes. Each propeller blade is mounted in the hub as a cantilever beam, in which the resultant thrust produces deflections as indicated in Fig. 4.

In Fig. 4,

δ_1 = the deflection at radius z which would be created by aerodynamic thrust and drag alone

δ_2 = the restoring deflection which would be created by centrifugal force if acting alone at deflection δ

δ = the resultant deflection which occurs from the combination of δ_1 and δ_2.

---

[3] See Appendix 1, Centrifugal Torque of Multiple Masses.

The centrifugal restoring moment acting alone would create a deflection equal and opposite to that from an equivalent distributed load T_c shown in Fig. 5. The forces F_c and T_c are shown acting upon a blade section of area A and unit length, it being necessary for equilibrium that the equivalent force be:

$$T_c = F_c \frac{\delta}{z} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [18]$$

The centrifugal force is:

$$F_c = \rho A z \omega^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [19]$$

Hence

$$T_c = \rho \delta A \omega^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [20]$$

By ordinary beam theory the equivalent centrifugal deflection is:

$$\delta_2 = \frac{1}{E} \int\int \frac{1}{J_{\text{maj.}}} \int\int T_c \, \overline{dz^4}$$

$$= \frac{\rho\omega^2}{E} \int\int \frac{1}{J_{\text{maj.}}} \int\int A \delta \overline{dz^4} \ldots\ldots\ldots [21]$$

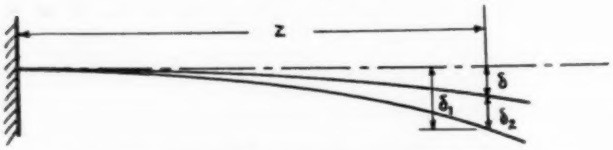

FIG. 4 COMPONENT DEFLECTIONS OF A PROPELLER BLADE

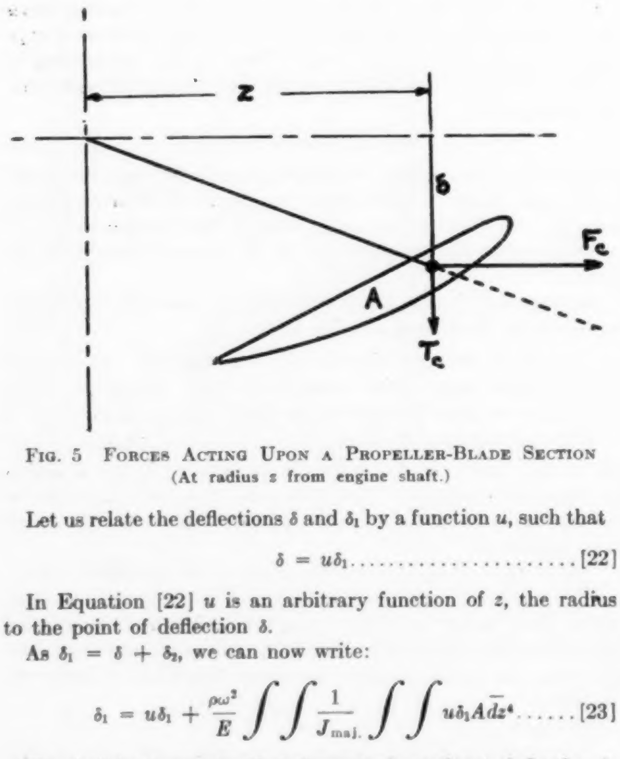

FIG. 5 FORCES ACTING UPON A PROPELLER-BLADE SECTION
(At radius z from engine shaft.)

Let us relate the deflections δ and δ_1 by a function u, such that

$$\delta = u\delta_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [22]$$

In Equation [22] u is an arbitrary function of z, the radius to the point of deflection δ.

As $\delta_1 = \delta + \delta_2$, we can now write:

$$\delta_1 = u\delta_1 + \frac{\rho\omega^2}{E} \int\int \frac{1}{J_{\text{maj.}}} \int\int u\delta_1 A \overline{dz^4} \ldots\ldots [23]$$

We shall now assume that the actual resultant deflection is everywhere proportional to the deflection which would occur with zero centrifugal force. Therefore u is constant, and Equation [23] reduces to the form:

$$\frac{1-u}{u} = \frac{1}{\delta_1} \left[\frac{\rho\omega^2}{E} \int\int \frac{1}{J_{\text{maj.}}} \int\int \delta_1 A \overline{dz^4} \right] \ldots\ldots [24]$$

In Equation [24] the form $(1 - u)/u$ is given instead of the direct solution for u, because the graphical evaluation is simplified, and the term $(1 - u)/u$ can readily be determined. From it a series of values of u can be found and plotted against z. If the assumption is valid that u is constant, a straight horizontal line will result.

Bending moments created by aerodynamic forces alone can be computed, and from them the corresponding deflections. Multiplication by the factor u will then give the resultant bending moments and deflections.

In order to study the bearing loads we can represent the forces as in Fig. 6, in which the bending moment resulting from thrust and centrifugal force has been analyzed above. The moment created by blade drag can be computed aerodynamically, and the two combined vectorially.

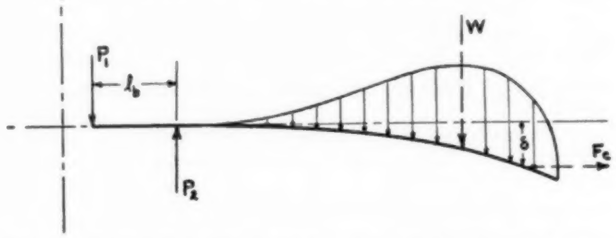

FIG. 6 LOADS AND BEARING REACTIONS UPON A PROPELLER BLADE

Thus:

$$P_1 = \frac{1}{l_b} \sqrt{({}_cM_t^2 + M_d^2)} \ldots\ldots\ldots\ldots\ldots [25]$$

$$P_2 = P_1 + W$$

$$= \frac{1}{l_b} \sqrt{({}_cM_t^2 + M_d^2)} + \sqrt{(\text{thrust}^2 + \text{drag}^2)} \ldots\ldots [26]$$

In Equations [25] and [26] the symbol ${}_cM_t$ represents the resultant bending moment at the blade root from combined thrust and centrifugal force as calculated above; M_d is the bending moment created by blade drag.

By the use of these two equations we can calculate approximately the forces experienced by the two lateral bearings of each blade. Having found the bearing loads, we can apply the proper friction coefficients, and thus obtain these moments which resist turning of the blades about their axes.

NUMERICAL EXAMPLE

The aerodynamic forces, moments, and deflections have been computed for a hollow steel blade of 9 ft. diameter, at 1800 r.p.m. and an assumed 140 m.p.h. forward speed. Curves showing pertinent data appear in Fig. 7. It will be noted that the curve of u versus z is flat over the region of highest deflection, and the assumption of constant u is thus shown to be reasonable within practical limits.

In one hub design which has been investigated the distance l_b is $7\frac{1}{4}$ in. Aerodynamic analysis indicates that the following values are representative:

$$\sqrt{({}_cM_t^2 + M_d^2)} = 6000 \text{ lb-in.}$$

$$W = 370 \text{ lb.}$$

From Equations [25] and [26] we obtain for the bearing loads in this design:

$$P_1 = \frac{6000}{7.25} = 828 \text{ lb.}$$

$$P_2 = 828 + 370 = 1198 \text{ lb.}$$

CONCLUSIONS

There have been presented in this paper two analytical studies the results of which can be applied directly to any particular design. First, a simple means has been developed by which the centrifugal torque in a given propeller blade can be readily determined for all angular settings, and, second, straightforward equations have been derived which make it possible to compute approximately the lateral bearing loads imposed by a blade under combined thrust, drag, and centrifugal force. Equations [11] and [13] are sufficient for the determination of centrifugal torque, while an aerodynamic analysis of blade deflections and the solution of Equations [24], [25], and [26] are necessary to compute lateral bearing loads.

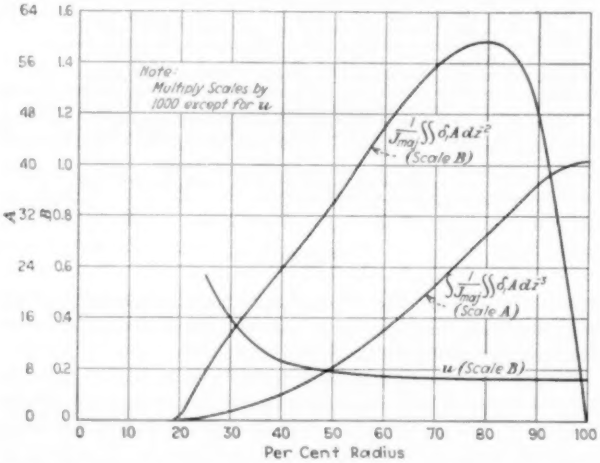

FIG. 7 STEPS IN GRAPHICAL INTEGRATION FOR THE SOLUTION OF FUNCTION u

The practical value of the analysis presented here lies in its reduction of the labor which has heretofore been necessary to compute a centrifugal torque-setting angle curve for a given propeller blade. Assurance can easily be gained that safe stresses are not exceeded in operating mechanisms, and in addition a systematic method is indicated for the design of a counterbalance to reduce the net centrifugal blade torque to any desired value at all settings. Such a method is developed in Appendix 1.

The method given here for the calculation of resultant lateral bearing loads with deflected blades is the first that the author has seen. He will appreciate critical examination of the process and will look for further experimental checks of the results.

It is hoped that this material will prove of practical worth to designers of pitch-control mechanisms and that a clearer understanding of phenomena involved may be gained from it by other readers.

Appendix 1

CENTRIFUGAL TORQUE OF MULTIPLE MASSES

This is an analysis of the combined centrifugal torque characteristics of a known propeller blade and two concentrated masses.

INTRODUCTION

The operating mechanisms of certain types of controllable-pitch propeller hubs include as common features an arm which is attached to the blade root and a connecting link by which the required turning moment is applied about the blade axis. It is desired to develop an analytical means for designing a counterweight to balance out, at all angular blade settings, the combined centrifugal torque of the blade, its arm, and connecting link.

ANALYSIS

Fig. 8 represents the projection upon a plane through the engine shaft (X-X axis) of a propeller blade section (hereafter referred to as "the blade") at the 42-in. station, where setting angles are customarily measured; a mass m_1 consisting of the operating arm and link referred to above; and a mass m which counterbalances the blade and mass m_1 in centrifugal torque. The actual distance of these members from the plane of projection has no bearing upon the subsequent analysis, and they can be represented as lying in the common plane shown. Rotation is about the X-X axis.

The angle θ represents the setting of the propeller blade and is the independent variable of the problem. It fixes the position of the entire assembly, which rotates together relative to the coordinate axes as the blade setting is varied by the pitch-controlling mechanism.

R_1 and m_1 are known constants, as is ϕ_1, the angle between the arm and the blade, while ψ_1 and ψ are angles which depend upon θ. The unknowns are m_1, R, and ϕ, independent of θ, to be determined for a balanced condition.

By analogy with Equation [13], the centrifugal torques of the masses m_1, m, and the blade are, respectively,

$$Q_1 = -{}_{m}Q_1 \sin 2\psi_1 \qquad [27]$$
$$Q = -{}_{m}Q \sin 2\psi \qquad [28]$$
$$Q_c = Q_m \sin 2(\theta + \lambda) \qquad [29]$$

For balance of moments,

$$Q = Q_c + Q_1 \qquad [30]$$

and, using geometrical equivalents for ψ_1 and ψ,

$$-{}_{m}Q \sin 2\left(\theta + \phi - \frac{\pi}{2}\right) = Q_m \sin 2(\theta + \lambda) - {}_{m}Q_1 \sin 2\left(\theta + \frac{\pi}{2} - \varphi_1\right) \qquad [31]$$

The right side of Equation [31] is a sine wave

$$y = Q_m \sin 2(\theta + \lambda) - {}_{m}Q_1 \sin 2(\theta + \beta) \qquad [32]$$

where

$$\beta = \frac{\pi}{2} - \phi_1$$

The maximum value of this wave occurs when $dy/d\theta = 0$, when $\theta = \theta_3$ Thus

$$2Q_m \cos 2(\theta_3 + \lambda) - 2{}_{m}Q_1 \cos 2(\theta_3 + \beta) = 0 \qquad [33]$$

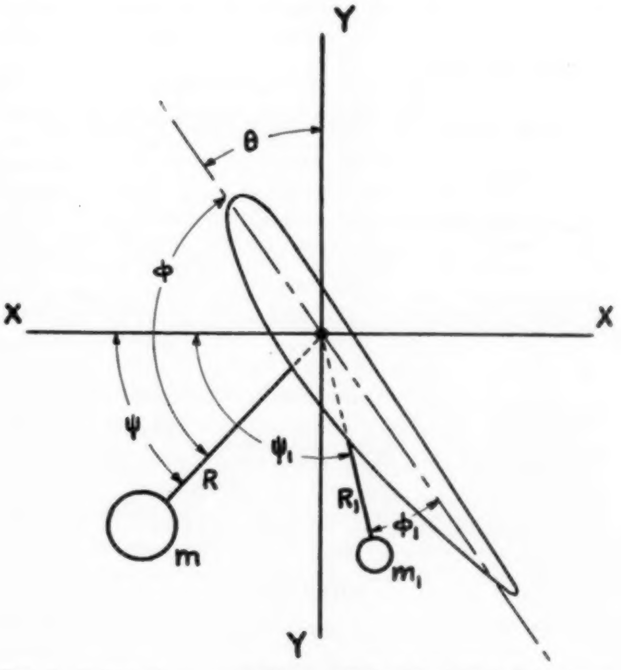

FIG. 8 THREE COMPONENT MASSES WHICH CREATE CENTRIFUGAL TORQUE ABOUT A BLADE AXIS

$$\tan 2\theta_3 = \frac{\cos 2\lambda - \frac{{}_{m}Q_1}{Q_m}\cos 2\beta}{\sin 2\lambda - \frac{{}_{m}Q_1}{Q_m}\sin 2\beta} \qquad [34]$$

Now Equation [34] can be solved for θ_3, which when placed in Equation [32] will give the maximum value of the wave. This maximum is evidently also the value of $-{}_{m}Q$ in Equation [31].

The intersection with the zero axis will be $\theta = \theta_3 - \frac{\pi}{4}$. Therefore (see Equation [31])

$$\phi - \frac{\pi}{2} = -\left(\theta_3 - \frac{\pi}{4}\right)$$

$$\phi = \frac{3\pi}{4} - \theta_3, \qquad [35$$

We have now derived relations by which the angle ϕ can be determined, at which a counterbalancing mass should be set for complete neutralization of centrifugal blade torque at all settings. A method for proportioning the mass and its lever arm will be presented in the following numerical solution of a test case.

NUMERICAL EXAMPLE

A tentative design of an operating arm, pin, and link for a typical mechanism indicates a total equivalent weight of 0.399 lb., at a radius of 2.86 in. from the blade axis.

The maximum centrifugal moment of this weight occurs when $\psi_1 = 45$ deg. Thus

$$\begin{aligned} {}_mQ_1 &= (\text{mass})\ (xy\omega^2) \\ &= 0.00422\omega^2 \text{ lb-in.} \\ &= 186 \text{ lb-in. at 2000 r.p.m.} \end{aligned}$$

The unbalanced moment of each of these component masses about its center of gravity is neglected.

For the blade considered in the body of this paper, we saw that

$$\begin{aligned} Q_m &= 1953 \\ {}_mQ_1 &= 186 \\ \lambda &= 9.875 \text{ deg. (use 10 deg.)} \\ \beta &= \frac{\pi}{2} - \phi_1 \end{aligned}$$

We observe that through the angle β the maximum torque depends upon ϕ_1, which in turn is different for various propeller applications. In order to investigate the effect of ϕ_1 upon θ_3, four computations were made:

ϕ_1	β	θ_3
7.5 deg.	82.5 deg.	36.0 deg.
12.5 deg.	77.5 deg.	36.8 deg.
17.5 deg.	72.5 deg.	37.1 deg.
22.5 deg.	67.5 deg.	37.35 deg.

The above results show that only a small error is introduced by using for design purposes average figures of about

$$\begin{aligned} \phi_1 &= 16 \text{ deg.} \\ \theta_3 &= 37 \text{ deg.} \\ \phi &= \frac{3\pi}{4} - \theta_3 \\ &= 98 \text{ deg.} \\ \beta &= \frac{\pi}{2} - \phi_1 \\ &= 74 \text{ deg.} \end{aligned} \qquad [36]$$

Equation [32] now becomes

$$\begin{aligned} y = {}_mQ &= 1953 \sin 94 \text{ deg.} - 186 \sin 222 \text{ deg.} \\ &= 2074 \text{ lb-in.} \end{aligned}$$

The torque created by the counterweight must be, from Equation [31]

$$\begin{aligned} Q &= -{}_mQ \sin 2\left(\theta + \phi - \frac{\pi}{2}\right) \\ &= -2074 \sin 2(\theta + 8 \text{ deg.}) \end{aligned} \qquad [37$$

The maximum value will be at $\psi = 45$ deg. Thus

$${}_mQ = \frac{mR^2\omega^2}{24} = \frac{mR^2}{24}(210)^2 = 2074 \qquad [38]$$

Ref. Equation [5]

Equation [38] can now be solved for the product mR^2, from which the required weight and radius can be related as follows:

$$W = \frac{36.4}{R^2} \text{ lb.}$$

where R = radius to center of gravity of counterbalance in inches

$W = mg$

For the above design, where $R = 3^1/_2$ in., $W = 2.98$ lb. total, including the equivalent weight of the arm which carries it.

The angle between this weight and the operating arm should be

$$\pi - (\phi + \phi_1) = 66 \text{ deg.}$$

NOTE: In a previous calculation, in which the operating arm and link were not considered, the weight was 2.66 lb. at 61 deg.

Appendix 2

LIST OF SYMBOLS

A = area of blade section at radius z
E = modulus of elasticity
F_c = centrifugal force on section of area A and unit thickness
$J_{\text{maj.}}$ = section moment of inertia about major axis
$J_{\text{min.}}$ = section moment of inertia about minor axis
$J(z)$ = $(J_{\text{maj.}} - J_{\text{min.}})$ expressed as a function of z
M_d = bending moment at root created by blade drag
${}_cM_t$ = bending moment at root created by combined thrust and centrifugal force
P_1 = inner radial bearing load
P_2 = outer radial bearing load
Q = centrifugal torque of counterbalance
Q_1 = centrifugal torque of operating arm and link
${}_mQ_1$ = maximum value of Q_1
Q_c = centrifugal torque of blade
Q_m = maximum value of Q_c
${}_mQ$ = maximum value of Q
R = radius from blade axis to c.g. of counterbalance
R_1 = radius from blade axis to c.g. of operating arm and link
T_e = equivalent distributed force creating same bending moments as centrifugal force
U = product of inertia
W = weight of counterbalance
X, Y, Z = coordinate axes
f_c = centrifugal force
f_e = equivalent force acting on an elemental mass to resist the centrifugal moment
l_b = distance between inner and outer radial blade bearings
m = effective mass of counterbalance and arm
m_1 = effective mass of operating arm and link
u = a function of z
x, y, z = rectangular coordinates
α = angle between the principal section axes and the coordinate axes about which U is taken
β = $\pi/2 - \phi_1$
δ = resultant deflection from the combination of δ_1 and δ_2
δ_1 = static deflection at radius z which would be created by aerodynamic thrust and drag alone
δ_2 = restoring deflection which would be created by centrifugal force if acting alone at deflection δ
θ = blade-setting angle, measured at 42-in. radius
θ_1, θ_2 = arbitrarily chosen angles for solution of Equation [11]
θ_3 = setting angle for maximum centrifugal blade torque
λ = negative setting angle for zero centrifugal blade torque
ρ = mass density of blade material
Σ_1, Σ_2 = total centrifugal blade torque at settings θ_1 and θ_2
ϕ = angle between projections on a plane perpendicular to blade axis, of counterbalance and major axis of 42-in. section
ϕ_1 = angle between projections on a plane perpendicular to blade axis, of effective radius of operating arm and major axis of 42-in. section
ψ = angle between counterbalance and X-axis
ψ_1 = angle between effective radius of operating arm and X-axis
ω = angular velocity of propeller.

Discussion

FRANK W. CALDWELL.[4] The paper summarizes some of the propeller-design problems that have furnished the basis of engineering discussion for a good many years.

The method of calculating the centrifugal torsion is described in the writer's paper, "American Progress in Controllable Pitch Propellers," presented to the International Congress for Aeronautics in London in 1923. It was earlier given in a different form by Drzwiecke in his book, "L'Hélice," published in Paris in 1920.

The method of applying the counterweight to balance the centrifugal moments was developed by the writer with the assistance of Mr. D. A. Dickey, now chief of the Propeller Branch at Wright Field, and Mr. E. G. McCauley. This work was done at McCook Field about 1920.

A method of calculating the bending stresses in the propeller blades, taking account of the deflection and resulting restoring moment, was developed by the writer and was published by the National Advisory Committee for Aeronautics about 1921 in a paper written jointly by Mr. N. S. Clay, of the Westinghouse Company, and the writer.

While these forces and stresses form a valuable background for the propeller designer, there are additional factors that must be taken into account if the design is to be successful. Two factors that have a profound influence on the design are the losses due to operation at high tip speed and the vibration stresses.

In a paper, "Physical Basis of Air Propeller Design," presented at the St. Louis Meeting of The American Society of Mechanical Engineers in 1920, Mr. E. N. Fales and the writer published some new data obtained in the wind tunnel at McCook Field on the characteristics of airfoils at high speeds. It was pointed out at that time that the old conception that propeller efficiency was a function only of V/nD would have to be revised. Airfoil and propeller tests during the past few years have made it apparent that the losses due to high tip speeds are a predominant consideration in propeller design. At the present time the only method known for minimizing these losses is through the use of thin sections, which can be most readily accomplished with the solid drop-forged blades.

The importance of the vibration stresses in propeller design is not reduced by the fact that they are difficult to calculate. While the vibration stresses are superimposed on the static stresses, they form the predominant stress in the propeller, and practically all failures in service are the result of vibration. In fact, it is very easy to break a propeller by means of vibration in the absence of any other stresses.

---

[4] Mt. Lebanon, Pittsburgh, Pa.

Some very valuable work on propeller vibrations was recently done by Mr. John E. Younger at Wright Field. Mr. Felix Pawlowski, also, while at Wright Field has collected some valuable data on the torsional characteristics of propeller sections for the purpose of calculating torsional characteristics.

The effect of vibration on the propeller-pitch-control mechanism is of the very greatest importance, and the most difficult problem in the design is provision for resistance to the destructive effects of vibration.

Fred E. Weick.[5] This paper, with its consideration of the various components of the centrifugal force and air loads on propeller blades, should be a great help to the large number of inventors of controllable and automatically variable-pitch propellers. After many discussions with the inventors about their propeller mechanisms, it would seem that very few understand the problem fully, particularly in regard to the torsional or twisting components.

One conclusion was made by the author which, while satisfactory for the purpose chosen, is not entirely correct, considering all the factors involved. This statement is that the aerodynamic torsion is so small in relation to the centrifugal and frictional moments that it need not be given quantitative consideration. This is probably satisfactory from the point of view of the moments required to turn the whole blade at the root. It is interesting, however, to consider the effect on the twist of the blade throughout its length and the resultant effect on the pitch. It happens that, at the outer portions of the blade where it is thin and flexible in torsion, the aerodynamic twisting moments are large compared to the twisting moments due to centrifugal force. In operation, therefore, the outer or working portion of the blade usually has a higher pitch than when at rest, even though the blade as a whole has a tendency to turn in the hub in such a manner as to reduce the pitch. This increase in pitch of the working portion of the blade is as much as 1 or 2 deg. with engines of high power. It is greater for conditions of take-off and climb than for high speed and cruising flight, which is exactly the opposite of the variation desired in a controllable-pitch propeller. This increases the difficulty of designing a self-operating propeller which automatically deflects to give the proper pitch change, but gives no particular difficulty in connection with the mechanically controlled type, in which it merely makes it necessary to use a slightly greater pitch change.

Author's Closure

The discussion contributed by Mr. Weick is constructive and to the point. It displays the intimate familiarity with propeller theory and practice which he has attained through his extensive experience in laboratory and flight investigations.

Much of the work which Mr. Caldwell has done in propeller development is widely known and acknowledged. As he points out, in 1923 he followed Drzwiecke with a paper which developed the centrifugal torque upon a single-blade section. In April, 1929, Messrs. Wood and Perring published another analysis of the same problem, in R. and M., No. 1274 (London). Four months later Mr. Caldwell included a repetition of his previous study as part of a paper entitled "Variable-Pitch Propellers," presented in 1929 before the Cleveland Aeronautic Meeting of S.A.E. In none of these earlier works was the analysis carried further than a single-blade section, and in applying their results it has always been necessary to perform a series of graphical computations to arrive at a torque-angle curve for an entire blade. Mr. Caldwell published such laboriously calculated curves in N.A.C.A. Technical Note No. 201 (1924) and in the foregoing paper. It might be suspected from both curves that their author did not recognize the centrifugal torque upon an entire propeller blade as a sine curve of 90-deg. wave length.

The differences between these curves and correct ones are of negligible numerical importance. The author wishes to point out, however, that they could have been computed more accurately with far less work by means of Equation [13] in the paper. In addition, this equation presents a rigorous analytical relation for the centrifugal torque on an entire blade, which is useful in further studies of propeller problems.

Such an application of the equation has been demonstrated in Appendix 1, where the torque relations of counterbalancing devices are analyzed. It is of course generally recognized that such devices are old in conception and use, Mr. Caldwell and his assistants having worked with them as early as 1920. The author has not located any analytical studies of their action in the literature, however, and it is probable that designs have heretofore been made upon elementary and trial-and-error bases.

The method of calculating the bending stresses in propeller blades referred to by Mr. Caldwell was published in 1924 in N.A.C.A. Technical Note No. 201, pp. 6, 7. In this study the resisting moment of the blade structure was completely neglected, and an attempt was made only to balance the bending moments from thrust and centrifugal force against each other. There was used for this purpose an assumption (p. 7, lines 11–13) which is erroneous in that it holds true only for a loaded string with zero moment of inertia which is given a straight-line deflection. An actual deflected propeller blade does not approach this condition.

"A rough approximation of the elastic stress" obtained on the basis of the foregoing assumption is too low, and since the error in the assumption depends upon the material used, the method cannot safely be used as a "means of comparison of propellers of different materials."

The author's paper deals with the problem in a more directly analytical manner, and it takes into account the simultaneous effects of thrust and centrifugal bending moments, as well as the internal resisting moment of the blade itself.

The particular propeller blade taken for the numerical examples was similar in plan form to the Navy No. 4350, but of hollow steel construction instead of solid aluminum alloy. In order to test the equations presented by application to a well-known standard blade, the centrifugal torque Equation [13] has recently been worked out for a Navy propeller No. 3792, 10-ft. diameter. The torque on this blade is expressed by an equation similar in form to Equation [17] of the paper:

$$Q_c(\theta) = 3333 \sin 2(\theta + 9.95 \text{ deg.}) \text{ lb-in. at 2000 r.p.m.}$$

Since the angle at which the torque becomes zero is —9.95 deg. as compared with —9.875 deg., the only practical difference in these equations is that the centrifugal torque in blade No. 3792 is 1.7 times that in the hollow steel blade previously calculated.

The time required for this additional calculation was about two hours for one man with a sliderule and a planimeter. A planimeter is convenient, but not essential.

The final four paragraphs of Mr. Caldwell's discussion are somewhat irrelevant in that they deal with problems which, although of recognized importance, have not been taken up in the present paper.

AER-54-20

Airplane Landing Gears

By FREDERICK KNACK,[1] MOLINE, ILL.

The landing gear is an important part of an airplane, for although failure may not be as dangerous to life as failure of another part, it is bound to be costly. Five things to look for in a landing gear are strength, satisfactory shock absorption, low drag, light weight, and stable taxying characteristics, and these are not necessarily antagonistic one to another nor difficult of attainment. Landing-gear failures are seemingly more frequent than other failures in spite of high load factors, possibly because taxying loads are neglected in specifying design loads. Small planes are often not able to make use of a retractable chassis, and the one-wheel chassis and tandem-wheel truck are suggested as possible methods of reducing chassis drag. Mention is made of the evolution of the Monocoupe landing gear toward decreased weight and resistance and greater dependability.

THE principal components of the airplane are five: the wings, fuselage, tail surfaces, power plant, and chassis. And the last of these five, the chassis, comprising landing wheels and tail skid, the only one of the five that does not perform a useful function when the airplane is in flight, is the one perhaps most likely to give trouble. The landing gear, used for only a few minutes at the start and at the end of each flight, a hindrance rather than a help to the performance of the airplane in its natural element, is a potent source of trouble, as most pilots and maintenance men will attest. Its duty is an important one, and while failure of the gear may not be as likely to result in serious injury or death to the occupants of an aircraft as would failure of the other principal parts, it may so result; and in any case expensive repairs, not only to the gear itself, but to the rest of the vehicle, are almost certain to be necessary. So it is well for designers to give considerable attention to this adjunct of the airplane, and indeed much that is worth while has been done in the way of improvement, both in aerodynamic and in strength properties.

The purpose of a landing gear is twofold. First, it functions to permit the transition from ground to air and from air to ground, and, second, it enables the aircraft to maneuver on the ground. Since it cannot aid the flight of a plane, the gear should be so made as to hinder it as little as possible; the wind resistance must be a minimum. To sum up, the characteristics to be sought in a good landing gear are:

(1) Strength
(2) Satisfactory shock absorption
(3) Low drag
(4) Light weight
(5) Stable taxying characteristics.

Adequate strength is necessarily a prime requisite of the landing gear and need not be difficult of achievement if the loads it will be called upon to resist be determined with fair accuracy. Current practice is to design for the loads specified by the Department of Commerce for the conditions of level landing, with and without side load, and three-point landing. In level landing the thrust line is assumed horizontal, and the ground reaction applied at the center of the wheel has a vertical component equal to the weight of the airplane (less chassis) multiplied by the required load factor, and a horizontal or drag component of not more than 25 per cent of this value, depending on the position of the wheels with respect to the center of gravity of the airplane. In the other principal loading condition, three-point landing, the vertical reaction is the same as in the first condition, but no drag component is specified. It is a question, however, whether these loading conditions cover the most severe stresses imposed on the undercarriage. True, they would seem to cover all possible attitudes of the airplane (an auxiliary loading condition is provided to take care of a one-wheel or side-slip landing), and the load factor would seem to be high enough considering that except in most unusual circumstances the airplane makes contact with the ground at such a speed and attitude that most of its weight is carried by the wings. Yet it is a fact that landing gears that show ample margins of safety when analyzed for the foregoing conditions frequently fail in ordinary use. Searching for a cause, one is struck by the thought that very likely the gears suffer much more by striking obstructions in the field during the landing or take-off run or while taxying than at the instant of landing. The obstruction might be nothing more than just the surface roughness of a poor field or a small ditch, a stone, or something of the sort. If this be the case, then it is apparent that the rules need revision, and a larger value of the drag component is indicated. Perhaps if a drag component were added to the three-point landing reaction, sufficient to cause the resultant to pass through the center of gravity, with the tail skid assumed to be just clear of the ground, this might more truly represent actual conditions. Or another loading condition might be worked out to care for the situation. Better landing fields will of course bring their own cure.

If the loads acting on the chassis are known, it is simple enough to design the members to have sufficient strength, but if there is an element of doubt it is well to provide against it by some such provision as pinning the landing gear to the fuselage structure through universal joints. Then in the event of a failure, the structure would fold up or be wiped off without, probably, a great deal of damage to the plane. If universal joints are not used, failure of a member of the gear usually means that fittings will be twisted and torn and fuselage members also twisted and bent, resulting in a sizable repair bill.

In the ideal gear, all members carrying load would meet in a point, and that point would coincide with the point at which the external load is applied. But such an ideal condition does not exist although it may be approached. In the gear shown in Fig. 1, the struts are so arranged that only the straight lower portion of the axle carries any bending. Consider the effect of the

---

[1] Chief Engineer, The Monocoupe Corporation. The author was born on April 11, 1906, in New York City. He was educated in the public schools and entered New York University in 1922, receiving the degree of B.S. in M.E. in 1926 and the degree of A.E. in 1928. Was instructor, 1926 and 1927, in the Daniel Guggenheim School of Aeronautics and operated the wind tunnel there. Joined Aerotech, Inc., consulting aeronautical engineers (Streator and Moline, Ill.), in 1927. Took his present position in 1930.

Contributed by the Aeronautic Division and presented at the Kansas City Meeting, Kansas City, Mo., Sept. 7 to 9, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

load component V in front elevation. If the oleo leg and axle meet in a point which is on the line of action of V, then obviously the loads induced in them will be purely axial except in the lower part of the axle, which must carry bending as well. Similarly, in plan view, the struts which resist the drag component D will have only axial loads produced in them, if, as shown, they intersect on the line of action of the external force. These two, V and D, are the principal loads to consider. There is also the side component H, which acts at the ground. Obviously the gear could not be designed to bring the intersection of the oleo and axle to coincide with the point of contact of wheel and ground, as this would result in a long lower axle having an unsightly appearance, and would move the oleo fitting so far from the center of the wheel as to cause excessive bending moments under the vertical and drag components, V and D. However, the load factor for this condition is only half as great as in the normal landing, so the stresses due to eccentricity of the side load should not prove critical for the structure. The brake load, shown in side elevation, must also produce bending, which will be resisted by the axial load in the rear strut, which intersects the axle below the center line, and being in compression due to the other loads acting in braked landing, sets up a counter torque. In this particular landing gear, the torque may be resisted in another way, so as not to stress the axle and drag strut.

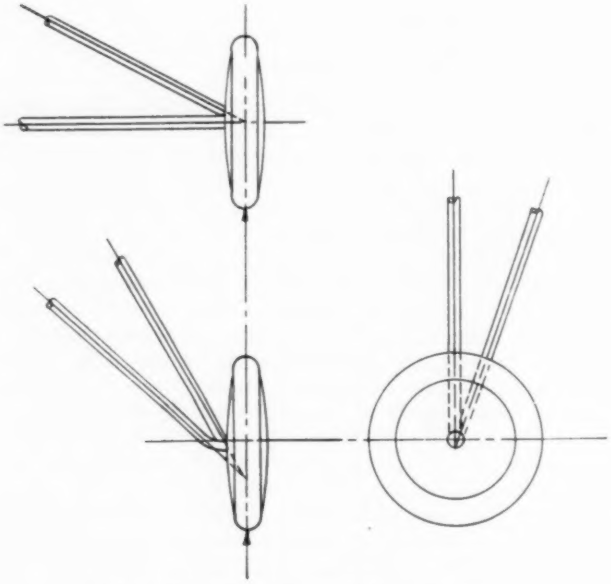

FIG. 1 IDEAL STRUCTURAL ARRANGEMENT

Heat treatment plays an important part in the building of the landing gear. The usual heat treatment leaves the metal, 4130 chrome-molybdenum steel, with an ultimate tensile strength of 180,000 lb. per sq. in. In this condition the material is tough and hard, but not brittle. Care must be exercised in the formation of pieces to be heat treated. In one instance it was found that the weld between an 18-gage tube and a 13-gage tube often cracked after heating, although the wall thickness of the one was only twice as great as the other, a condition well within the bounds of ordinary welding limits. It was necessary to substitute 16-gage material in the lighter member to cure the trouble. In another instance a 1025-steel strap was welded over the upper end of an axle as part of the fitting, and after heat treatment cracks often developed in the axle just below the strap. A cure was effected by using a 4130-steel strap and so placing it on the axle that the weld did not occur at the same place on both sides (Fig. 2).

A second requirement of the Department of Commerce is that the shock-absorbing device must absorb the energy of a free fall of 18 in. without subjecting the structure to loads great enough to cause failure. This seems a reasonable value and is undoubtedly a greater test than the absorber will be asked to pass in service. The passing of the old straight-axle type of landing gear was closely followed by the elimination of rubber cord as the shock-absorbing medium. Cord was objectionable for many reasons, such as the fact that its properties varied with age, that it deteriorated rapidly, and was not smooth acting. Practically all planes are now equipped with either oildraulic or pneumatic shock struts, which take the impact on oil and air. Both types operate satisfactorily, although the former may frequently break the rebound spring and the other requires attention to the air pressure, which must be kept at the specified figure and at the same value for both struts.

Another function which the shock strut is called upon to perform in certain types of undercarriage is to resist the brake loads. In the gear shown in Fig. 3 it is a question as to whether, when the brakes are applied, the resulting torque is taken through the axle or vee struts or by the oil strut. The oil strut will do the trick providing there is no opportunity for play in the fitting at the wheel. This assumption is borne out by the fact of breakage on many Monocoupes of the $^5/_{16}$-in. nickel-steel bolt in this fitting. This particular bolt had ample strength except in the condition where brake torque is assumed to be resisted by the shock strut, where the margin of safety was small; so that it seems fairly evident that breakage was due to that cause, especially as the bolt in the upper end of the strut never failed. The breakage was not always immediately evident, and it happened occasionally that a bolt, previously broken but unnoticed, permitted the wheel to drop down while the plane was in flight, resulting in a dangerous condition. To overcome this, a piece of $^5/_8$-in. outside diameter 16-gage tubing was welded to the lower end of the shock strut, and

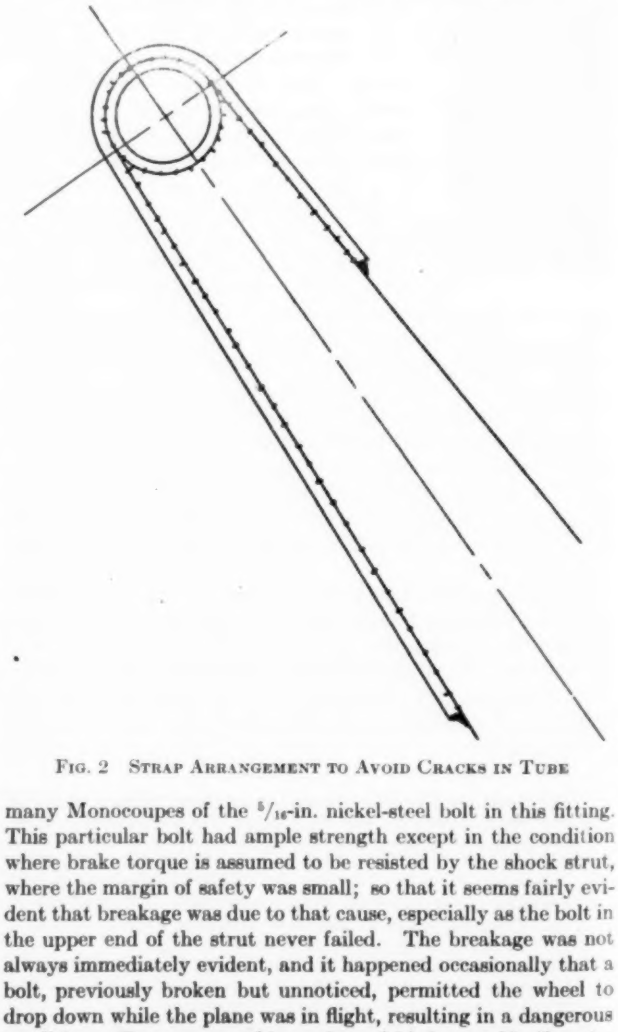

FIG. 2 STRAP ARRANGEMENT TO AVOID CRACKS IN TUBE

a $^3/_{16}$-in. bolt was passed through it and the fitting (Fig. 4). This bolt is normally never in contact with the strut and interferes with it in no way; but should the main bolt fail, it will prevent the shock strut from separating from the rest of the gear, and permit a landing, the landing loads passing directly from the shoulder of the shock strut to the fitting and not through the $^3/_{16}$-in. bolt. In fact, this condition (of a broken main bolt) might exist indefinitely and the plane be flown with safety, but it is almost certain that the pilot would be warned by the rattling of the gear and would effect the necessary repairs. The $^5/_{16}$-in. bolts were of course replaced by $^3/_8$ after proving too light in service, and since making the change no failures have been reported, but the safety-bolt feature is incorporated in all landing gears and is recommended as a simple precaution against failure and damage to the plane in an instance of this kind.

Sought as much as strength in a gear is low wind resistance, and the two factors are not necessarily antagonistic. The strong gear will probably have short members, for one thing. Earlier the point was brought out that curving the lower end of the axle reduced the bending loads in the members and resulted in a stronger gear. But this is not the only advantage gained, as it is evident that by so doing the interference between axle and shock strut is lessened and the drag lowered, thus adding an aerodynamic to a structural reason for adopting this procedure where the design is such that it can be used. Recently wheel streamlines, known as wheel pants, have come into considerable favor. There is no question that well-designed pants improve the performance and appearance of an airplane, but they also introduce another problem. They add considerable keel area forward of the center of gravity and thereby disturb the directional stability of the airplane. On small planes, at least, it is enough to place the airplane, normally having satisfactory stability, in a condition of rather poor stability in yaw, having in this respect almost as great an adverse effect as the addition of pontoons. Greater fin area seems to be indicated in such cases.

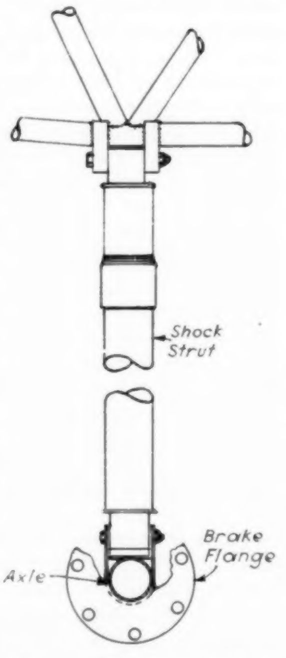

Fig. 3 Shock Strut Resisting Brake Torque

Retractable landing gears are receiving much attention, as they should, because by this means the ideal of no landing-gear drag at all is achieved. But however desirable it may seem, this solution of the problem is not practical for small planes, particularly if they are not of the low-wing cantilever type, which affords a fairly large space for the folded wheels. As this paper is written, two promising solutions to the small-plane problem are under investigation. The first is a one-wheel landing gear. This sounds fantastic, but is not necessarily so; a gear of this type was used with fair success a year ago on a plane entered by Hosler in the Cirrus Derby. O. A. Wheelon, of Curtiss-Wright, has been working along these lines, and the following paragraphs are taken from his notes.

They are the result of a series of model tests and calculations on the directional stability of a monowheel chassis, and although the investigation is not complete, the results are encouraging.

The monowheel chassis is essentially a central wheel conventionally located slightly ahead of the center of gravity. Directional control is maintained by a steerable tail wheel, a very important feature. Tip skids are used to prevent damage to the wing tips and to maintain a nearly level keel in taxying.

Reasons for its use are simplicity of structure in the case of low-powered planes or amphibions, and when used with retracting gear in a high-performance biplane exceptional speed characteristics would be obtained.

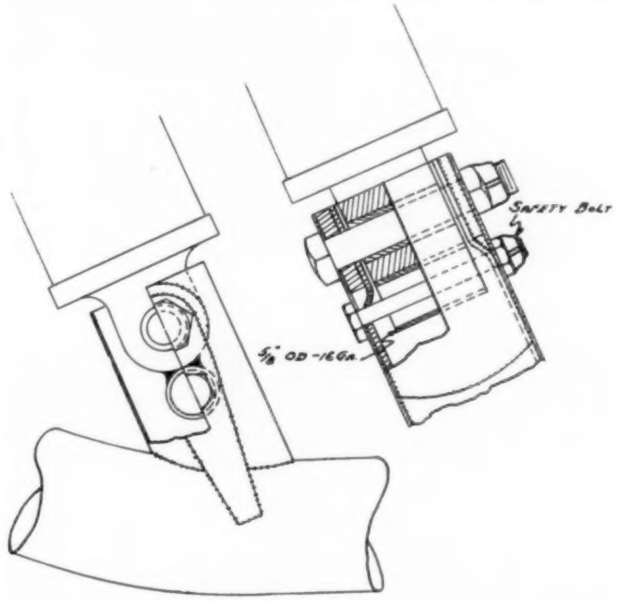

Fig. 4 Safety Bolt Arrangement

In Germany, as well as in this country, single-wheel and single-skid gliders have met with greater success than two-wheel or two-skid layouts. Some have explained this by the instantaneous sense of lateral balance before take-off and follow-through on landing. The mental hazard perhaps offers the greatest opposition. Most pilots believe they would have no difficulty with a single-wheel job but have horrors of a "dub" pilot trying it. Perhaps if we could eliminate the dub pilot from the "hot" plane classification and settle him with the low-powered category whose characteristics are so similar to the gliders that his still-less-experienced friends fly every day with one wheel and no difficulty, our viewpoint will change.

The degree of directional stability considered from ground reactions alone depends upon three factors. First, the fore-and-aft location of the center of gravity; that is, the more weight carried on the tail wheel, the greater degree of stability. The second is the tip angle, or the angle of clearance between the tip and the ground; the smaller this angle, the greater the degree of stability. The third factor is the height of the center of gravity above the ground; the lower the center of gravity, the greater the degree of stability and of course the lighter the tip loads. The last two are very closely connected, and might be jointly considered as the percentage of the weight carried at the tip when down.

In all cases the system is considered stable when the yawing moment capable of being developed by the tail wheel exceeds that present due to the yawing moment of the tip skid.

The foregoing considerations neglect all air controls which in themselves should be sufficient for control.

Other factors governing the characteristics are the relative amount of fin area fore and aft of the center of gravity and the proportions of control surfaces. The ground angle should be less than the burble point to facilitate take-off with the tail down.

The degree of stability desirable in any plane is best determined by varying the fore-and-aft location of the front wheel, keeping the tip angle as small as possible and still not having both tips drag. Theoretical considerations show that it is possible to develop tip load factors several times greater than that on the tail and still to maintain directional control.

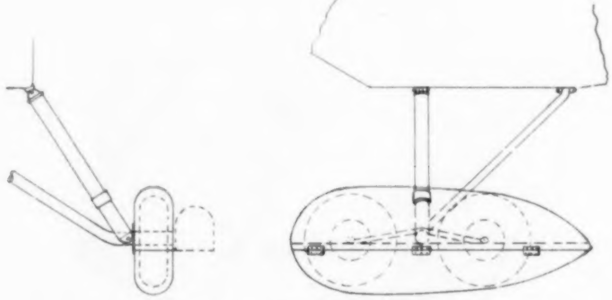

FIG. 5 TANDEM WHEEL GEAR

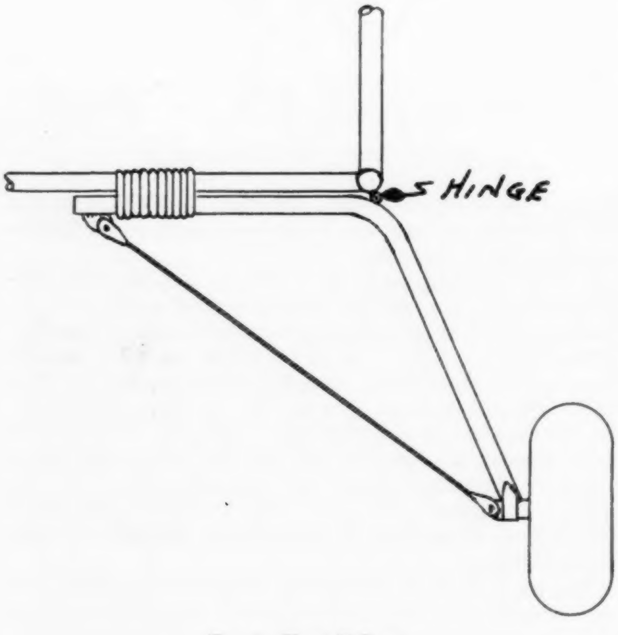

FIG. 6 TYPE F GEAR

The only time when the plane is directionally unstable is in the case of a tail-high landing with a tip down, and at such an attitude the rudder should still be effective. The duration of bumps is so short that it seems unlikely that angular acceleration could take place before restoring conditions are present.

From a common-sense viewpoint it would seem desirable to use an oversize unsprung air wheel with moderate wing loadings. In higher performance ships it would seem highly desirable to have a long throw oleo and taxi on the air wheel.

Structurally the arrangement should prove less likely to encounter failure as is so evident in narrow-tread gears at present where the entire load factor is at times developed on one wheel, causing failure which need not be anticipated with a one-wheel design. It has the added attractiveness of being less expensive than a two-wheel chassis, and even on a small high-wing monoplane it is probable that space could be found in which to stow the retracted single wheel.

The other gear which is under test is of a more practical nature (Fig. 5). It consists of two small wheels mounted in tandem on a truck which is slid on the axle in place of the conventional wheel, and can be used on any size airplane, although naturally it is more useful on planes to which a retractable undercarriage cannot be adapted. The whole thing can be enclosed by pants which, because of the size of the wheels relative to the size of a single wheel to carry the same load, will have only about one-quarter the frontal area of pants for the single wheel, with an even greater reduction in keel area. Because the pants are so small, it is possible to so arrange that in flight the bottom of the wheels, as well as the top, may be covered, still further decreasing the drag. The frame or truck is free to move on the axle through a limited angle, this being necessary so that in taxying over rough ground the wheels are enabled to climb over obstacles without disturbing the position of the fuselage by causing it to pitch. The pants for this tandem truck are made in two halves divided on a plane which is substantially parallel to the ground and slightly below the center of the wheels. The upper half is attached rigidly to the frame, and the lower is hinged to it along one side. While the airplane is in flight, the case entirely surrounds the wheels. When the airplane is ready to land, the pilot by a suitable mechanism causes the lower half to open up, exposing the lower part of the wheels, and permitting the plane to land, and to take-off or taxi on the ground. Some of the advantages of this gear are (1) lighter weight, (2) less drag, (3) lessened tendency to nose over when brakes are applied, (4) softer taxying, as in moving over rough ground only half the vertical displacement of each wheel is transmitted to the fuselage.

As this paper is written, the tandem-wheel arrangement has not yet been tried on an airplane, but it is expected that by the time of the meeting data on the flight tests will be available.

The airplane spends as little time as possible on the ground, but it should be able to move about on it easily at the pilot's will and not its own caprice, so that attention must be given to the taxying qualities of a landing gear. The shock absorber must of course be able to level out the inequalities of the surface so that riding will not be unpleasant, but more than that it must be amenable to guidance. The tread must not be so wide nor the wheels so far forward as to make it possible for ground looping to occur, nor should the tread be so narrow that the plane may tip over, nor the wheels so far back that it is in danger of nosing over. Brakes now so generally used complicate the problem. A delicate adjustment of the position of the wheels must be made to place them at just the point where the plane will not nose over when brakes are applied or ground loop, and the allowed variation is not great. Experience seems to show that the angle between a perpendicular to the ground and a line passed through the center of gravity and the axle, with thrust line horizontal, should be greater than 14 deg. but less than 17 deg.

If the shock strut is so placed that, as it shortens under the load, it permits the wheel to move forward, an unstable condition exists. Should the plane start to ground loop to the right, for example, the greater load is thrown on the left wheel, which then moves forward with respect to the right, and the tendency is for a still sharper turn in the same direction. It is better that the wheels move straight out from the fuselage as the struts deflect, although perhaps a slight rearward movement would not be undesirable.

It may be of interest to consider the evolution of the landing gear on one plane, the Monocoupe. This, a two-place, high-wing monoplane, has not changed greatly through the years, except to be constantly refined. The first model, built in 1926, had the conventional straight-axle landing gear common at that time, with rubber-cord shock absorbers. The next year, following the trend away from the straight axle, which often fouled grass and obstructions, a switch was made to a divided-axle type, with the shock strut running to the top longeron and a vee strut to the center of the fuselage. Rubber cord was retained as the shock-absorbing material. This gear, adopted in deference to the agitation against the straight axle, has disadvantages of its own, such as increased weight and an increased drag, which resulted in a top speed lowered by, roughly, 3 miles an hour. Shortly the rubber-cord shock strut was abandoned in favor of an oildraulic strut, which measurably improved the performance of the gear, but did not help the weight and drag factors any.

In 1929 this gear was modified by running the shock strut to the lower longeron, instead of to the upper, with a great reduction in weight and a return of the wind resistance to about the same figure as for the straight axle. This gear was first tried out and developed on a racing-model Monocoupe. The principal source of trouble was the spring in the oildraulic strut; if too flexible, it compressed too easily in taxying, and if the loads on the wheels were slightly unbalanced, it encouraged ground looping by letting one side of the plane drop much lower than the other; if too stiff, taxying was very rough. In either case, it was common to have the spring break after short usage, and often this resulted in a failure of some other part of the landing gear. As the spring comes into play in taxying, it serves to bear out the contention made earlier that taxying is more severe on the chassis than landing. The latest development in the Monocoupe gear is one in which a tierod replaces one of the tubular members, and the other two are narrowly spaced and may be faired together (Fig. 6). This has resulted in an improvement in top speed of 5 miles per hour over the previous gear. The structure is cantilever in a sense.

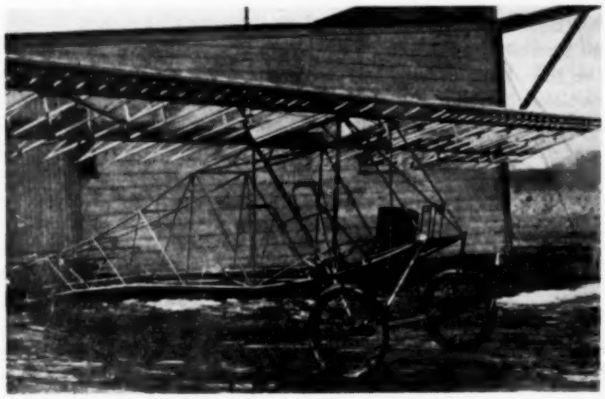

FIG. 7 AIRPLANE LANDING GEAR—STRAIGHT AXLE CHASSIS

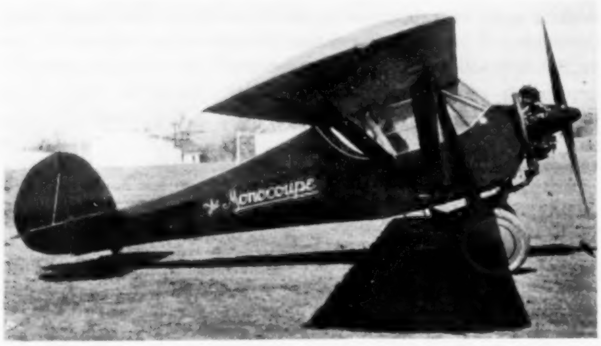

FIG. 8 AIRPLANE LANDING GEAR—DIVIDED AXLE, LONG STRUT

The axle is a continuous member, running from the wheel to a hinged fitting on the lower longeron and thence horizontally into the center of the fuselage. This horizontal portion is wrapped with shock cord, thus returning to one of the earlier evils, but the advantages gained are felt to overcome this disadvantage. To relieve the axle of the enormous bending loads it would carry as a full cantilever, its two extremities are joined by a streamlined tierod. The drag component of the load is taken by the strut which lies in the plane of the vertical portion of the axle. This landing gear, while only recently tried out, has so far behaved excellently. At present optional equipment, it may soon be made standard. It is both cheaper and lighter than the old gear.

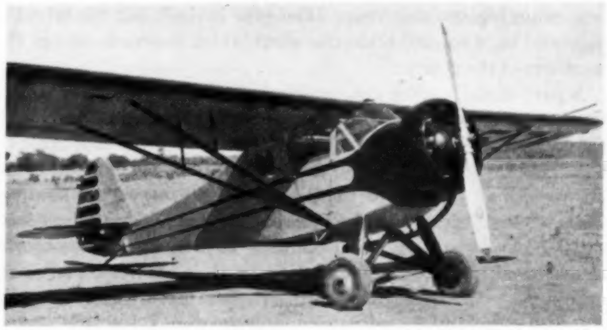

FIG. 9 AIRPLANE LANDING GEAR—DIVIDED AXLE, SHORT STRUT

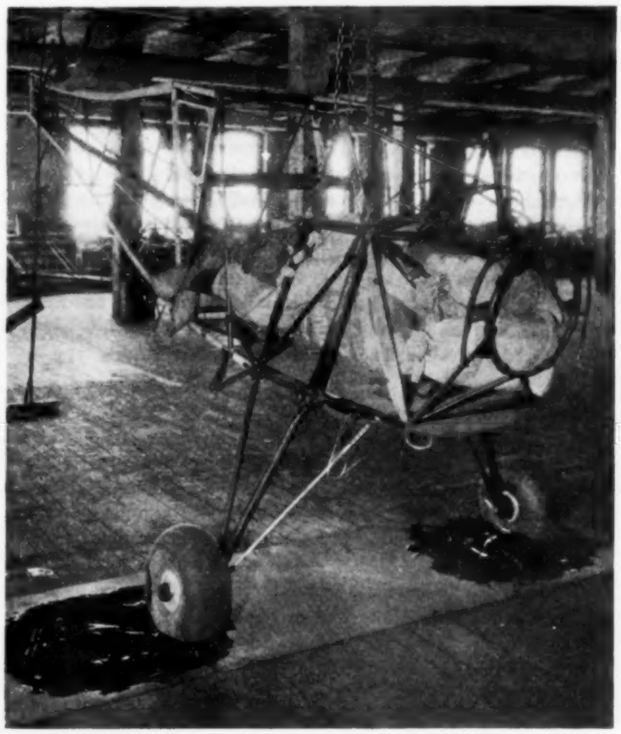

FIG. 10 AIRPLANE LANDING GEAR—DIVIDED AXLE, NEWEST GEAR

Many manufacturers are working toward the improvement of the landing gear. When balloon wheels were introduced by Goodyear a few years back, it was thought they would make it possible to eliminate other shock absorbers and permit the use of a rigid gear. Such hopes proved vain, for experiments have proved that a shock unit in addition to the wheels is desirable and that a combination of balloon wheel and shock absorber gives excellent performance under all conditions, although we prefer the smaller and lighter semi-balloon to the full balloon tires. Even so, the rigid chassis is not an impossibility, as Waco demonstrated on its new cabin biplane this year. The gear is rigid, but the wheel is mounted on a splined oildraulic strut which moves in one of the members of the gear.

A part of the landing gear which does not always receive the attention it deserves is the tail skid. Its design depends largely upon whether or not brakes are used. If not, then the skid must be a rigid affair or the plane will prove uncontrollable in a wind, and no wheel may be used or the plane will roll forever on landing. Many types of skids have been used, but the leaf-spring type is as satisfactory as any on small planes. It is inexpensive, absorbs shocks well, requires no attention, and is easily replaced, if necessary. The question of a suitable shoe is more difficult. No material seems able to withstand long the abrasive action of concrete runways, or even cinder or gravel. It may be Stellited, but this process is far more expensive than the cost of the shoe itself. After tests on Monel metal and Illium, two alloys noted for their resistance to abrasion, it was found that ordinary malleable cast iron had greater resistance. Shoes of this material can be had for 6 cents apiece. Stelliting would add a dollar to their cost; so the policy of this company is to equip with the cast-iron shoes and make them cheap enough so that the owner can replace them as often as necessary.

On a plane equipped with brakes, a tail wheel is possible as well as desirable. One difficulty with wheels having a plain journal bearing is that dirt and grit quickly get in and wear the axle, or stop the wheel from turning, with the result that it is subjected to the same wear as a skid shoe. If the wheel is movable, it should of course be castered; but on small planes, even with the help of brakes, it is often difficult to taxi in a wind if the tail wheel is pivoted. A steerable wheel is much the more desirable type.

Discussion

WELLWOOD BEALL.[2] Landing-gear problems are a source of great annoyance to every engineer. Landing-gear failures are prevalent at every airport. Hence, as the author has suggested, engineers should study this problem more deeply.

Several points were mentioned that are very important. The center lines of all the struts in the landing gear should meet at a common point somewhere in the wheel. The lower this intersection is, or the closer it is to the ground, the better. The disadvantage of having this point close to the ground is the large bend that is required in the axle. However, a compromise can be made. The importance of this consideration is little appreciated by many designers, but if many of the present landing gears were redesigned at the lower end and the fitting was made so that the axes of the struts intersect at a common point, many of the troubles in the landing gear would be eliminated.

Since, as has been mentioned, the forces that tend to break down the landing gear are usually induced from taxying, rather than from landing impacts, the method of fabrication of the fittings and the struts must be carefully considered. In other words, fatigue set up by rough taxying must be compensated for in improved design; hence, the author's remarks concerning welding practice on the landing gear.

Another source of trouble in landing gears in which brakes are used is the method of absorbing brake torque. There have been several methods used to absorb this torque, but at the present time most installations take the torque through the pin joint to the bottom of the oleo strut and through the walls of the oleo strut. It has been found that oleo struts are much more effective when they do not have to carry this torque which induces a bending moment in the strut. One method of taking this brake torque was used on a Ford tri-motor, where the torque was taken through an auxiliary strut attached to the brake disk and to a point above the oleo strut. This, however, was not entirely satisfactory, as the action of the oleo tended to rotate the brake around the axle, thus giving uneven deceleration. This sensation was rather uncomfortable. On the later Fords, this long auxiliary strut has been connected to the bottom, or the unsprung, portion of the oleo, but the disadvantage of this is that they are carrying bending moment through the oleo gear.

The safety bolt used in the Monocoupe landing gear, as described, is ingenious. However, it is the writer's opinion that the landing gear described in Fig. 6 will not prove as satisfactory as is expected. The reasons for this are that the rubber shock-absorbing unit has never proved itself satisfactory and that the landing gear as designed will carry considerable shock to the fuselage through the hinge point. This shock is carried to the fuselage from the wheel directly up the strut and through the hinge joint, since the design is of semi-cantilever construction. This type of landing gear and spring suspension has been tried many times before, but it has been found that with the shock-absorbing unit on the opposite side of the hinge point from where the shock is applied, a considerable amount of the shock is transmitted to the hinge point without ever reaching the shock-absorbing unit.

A Study of Light Signals in Aviation and Navigation

By I. LANGMUIR[1] and W. F. WESTENDORP,[2] SCHENECTADY, N. Y.

I. Langmuir

W. F. Westendorp

Laboratory experiments have been devised to make measurements of the visibility of light signals under conditions essentially similar to those encountered by the aviator or the navigator. Data have been collected on the direct visibility of flashing-point sources of light of different colors, flash lengths, and intervals, against different backgrounds. The time taken to locate a visible beacon was studied as a function of the beacon intensity and frequency of flashing.

The threshold candlepower required for visibility of a point source against a background is given by an empirical equation. Colored point sources were not found to be useful except in the case of red lights with background intensities above moonlight. For an airplane approaching a beacon it is advantageous to use frequencies of flashing as high as 12 to 30 per min., although with exceptionally clear atmosphere, lower frequencies may be better. In a study of the visibility of flashes of diffused light superimposed on a steady white background, white-light flashes gave the best results. A selective differential photoelectric receiver is described which detects signals of modulated diffused light of low intensity. This sensitivity is independent of the steady background brightness up to 100 times moonlight, and is from 6 to 13,000 times as great as that of the eye in the range of background intensity from darkness up to moonlight. The greatest difficulty in transmission of light signals through fog lies in the loss of advantages of the point source. Dense fog may increase the distances at which diffused-light signals may be detected. The range depends to a considerable extent on the reflectivity of the ground. A theoretical treatment of the diffusion of light through fog, based on the scattering of the light rays by fog particles, indicates that airplanes can be guided through fog at distances of several miles by means of diffused modulated light acting on a differential photoelectric receiver.

In all forms of traffic, whether it be navigation, automobiling, or simply walking, we depend on the use of our eyes; but most strikingly is this true in aviation. At present the pilot depends on direct vision for guiding his plane, and hence "visibility" is a vital factor in aviation. Methods have been developed recently by which "blind" flying is possible and practical for definite commercial routes. The extent to which these methods will prove useful cannot be predicted, but it is probable that light beacons and direct visibility will continue to be of great importance to the aviator.

Very little systematic experimental work seems to have been done previously on the visibility of light signals as used in aviation. The purpose of this paper is to present some results that have recently been obtained by the authors.

The most obvious method to obtain data on the visibility of light beacons is to set up different types of beacons and to observe them from an airplane under various conditions. However, this method lacks a fundamental quality of most scientific investigation—that of arbitrary control of all conditions; the weather would be different on different nights, and furthermore, even during a single night the background illumination due to moonlight or starlight would vary.

The plan was therefore adopted of making measurements on visibility in a dark room in the laboratory where there is complete control over the illumination of the background, the location,

---

[1] Associate Director, Research Laboratory, General Electric Company. Dr. Langmuir was graduated from Columbia University in 1903 with the degree of metallurgical engineer, and then spent three years in post-graduate work in Germany at the University of Göttingen under Professor Nernst, where he received the Ph.D. degree. Upon his return to America in 1906 he became an instructor in chemistry at Stevens Institute of Technology. Three years later he entered the Research Laboratory of the General Electric Company at Schenectady, N. Y., where he is now located.

Dr. Langmuir has been the recipient of distinguished honors in the fields of chemistry, physics, and engineering. Among the awards made to him have been the Nichols medal, given by the N. Y. Section of the American Chemical Society and awarded to him in 1915 and again in 1920; the Hughes medal, awarded by the Royal Society of London, 1918; the Rumford medal by the American Academy of Arts and Sciences, 1921; the Cannizzaro prize, awarded by the Royal National Academy of the Lincei, Rome, Italy, 1925; the Perkin medal by the American Section of the Society of Chemical Industry, January, 1928; the School of Mines medal, Columbia University, 1929; the Chandler medal, 1929; and the Willard Gibbs medal, in May, 1930.

Dr. Langmuir has received the following honorary degrees: University of Edinburgh, LL.D., 1921; Northwestern University, D.Sc., 1921; Union College, D.Sc., 1923; Columbia University, D.Sc., 1925; Kenyon College, D.Sc., 1927; Technische Hochschule, Berlin-Charlottenburg, D.Ing., 1929.

[2] Research Laboratory, General Electric Company. Mr. Westendorp was born in Amsterdam, Holland, in 1905. He was graduated from the University of Delft in 1928, coming to the United States in July of that same year. He became associated with the General Electric Company in the radio engineering department, and is a graduate of the "Advanced Course in Engineering" of that company. In September, 1929, Mr. Westendorp was transferred to the Research Laboratory.

Contributed by the Aeronautic Division, cooperating with the American Institute of Physics, and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the color, and the flashes of the beacon or other light source. It has been the aim to duplicate as far as possible in the laboratory the conditions of visibility encountered by the aviator or navigator, especially those characteristic of poor visibility.

In reasonably clear weather, when the direct rays from a beacon can reach the eyes of the aviator, he perceives the signal as a flash of light from a point source. The visibility of such point sources depends on many factors, such as the candlepower of the sources, the distance from the observer, the absorption or scattering of light by the intervening atmosphere, the color of the light, the diffused background illumination (starlight, moonlight, or sunlight), the duration and the frequency of the flashes, the presence of other disturbing point sources of light, and finally upon the qualities of the observer—his eyesight, his mental condition, and especially his attentiveness.

Under conditions of poor visibility, particularly those due to the presence of fog, the light from a beacon or other source may be scattered to such an extent that the direct rays are not visible, although diffused light from the source may still reach the aviator in perceptible amount.

The visibility of such diffused light signals depends primarily upon the brightness of illumination in the fog surrounding the aviator produced by the signal, the color of the light, the intensity of any steady illumination of the fog (starlight, moonlight, etc.), and the duration and frequency of the flashes of the signal.

It will be shown that the eye is relatively insensitive to diffused light as compared to that from point sources. On the other hand, it has been made possible by use of a photoelectric cell with amplifier equipment to detect diffused light many thousands of times too faint to see with the eye.

Any estimate of the distance to which diffused light signals of this kind can be transmitted involves a study of the laws of the scattering of light by fog. It will be shown that under certain conditions signals may be transmitted to relatively great distances through fog.

The aviator will be particularly interested in the time required to detect or locate a visible light signal. If a point source is of such low intensity (threshold intensity) that it is barely visible when pointed out to the observer, it takes an indefinitely long time for the observer to locate the source if it is in an unknown position in a large and uniformly illuminated background.

The threshold intensity for a flashing point source is that which is required to render the flash barely visible when occurring at regular intervals and in a known position. If the flashes are then made to come at irregular intervals or in unknown positions, a relatively long time may be required to become aware of them.

A useful signal to the aviator must be recognizable within a very short time, and must therefore be of an intensity appreciably greater than the threshold.

Visibility of Point Sources. When the light from a steady point source falls on the eye of the observer, it is focused by the lens of the eye upon a very small area of the retina. The amount of light so focused is proportional to the area of the pupil opening of the eye and to the light flux density F in lumens per square centimeter.

In clear air, without scattering or absorption,

$$F = C/D^2 \qquad [1]$$

where C is the candlepower of the source in the direction toward the observer and D is the distance from the source to the observer.

In the presence of haze or fog the direct light flux from a point source decreases exponentially with increasing distance, so that in general we have:

$$F = (C/D^2)e^{-D/\lambda} \qquad [2]$$

where $1/\lambda$ is the scattering or absorption coefficient characteristic of the fog or haze and λ may be looked upon as the mean free path of the light rays.

A discussion of the magnitude of λ under various conditions of haze, for light of different colors, has been given by F. Benford.[3] It is of the same order of magnitude as the distance termed "visibility" by the aviator, and thus except under conditions of fog is ordinarily to be measured in miles.

In their laboratory experiments the authors have not studied the effect of haze in decreasing the light flux received from a source. They have, however, determined under various conditions the visibility of light sources which produce known flux intensities F at the eye of the observer. These data are obviously applicable to the conditions encountered by the aviator if λ is known or if the exponent D/λ is small compared to unity—that is, if λ is large compared to the distance D.

The visibility of a point source depends to a very great extent upon the brightness of illumination of the background. The aviator may encounter background intensities which range from that produced by bright sunlight on snow down to that of starlight on a cloudy night with forest-covered ground.

When light from a point source, giving a flux intensity F in accord with Equation [1], falls perpendicularly upon a plane surface of a perfect diffuse reflector, the brilliancy of illumination H of the surface in candles per square centimeter is

$$H = F/\pi \qquad [3]$$

In Table 1 are given values of F and H characteristic of various sources. These light intensities[4] are those that would be observed at sea level when the point source is at the zenith of an exceptionally clear sky. Stars of the sixth magnitude corresponding to $F = 10^{-12}$ lumens per sq. cm. are the faintest that can ordinarily be seen with the unaided eye.

TABLE 1

(Light flux density F and brightness of illumination H produced by various sources)

Source	F (lumens per sq. cm.)	H (candles per sq. cm.)	Brightness of source (candles per sq. cm.)
Sun	10.4	3.3	150,000
Full moon	2.2×10^{-5}	7.1×10^{-6}	0.37
Venus (max. brightness)	1.1×10^{-8}	3.5×10^{-9}	..
1st-magnitude star	8.5×10^{-11}	2.7×10^{-11}	..
6th-magnitude star	8.5×10^{-13}	2.7×10^{-13}	..
Average starlight	1.8×10^{-7}	5.8×10^{-8}	5.8×10^{-9}
1 candle at 1 km	10^{-10}	3.2×10^{-11}	..

Effect of Flashing. If the light source consists of separate flashes of candlepower C, each of which lasts for a time t_o, the candlepower required for threshold visibility will in general be greater than that required for a steady light.

Blondel and Rey[5] have found that the threshold intensity F required for visibility of a light of duration t_o seconds is given by

$$Ft_o = F_\infty (t_o + 0.21) \qquad [4]$$

---

[3] F. Benford, *Gen. Elec. Rev.*, vol. 29, p. 873 (1926).

[4] These values have been calculated from data given in Russel, Dugan, and Steward's book, "Astronomy," vol. 2, pp. 613, 625, 626, Ginn & Co. (1927). The value of H for starlight is based upon the statement that Rhijn found that the total light of the sky on a clear dark night is six times the light from all the stars and that the latter is equivalent to that of 1440 stars of the first magnitude. Thus the brightness H corresponds to that produced by 2160 first-magnitude stars at the zenith.

[5] A. Blondel and J. Rey, *Jour. de Phys. et de le Radium*, vol. 1, pp. 530–551 (1911).

where F_∞ is the threshold intensity for a steady light. Thus when a flash lasts several seconds, so that 0.21 is negligible, the threshold is the same as for a steady light, but for flashes of very short duration ($t_o \ll 0.2$) the visibility depends only upon the total quantity of light received—i.e., the product Ft_o, which must then be equal to 0.21 F_∞.

The aviator flying in clear weather in full moonlight is not in great need of light beacons as the natural illumination is sufficient to make landmarks discernible. For this reason the authors in their experiments confined the background brightness to an upper limit of full moonlight falling perpendicularly on a white diffusing surface, corresponding to a brightness of 7×10^{-6} cp. per sq. cm.

Experiments on the Visibility of Flashing Point Sources

The following arrangement was used. The observer was placed at distances ranging from 1.5 to 6 m. from a vertical white screen 1.5 m. by 1.5 m. in size, with its center about the height of the eye. Lamps, behind the observer and screened from his direct view, illuminated the screen so that its brightness could be varied from that of moonlight down to zero. These low brightnesses were measured indirectly by photometering the brightness of a similar surface at one-tenth the distance from the lamps and dividing the value by 100.

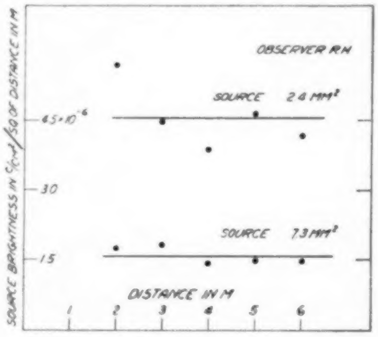

Fig. 1

(Visibility of small flashing illuminated areas as affected by their size and their distance from the observer. Screen is 1.5 m. square with steady illumination of moonlight brightness. The ordinates represent threshold values.)

In the screen there were 150 small round holes ranging from 2 mm.² to 66 mm.² area and one square hole of 1 sq. cm. area. The area of the latter could be varied by means of a plane diaphragm so that the opening always remained square and could easily be measured. All the holes were covered on the front by white paper 0.11 mm. thick, so that they were invisible unless illuminated from behind. When so illuminated by a small lamp, the surface brightness could be varied either by regulating the current or by changing the distance of the lamp. Flashing was produced by interrupting the current or by intercepting the light by means of a pendulum shutter. These illuminated spots of light served as point sources.

The threshold value of the intensity of the point source was determined by gradually decreasing the intensity until the observer lost track of the flashes. This method eliminates all uncertainty as to the location of the light source. In the experiments on threshold intensity, the observer remained in a dark room for a half hour for dark adaptation; then the flashing light was increased until he could easily see it, and the observer was asked to signal by tapping at every flash. By reducing the light until his signaling became irregular or stopped, the threshold was determined. The values given in Figs. 1 to 7 are the average of three, or more often of ten, observations. This "threshold" will later be used as a unit of light intensity in the determination of the time to locate a flashing light.

If an illuminated area is of sufficiently small size, its visibility will depend upon the total light from it—i.e., upon the product of its area and its surface brightness. If an area is so large that it is clearly perceived as a surface instead of a point, its effect depends rather upon the contrast in brightness between it and the surrounding surface. Whether an area is recognized as a point or as an extended surface depends upon the visual acuity, and this in turn varies with the brightness of the background illumination. With starlight intensity, or less, a relatively large area is equivalent in its effect to a point source. For an illuminated surface surrounded by a completely black background, Ricco's law states that the total light (area × brightness) determines the visibility if the angle subtended by the source is less than about 1 deg. With higher background brightness the total light will determine visibility only for areas which subtend much smaller angles.

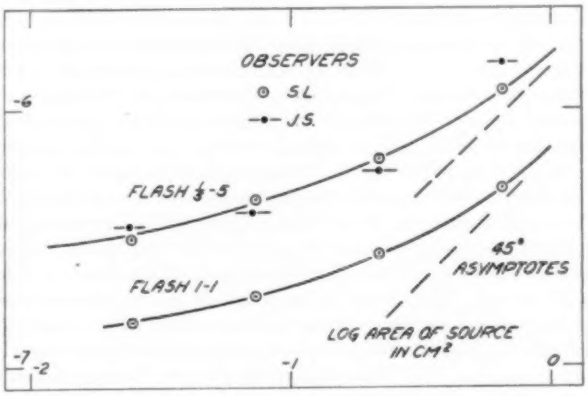

Fig. 2

(Effect of the size of the illuminated area and the duration of flashes on visibility. Screen of moonlight brightness at 1.5 m.)

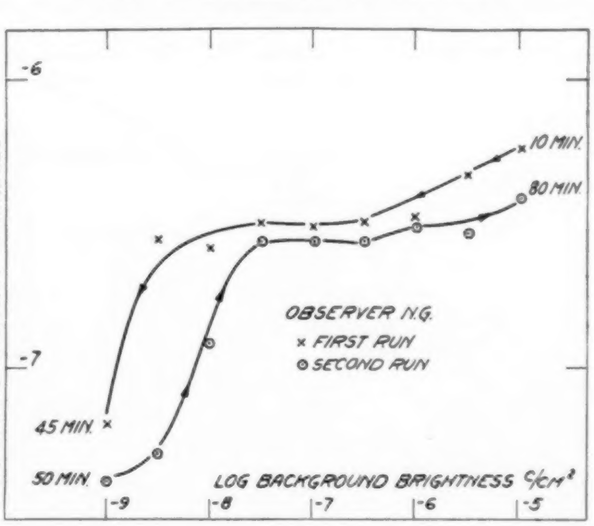

Fig. 3

(Effect of background brightness and adaptation on the visibility of flashing point sources. Flashes are 1 sec. on and 1 sec. off. Observer is 3 m. from screen. The arrows indicate the sequence of the observations.)

It was therefore of interest to determine in the experiments the conditions under which the illuminated areas were effectively point sources. It also was desired to know whether the apparent size of the large screen was of importance in determining the threshold intensity of the point sources.

Fig. 1 represents the results of a series of observations in which the brightness of the screen was kept constant at 8×10^{-6} cp. per sq. cm. and the distance of the observer from the screen was varied from 2 to 6 m., while the square point source was flashed for 1/5 sec. every 5 sec. By division of the surface brightness of the source at threshold intensity by the square of the distance to the observer, a value independent of the distance would be obtained, if the source is effectively a point source and if the screen area is without effect. This appears to be valid within a range of variation that can be accounted for by fatigue of the eye or other personal factors.

It also should be noted that when the area of the source is cut down to one-third, the surface brightness for threshold visibility must be increased threefold. A square source of 7.3 sq. mm. area at a distance of 2 m., which subtends an angle of 5 min. of arc, is small enough to act as a point source with a background of moonlight brightness.

In the experiment, which gave the data shown in Fig. 2, the observer was 1.50 m. from the screen, having moonlight brightness. The common logarithm of the threshold candlepower is plotted against the logarithm of the area of the source. The visibility of small sources depends only on the candlepower, but with large areas the threshold candlepower increases in proportion to the area, indicating that a constant contrast is required for threshold visibility. From the position of the 45-deg. asymptotes it is calculated that the additional brightness to make sources visible that have a subtended angle of more than 0.3 deg. is 20 per cent for the 1 sec. on and 1 sec. off flashes and 40 per cent for the 0.2-sec. flashes. Areas less than about 3 sq. mm. which subtend an angle of about 5 min. are approximately equivalent to point sources. In further experiments the illuminated holes having an area of 2.2 sq. mm. were used as point sources.

Effect of Background Brightness on the Visibility of Flashing Point Sources. Fig. 3 gives some data on the threshold values of the candlepower of flashing point sources as influenced by the brightness of the background illumination. Observations were started after only 10 min. for dark adaptation; after these the screen brightness was decreased, and again four observations were taken, etc. Every cross on the graph represents the average of four observations. After 50 min. the screen brightness was increased again, and after 80 min. the original brightness was reached. Apparently a continued dark adaptation stronger than any effects of fatigue must account for the lower values of the second series. Figs. 4 and 5 show curves for two observers at 3 and 6 m. distance and a 1 sec. on and 1 sec. off flash after half an hour for dark adaptation. The asymptotic values for zero background brightness are indicated by the arrows and are of the same order as those for 10^{-9} cp. per sq. cm.

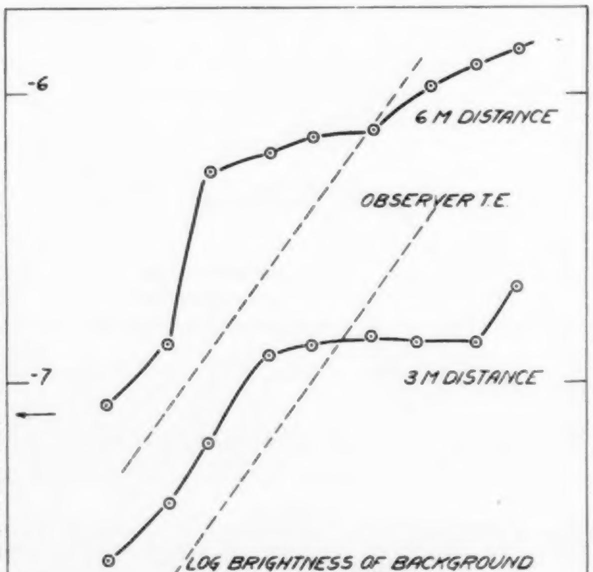

FIG. 4

(Effect of background brightness and distance on the visibility of flashing point sources. The broken lines correspond to Equation [5].)

The curves obtained by different observers differ considerably, but all agree in showing that the threshold value of candlepower increases much slower than in proportion to the background brightness. Starlight ($H = 6 \times 10^{-8}$) is sufficient to require an increase of fivefold to tenfold in the threshold candlepower of a point source.

It is interesting to compare these data with astronomical observations on the visibility of stars. Ordinarily a star of the sixth magnitude ($F = 8.5 \times 10^{-13}$ lumens per sq. cm.) is the faintest that is visible to the unaided eye against the background of starlit sky ($H = 6 \times 10^{-8}$). This corresponds to 7.6×10^{-8} cp. at a distance of 3 m. This point has been plotted in a circle in Fig. 5 and is seen to be in fairly good agreement with the observations of point sources at 3 m. distance.

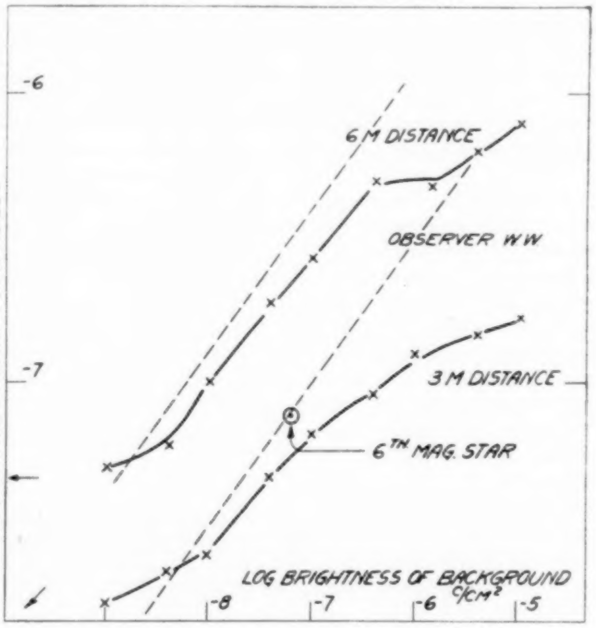

FIG. 5

(Effect of background brightness and distance on the visibility of flashing point sources. The broken lines correspond to Equation [5].)

Russell[6] finds, however, that stars of magnitude 8.5, for which $F = 8.5 \times 10^{-14}$, are recognizable if the light of the neighboring parts of the sky are screened off. This is in reasonable agreement with the values of F ranging from 1.3 to 2.3×10^{-13} obtained from the threshold candlepowers observed with zero background intensity (see arrows in Figs. 4 and 5) by dividing by D^2, D being the distance in centimeters.

Venus, when of maximum brightness (magnitude —4.3), can be seen very readily at noontime on a clear day if its exact location in the sky is pointed out, although once lost it may be difficult to find again. Its brightness, which corresponds to $F = 1.1 \times 10^{-6}$ lumens per sq. cm., is distinctly above the threshold value of visibility for a point source in a clear sky at noon which has a brightness of the order of $H = 1$ cp. per sq. cm.

The following empirical equation seems to be in reasonable agreement with these data:

$$F = C/D^2 = 3.5 \times 10^{-9} H^{1/2} \text{ lumen per sq. cm.} \ldots\ldots \quad [5]$$

---

[6] H. N. Russell, *Astrophys. Jour.*, vol. 45, p. 60 (1917).

where F and C are threshold values for a steady point source in a background of brightness H, expressed in candles per square centimeter.

TABLE 2

(Comparison of observed and calculated threshold values for point sources with backgrounds of various brightness)

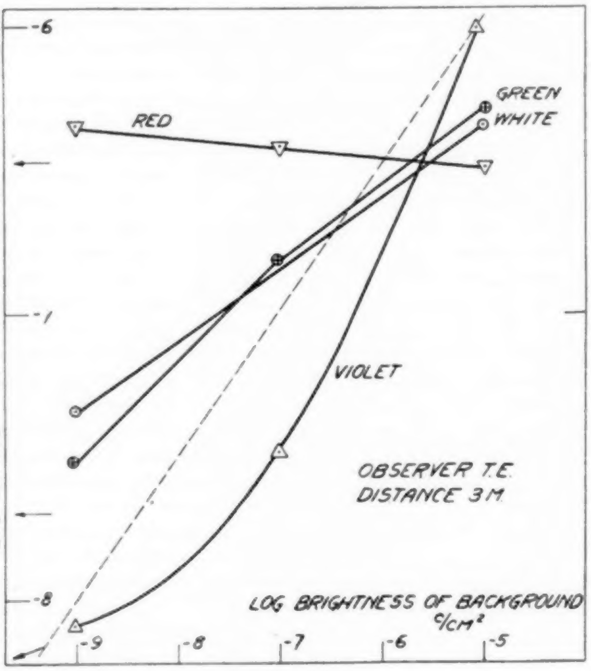

FIG. 6

(Visibility of colored flashing point sources as affected by the brightness of a background illuminated by white light. Flashes are 1 sec. on and 1 sec. off. Screen is at 3 m. The broken line corresponds to Equation [5].)

The second column of Table 2 gives the light flux density F from various heavenly bodies. The third column gives the background brightness H under which it is observed. The value of F calculated from H by Equation [5] is given in the last column.

The empirical square-root relation seems to give an approximately correct value for the visibility of steady light sources over an extremely wide range of values of H from 10^{-9} to 1.

According to Blondel and Rey's law, as given by Equation [4], the threshold brightness for flashes of 1 sec. duration is only 21 per cent greater than for a steady light. Thus the square-root relation found for steady sources should be roughly applicable to the experiments with 1-sec. flashes.

The broken lines in Figs. 4 and 5 give the threshold candlepower calculated by Equation [5]. These straight lines give values of F which agree with the observed within a factor of about 3. The discrepancies appear in large part to be individual characteristics of the observers.

In clear air the visibility of point sources is extremely high. Thus by Equation [4], or Table 2, at a distance of 10 km., a light of 0.11 candle is visible with a completely dark background, 0.85 candle with starlight, 5 candles with moonlight, 85 candles with twilight (stars just visible), and 8500 candles in daylight. These values are to be regarded as lower limits. For signaling purposes it will be shown that candlepowers about 30 times greater than these values should be used.

Colored Point Sources. Similar measurements were made with red, green, and violet sources. The color filters used were Wratten No. 70 red-pass beyond 6400Å, No. 74 green-pass from 5100 to 5700Å, and No. 76 violet-pass from 3100 to 4800Å. For calibration of the source the colors were matched with white in a photometer with an accuracy of about ±20 per cent. Fig. 6 shows the result of measurements at 3 m. distance with 1 and 1 sec. flashes. The visibility of red point sources is independent of the white background brightness; violet point sources are more than 100 times as visible against an absolutely dark background as against a moonlight background. The high visibility of violet at low intensities is of doubtful practical value, for it can be obtained only if the observer does not look straight at the source, the center of the retina being less sensitive for violet. Green light acts like white. The remarkable difference between red and violet is due to the Purkinje effect. It is accounted for by a shift in the visibility curve toward the blue end of the spectrum as the brightness of object and surroundings decreases. Houstoun[7] has plotted relative visibility against the logarithm of the wave length at high and low brightnesses and finds two curves with a shift of 480Å, closely resembling probability curves.

Time to Locate a Flashing Point Source of Light. In aviation, we are not interested in the intensity at which we lose sight of a beacon, but we do want to know when we can pick it up. Thus as a first requirement it may be stated that, in order to pick up a light, it must have an intensity above the one determined as threshold in the experiments. If this requirement is fulfilled, we can see the light, and next we want to know the length of time necessary to locate it.

To determine this experimentally, the authors used 30 holes in the screen distributed irregularly over an area of 50 cm. height and the full width of 150 cm., leaving 50 cm. above and 50 cm. below without holes; these blank areas correspond to the sky and the foreground. The flashing light (0.2 sec. on and 4.8 sec. off) could be placed behind any of the holes. This adjustment of the flashing source could be done behind the screen unseen by the observer who sat at 1.5 m. in front of the screen. The area of each of the holes was 2.24 sq. mm., and the brightness of the screen was moonlight. The measurement itself consisted merely in measuring the time from the instant the flasher circuit was

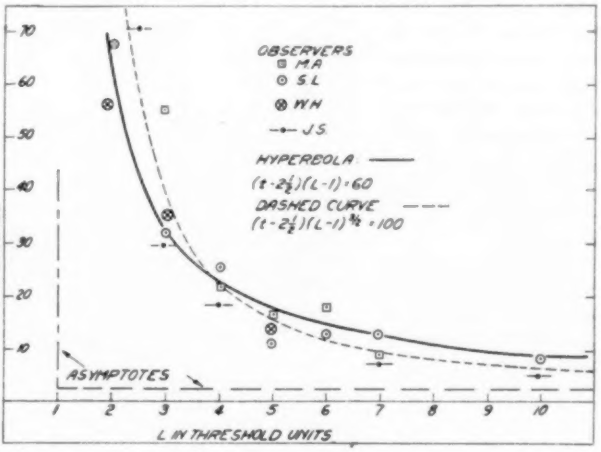

FIG. 7

(Time needed to locate a flashing point source in an unknown position within a field subtending a horizontal angle of 56 deg. and a vertical angle of 19 deg. of moonlight brightness, $H = 7 \times 10^{-6}$ cp. per sq. cm. The abscissas give the brightness of the source in threshold units. Flashes are 0.2 sec. on and 4.8 sec. off.)

---

[7] R. A. Houstoun, *Phil. Mag.*, vol. 10, pp. 416–432 (1930); see especially p. 420.

closed and the observer was told to look for the light, until the instant he signaled that he had located the flash.

Fig. 7 shows the time as a function of the intensity of the flash expressed in threshold units, each point being an average of ten observations; the use of the threshold unit gives a common scale in spite of different observers having different threshold intensities. An interesting result is that a flash equal to ten times the threshold is seen practically always at the first flash, while it takes three flashes before the light is located if it is only five times the threshold. Naturally the threshold is an asymptote; so is also the 2.5-sec. line, since the average is half the time interval between flashes if the first flash is seen.

This suggests an hyperbola as an appropriate empirical equation. The full-line curve in Fig. 7 is a plot of the equation

$$(t - 0.5T)\ (L - 1) = 60$$

where T, the period of the flashes, is 5 sec. A better approximation is obtained by using an exponent 3/2 for the factor $L - 1$. The broken line curve also plotted in Fig. 7 has the equation

$$(t - 0.5T)\ (L - 1)^{3/2} = 100 \ldots\ldots\ldots\ldots [6]$$

The fact that it takes a relatively long time to find flashing point sources only a few times brighter than threshold proves that they are observed only by a searching process during which the eye scans the whole field in which the point source may occur. Unless the eye happens to be looking at or the attention is fixed upon a small area which contains the light at the time of the flash, the flash will not be seen. For flashes of low intensity and short duration, the average finding time should thus be proportional to the period T and to the solid angle φ in which the flash is to be sought.

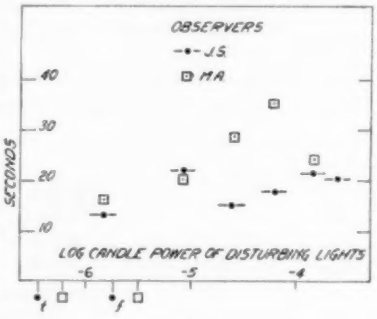

FIG. 8

(Time required to locate a flashing point source of five times threshold intensity in presence of 30 disturbing lights of intensities up to 500 times threshold. Flashes are every 5 sec.)

In the foregoing experiments the flashes were located within an area 50 × 150 cm. at a distance of 150 cm., so that the solid angle was $\varphi = 0.30$.

We may thus write Equation [7] in the following form:

$$(t - 0.5T)\ (L - 1)^{3/2} = 67\ \varphi\ T \ldots\ldots\ldots\ldots [7]$$

This equation, which is now generally applicable, gives the average time t required to detect the presence of light flashes of short duration and of period T in an unknown position within a known area which subtends the solid angle φ; L measures the light intensity of the flashes in threshold units—that is, in terms of the threshold light intensity of similar flashes (the same duration and period) in known positions. The experiments indicate that this equation is valid for background brightnesses ranging from zero up to that of moonlight, the effect of the background being only to change the magnitude of the threshold unit. The equation is probably applicable only when T is greater than one or two seconds.

To obtain a signal which can be detected within two or three flashes, say within an average of $t = 2.5T$ we see by Equation [7] that

$$L > 1 + 10\ \varphi^{2/3}$$

Thus with solid angles, such as those within which the aviator must seek beacon signals, the signals should be at least 10 times threshold.

For flashes of 1 sec. duration one may safely take as a threshold a value three times that given by Equation [5], and therefore may conclude that a flashing white light source to be useful as a signal to an aviator (visible on first or second flash) should be of an intensity such that it produces an illumination F at the position of the observer at least as great as

$$F = C/D^2 = 10^{-7}\ H^{1/2} \text{ lumen per sq. cm.} \ldots\ldots [8]$$

For signals to be transmitted 10 km. in clear weather with a background of bright moonlight on a snow-covered surface, a point source should then have at least 250 candlepower.

The Effect of Disturbing Lights on the Visibility of Point Sources. To find the effect of disturbing lights among which the aviator has to find a flashing beacon, there were placed 30 constant lights behind the holes in the screen. The lamps were all connected in series so that simultaneously their intensity could be adjusted up to 500 times the threshold of visibility. The flashing light (5 sec. period) was adjusted at five times the threshold for each observer and for each observation placed in an unknown position behind the screen as in the previous experiment. The finding times were determined with the disturbing lights at different intensities ranging from 4 times up to 500 times the threshold. The results were very surprising, as can be seen from Fig. 8, where the finding time is plotted against the logarithm of the candlepower of the disturbing lights. Apparently the influence of the disturbing lights is very small, the time being less than doubled if the 30 disturbing lights are made 100 times as strong as the flashing light when this is adjusted at five times the threshold. The marks t at the lower margin indicate the thresholds for the two observers and f the candlepower at which the flashing source was adjusted. Every point in the plot represents the average of 10 observations.

The disturbing lights in the foregoing experiments were paper-covered holes of 2.24 sq. mm. area illuminated to various brightnesses.

In a later series of experiments, disturbing lights having still greater intensities were produced by illuminating holes having areas 7.3, 22, and 66 sq. mm., the surface brightness in each case being 5×10^{-3} cp. per sq. cm., the candlepowers thus being 0.00036, 0.0011, and 0.0033, respectively. The screen was at a distance of 1.5 m.

The observer J. S., as an average of 30 observations with disturbing lights of 0.0033 cp., required a finding time of only 12 sec. for a flashing light of five times threshold intensity. With lights of 0.0011 cp., the time was 11 sec. as an average of 32 observations. Notwithstanding the greater intensities of these disturbing lights, the finding times are considerably less than those shown in Fig. 8. It appears that the observer J. S., as a result of continued training, had developed skill in locating the flashing light among the disturbing lights.

The holes in the screen which were used as light sources in these experiments were rather uniformly distributed over its surface. No hole was at a distance of less than 8 cm. from its nearest neighbor, so that the flashing light had in no case been within less than 3 deg. from the nearest steady disturbing light. It was thought that this might be the reason for the small influence of the disturbing lights upon the finding time.

Several holes were therefore made at distances of 2 cm. from disturbing lights corresponding to angular distances of 0.75 deg.

Among a set of 60 observations by J. S. were interspersed 28 in which the flashing light was only 2 cm. from the nearest disturbing light, while in the other 32 the distance was 8 cm. or more.

In both cases the flashing lights were of 1.7×10^{-6} cp. (five times threshold), while the disturbing lights were 3.6×10^{-4} cp. (1100 times threshold). The average finding times were 31 and 6.3 sec., respectively. It may be concluded from this experiment that steady lights at an angular distance of 3 deg. from the beacon have very little effect on its visibility, but that if they are at 1 deg. or less from the beacon, they may increase by many fold the time needed to locate it.

Effect of Duration and Frequency of Flashes on Visibility of Point Sources. If the source is a steady light of definite candlepower, one may wish to know the best way of interrupting the light to make it most conspicuous. The two variables are T, the flashing period, and t_o, the duration of each flash in seconds.

In the measurements the authors have used as a criterion for conspicuousness the average time to find the flashing light. The apparatus consisted of a small tubular projector with which a starlike spot of light approximately 1 sq. mm. in area could be focused on any point of the surface of a white screen 150 cm. by 150 cm. In front of this projector an interruptor disk was rotated with a speed adjustable between 6 and 240 r.p.m.; the disk was cut out so as to make the light pass during $^3/_4$ or $^1/_2$, $^1/_4$, $^1/_8$, $^1/_{16}$, $^1/_{32}$, or $^1/_{64}$ of the revolution. In front of the disk a shutter was placed which could be opened by pushing a button. Thus at any given instant a series of flashes could be projected on the screen, for which T could be between 0.25 and 10 sec. and t_o/T between $^3/_4$ and $^1/_{64}$. The observer sat 2 m. in front of the screen with his eyes about 50 cm. below the center. At the instant he heard the shutter click he started looking for the light, and with a stopwatch the time elapsing between opening the shutter and the observer's signal of locating the light was measured. By taking the average of 10 to 30 such observations, there was determined the average finding time of a flashing light having a definite T, t_o, and intensity.

The experiments showed that for moonlight, starlight, or dark background and with an interrupted source of fixed candlepower the light is most conspicuous when T lies between 0.5 and 1.0 sec. and t_o/T is between 0.5 and 0.75 sec. Decreasing T or increasing t_o/T decreases the flashing or flickering appearance and makes recognition difficult. Decreasing t_o/T below 0.5 increases the average finding time (with values of T as low as 1 sec.) because of the lowered visibility of short flashes in accordance with Equation [4]. When T is increased above 1 sec., the finding time is increased, because the eye, in wandering over the screen in search of the light, may pass by it during the intervals between flashes, whereas it would not do so with shorter intervals.

When T is greater than 1 sec., there is also another cause which increases the finding time. Even for bright flashes there is a theoretical lower limit for the average finding time which can be verified by experiment. This is determined as follows: The probability of opening the shutter while the light is shut off by the interrupter disk is $1 - (t_o/T)$; if the shutter is opened during the dark part of the cycle, the average time elapsing before the light comes on will be $0.5\ (1 - t_o/T)T$. For the cases that the shutter opens while the flash is on, the minimum locating time is zero; therefore the average finding time of a flashing light is at least $0.5\ (1 - t_o/T)^2T$. For rotating beacons t_o/T is very small, e.g., 5/360 deg., and the minimum average finding time or waiting time is $0.5 \times T$—that is, one-half of 10. This was checked experimentally, as the finding time for a strong light, and T larger than 1 sec. is very little different from the theoretical limit.

The relative visibility of flashes of different durations with moonlight background brightness was also determined in connection with these experiments. Results in reasonable agreement with Blondel and Rey's relation, Equation [4], were found. For example, with a flashing point source in a known location, the threshold intensity for flashes lasting 1 sec. was only 0.65 of that required for flashes lasting 0.2 sec. This result is in reasonable agreement with Blondel and Rey's Equation [4], according to which the threshold intensity for a 1-sec. flash should be 0.59 as great as for a flash of 0.2 sec.

Rotating Beacons. When a rotating beacon is used to produce light flashes, the conditions are in some ways essentially different from those just considered. The lamp used has a definite output in lumens, but the beam candles projected toward the aviator vary with the angular horizontal beam width θ_H, while t_o, the duration of the flash, varies in proportion to $T\theta_H$, T being the period of rotation.

Let it be assumed that the beacon projects a beam of rectangular cross-section with vertical and horizontal angles θ_V and θ_H, respectively, measured in radians. Then if I is the total luminous output of the beacon in lumens, the candlepower within the beam is $I/\theta_V\theta_H$. By Equation [2] it is found that the light flux density within the beam at a distance D from the beacon is

$$F = \frac{I}{D^2\theta_V\theta_H}\, e^{-D/\lambda} \ldots\ldots\ldots\ldots \text{[9]}$$

The duration of the flash is:

$$t_o = (\theta_H/2\pi)T \ldots\ldots\ldots\ldots \text{[10]}$$

If the value of F in Equation [9] is to be equal to the threshold value, we may combine Equations [9], [10], and [4] and obtain:

$$Ft_o = F_o(t_o + 0.21) = (IT/2\pi\theta_V D^2)e^{-D/\lambda} \ldots\ldots \text{[11]}$$

Since F_o is constant (independent of t_o), it thus appears that to obtain the most efficient use of the light (minimum I), t_o and therefore θ_H should be made as small as possible, preferably at least as small as 0.1 sec. With a 10-sec. period this requires a horizontal beam width of not over 3.6 deg.

Let these equations be applied to a typical airport beacon of the Department of Commerce design. The concentrated filament lamp is of 1000 watts and gives 22,500 lumens. The parabolic mirror subtends an angle of 120 deg. from the lamp filament, and thus receives light from a solid angle $\varphi = \pi$, or 25 per cent of the total. Allowing for intercepted light and imperfect reflection, it may be assumed that 20 per cent of the 22,500 lumens is utilized in the beam, so that $I = 4500$ lumens. Measurements show that the effective beam widths θ_H and θ_V are both 3.5 deg., or 0.061 radians. Thus the average beam candles should be $4500/(0.061)^2 = 1.2 \times 10^6$, which agrees well with experimental determinations with this beacon.

Substituting these values of I, θ_V, and θ_H in Equations [10] and [11] and eliminating t_o, we find

$$F_oD^2e^{D/\lambda} = \frac{5.6 \times 10^4\ T}{1 + 0.046\ T} \ldots\ldots\ldots\ldots \text{[12]}$$

To calculate the maximum distance at which this beacon can be seen, we should put F_o equal to the threshold value for steady sources, which by Equation [5] is approximately $F_o = 10^{-11}$ lumens per sq. cm. for moonlight background brightness. Thus if D_1 is the distance at which the intensity corresponds to the threshold value ($L = 1$), we have from Equation [12], after taking the square root,

$$D_1e^{D_1/2\lambda} = 7.5 \times 10^7\ [T/(1 + 0.046\ T)]^{1/2} \ldots\ldots \text{[13]}$$

If the atmosphere were absolutely clear so that $\lambda = \infty$, the light intensity would vary according to the inverse-square law, and in this case the beacon could theoretically be seen at a distance of 1.96×10^8 cm. (1960 km.) if the period of rotation is $T = 10$ sec., or 1.51×10^8 cm. (1510 km.) if $T = 5$ sec.

TABLE 3

(Pick-up of Department of Commerce type of rotating beacon by approaching airplane moving with velocity v = 5000 cm. per sec. = 180 km. per hour = 112 miles per hour; $\varphi = 0.5$; T = period of rotation in seconds)

λ (cm.)	Visibility, 2.3λ (km.)	Maximum range D_1 (cm.) $T = 5$	$T = 10$	$T = 20$	Additional distance for pick-up Δ (cm.) $T = 5$	$T = 10$	$T = 20$	Effective range $D_1 - \Delta$ (cm.) $T = 5$	$T = 10$	$T = 20$
10^7	230.0	3.18×10^7	3.49×10^7	3.76×10^7	3.49×10^6	4.64×10^6	5.96×10^6	2.83×10^7	3.03×10^7	3.16×10^7
10^6	23.0	6.35×10^6	6.78×10^6	7.10×10^6	8.8×10^5	1.12×10^6	1.37×10^6	5.47×10^6	5.66×10^6	5.73×10^6
10^5	2.3	1.00×10^6	1.05×10^6	1.09×10^6	1.83×10^5	2.24×10^5	2.70×10^5	8.2×10^5	8.3×10^5	8.2×10^5
5×10^4	1.15	5.60×10^5	5.83×10^5	6.00×10^5	1.12×10^5	1.36×10^5	1.68×10^5	4.48×10^5	4.47×10^5	4.32×10^5
2×10^4	0.46	2.54×10^5	2.66×10^5	2.71×10^5	5.8×10^4	7.40×10^4	1.00×10^5	1.96×10^5	1.92×10^5	1.71×10^5
10^4	0.23	1.39×10^5	1.45×10^5	1.48×10^5	3.72×10^4	5.03×10^4	7.58×10^4	1.02×10^5	9.5×10^4	7.2×10^4
5×10^3	0.12	7.6×10^4	8.0×10^4	8.1×10^4	2.52×10^4	3.80×10^4	6.29×10^4	5.1×10^4	4.2×10^4	1.8×10^4

The absurdity of this result indicates that the maximum range of such bright light sources at night is always determined by the scattering or absorption coefficient, so that it is not justifiable to put $\lambda = \infty$. The distance in which the intensity of a parallel beam falls to one-tenth because of scattering or absorption is 2.3λ, and this may be roughly taken to be equal to the distance denoted by the term "visibility" in aeronautical weather reports.

The columns headed D_1 in Table 3 give values of the maximum range D_1 for a series of different visibilities and for three rates of rotation of the beacon corresponding to periods of 5, 10, and 20 sec., respectively. These data have been calculated from Equation [13] by plotting curves giving λ as a function of D_1 (for each of the three values of T).

It should be noted that with more rapid rotation the amount of light received in each flash decreases. If the visibility were really unlimited ($\lambda = \infty$), the ranges would be in the ratio 1 to 1.30 to 1.59 for T = 5, 10, and 20 sec., respectively.

Examination of the data of Table 3 shows that the effect of the limited visibility is to bring these ratios far closer to unity. For example, with $\lambda = 10^5$ (1 km.), the ratios are 1 to 1.05 to 1.09. Thus the decreased flash intensity caused by rapid rotation becomes of minor importance even in determining the maximum range.

Pick-Up of Beacon by an Approaching Airplane. We have seen in the derivation of Equation [7] that a considerable time interval is necessary to "pick up" a flashing source of light if its visibility is only little above the threshold value. A rapidly moving airplane may thus approach within a distance D, which is far less than the maximum range D_1, before the signal will be seen. To estimate the effective range of a beacon we want to determine this average distance D.

If, as before, L denotes the intensity of the beacon flashes in threshold units, at any distance D, we have, by Equation [11],

$$L = (D_1/D)^2 e^{(D_1 - D)/\lambda} \qquad [14]$$

Consider an airplane moving directly toward a beacon. When it reaches a point corresponding to D_1, the value of L is unity. Let x measure the distance along the path of the plane from this point so that $x = D_1 - D$. Taking the logarithm of Equation [14] and differentiating at the point $x = 0$, we have

$$\frac{d \ln L}{dx} = \frac{1}{\lambda} + \frac{2}{D_1}$$

Thus for reasonably small values of x the variation of L with x is given by

$$L = \exp\left[x\left(\frac{1}{\lambda} + \frac{2}{D_1}\right)\right]$$

or which may be written

$$L = e^{x/\lambda'} \qquad [15]$$

where

$$\frac{1}{\lambda'} = \frac{1}{\lambda} + \frac{2}{D_1} \qquad [16]$$

Inspection of Table 3 shows that D_1 is considerably larger than λ. The variation of L due to absorption is thus usually much greater than that due to the inverse square law at distances such that the beacon is barely visible.

Equation [7] gives us the average time t required to pick up a flashing light having flashes of uniform intensity. In the present case the successive flashes are of increasing intensity. The reciprocal of t is the probability per second of picking up the light. The average distance Δ which the observer must travel toward the beacon before seeing it is thus the distance over which the time integral of this probability is unity. Thus

$$\int_0^{\Delta} \frac{dx}{vt} = 1$$

where v is the velocity of the plane toward the beacon. Substituting into this the value of t given by Equation [7] and the value of L from Equations [15] and [16], we obtain

$$\varphi T v/\lambda' = \int_0^{\Delta/\lambda'} \frac{du}{\frac{1}{2\varphi} + 67\,(e^u - 1)^{-3/2}} \qquad [17]$$

When Δ/λ' is sufficiently small, the term $^1/_{2\varphi}$ can be neglected, and we have

$$\left.\begin{aligned} 67\,\varphi T v/\lambda' &= (2/3)p^{3/2} - 2p^{1/2} + 2\tan^{-1} p^{1/2} \\ \text{where} \qquad p &= e^{\Delta/\lambda'} - 1 \end{aligned}\right\} \qquad [18]$$

When $\Delta/\lambda' < 0.1$, this reduces to

$$67\,\varphi T v/\lambda' = (2/5)\,(\Delta/\lambda')^{5/2} \qquad [19]$$

For large values of Δ/λ', $(e^u - 1)^{-3/2}$ may be replaced by $e^{-3u/2}$ and integration then gives

$$T v/\lambda' = 2\,[(\Delta/\lambda') + (2/3) \ln (1 + 134\,\varphi e^{-3\Delta/2\lambda'}) - K] \qquad [20]$$

where K is an integration constant.

In applying these results to the beacon we are considering let us place $\varphi = 0.5$. This corresponds to a field of view, in which the beacon is to be sought, measuring 20 deg. vertically and 82 deg. horizontally. With this value of φ, Equation [18] is found to be reasonably accurate for all values of $\Delta/\lambda' < 1$; and Equation [20], which holds accurately for $\Delta/\lambda' > 3$, reduces to

$$\varphi T v/\lambda' = \Delta/\lambda' - 2.897 + 0.285 \log_{10}(1 + 67\, e^{-3\Delta/2\lambda'}) \qquad [21]$$

TABLE 4

(Table of values of the integral of Equation [17] for the case $\varphi = 0.5$. Below about $\Delta/\lambda' = 1$, these values are independent of φ)

Δ/λ'	$\varphi T v/\lambda'$	Δ/λ'	$\varphi T v/\lambda'$	Δ/λ'	$\varphi T v/\lambda'$
0.1	1.98×10^{-5}	1.4	0.0310	5.0	2.124
0.2	1.21×10^{-4}	1.8	0.0737	6.0	3.10
0.4	7.75×10^{-4}	2.2	0.1516	8.0	5.10
0.6	2.36×10^{-3}	2.6	0.281	10.0	7.10
0.8	5.25×10^{-3}	3.0	0.470	20.0	17.10
1.0	1.070×10^{-2}	4.0	1.204		

For $\Delta/\lambda' > 6$; $\varphi T v/\lambda' = \Delta/\lambda' - 2.90$.

In the range from 1 to 3, numerical integration was resorted to.

Table 4 gives some typical values of Δ/λ' and $\varphi Tv/\lambda'$ from which a curve may be prepared.

In Table 3 are given values of Δ calculated for a plane moving toward the beacon with a velocity of 5000 cm. per sec. (180 km. per hour, or 112 miles per hour). This represents the average additional distance the plane must travel from the point where threshold visibility is reached before the beacon is seen within a large field which subtends a solid angle $\varphi = 0.5$. These values of Δ were calculated by means of a curve prepared from the data of Table 4. The values of λ' were first calculated by Equation [16] from λ and D_1, and then $\varphi Tv/\lambda'$ was obtained; the corresponding value of Δ/λ' from the curve multiplied by λ' then gave Δ.

It should be noted that Δ is relatively large. For example, with a "visibility" of 23 km. and with a beacon rotating once in 10 sec., the plane will travel on the average a distance of 11.2 km. from the point where the threshold is reached before the beacon is seen. It takes the plane 224 sec. to travel this distance, so that an average of 22.4 flashes above threshold value are needed before the beacon is observed. At the end of this time the intensity of the light from the beacon is 4.25 threshold units. The effective range, which is perhaps the best measure of the value of a beacon under given conditions of visibility, is thus $D_1 - \Delta$, as given in the last three columns of Table 3. It should be observed that, with the highest visibility, slightly greater effective ranges are obtained with $T = 20$ sec. than with 10 or 5 sec. But with a "visibility" of 2.3 km., the range is greater for $T = 10$ sec. than for either 5 or 20. With still poorer visibility the maximum range shifts gradually to the beacon with $T = 5$. Similar calculations show that with λ as low as 10^4 the maximum effective range occurs with T about 2 sec.

These results indicate that under conditions of poor visibility considerably more rapid rates of rotation than the standard 10-sec. period are desirable. The lowering of the light effect of each flash, which causes D_1 to decrease with T, is more than offset by the greater ease and rapidity with which the more frequent flashes can be detected in unknown positions within the large field of view presented to the aviator.

VISIBILITY OF FLASHES OF DIFFUSED LIGHT

The light from cities reflected from the lower surfaces of high stratus or cirrus clouds can frequently be seen from the ground at distances as great as 50 miles on clear, dark nights. Similarly an aviator flying high above clouds covering a city can see an illuminated area in the upper surface of the clouds at great distances. In these cases recognition of the source of light is facilitated by the contrast in intensity between the illuminated area and its surroundings.

If the aviator flies at night within a cloud over a city, he may have difficulty recognizing the increased intensity of diffused light because of its uniformity and steadiness. Charles A. Lindbergh has stated to one of the authors that under such conditions the flash of green light produced by a trolley was visible when large steady flares at a nearby airport were not recognizable.

Useful signals can thus be transmitted through fog by sudden flashes of a light source which is producing a general illumination of the fog.

A rotating beacon immersed in a fog or just below low clouds produces a nearly steady or only gradually changing illumination of the fog. Definite interruptions by means of a shutter mechanism may increase the visibility under these conditions, and the best results could then be obtained if the beacon were pointed toward the zenith.

With a desire to overcome the loss of efficiency due to interrupting a steady source and to obtain flashes of short duration and great intensity, a special flashing arc beacon was constructed. The flash is produced by making and breaking a contact between an iron-rod cathode and a copper block as anode. A large reactor stores up energy during a short circuit period and delivers it to the arc when the electrodes are separated. This increases the duration and intensity of the arc and reduces the maximum current and voltage required. The device is fed by direct-current line or from a 9-kw. 150-v. direct-current generator or mercury-rectifier outfit.

The maximum arc current is about 200 amp. The surge resembles a half-cycle of sinusoidal wave and is of a total duration of about 0.2 sec. The device is usually adjusted to give a flash every 2 sec. A reflector is used to throw the light which would strike the ground up into the sky. The light output per flash is about 50,000 lumens per sec., and the effective duration is about 0.1 sec., and thus, according to Equation [4], the visibility of these flashes should be the same as those of an interrupted steady source of $F_\infty = 160{,}000$ lumens.

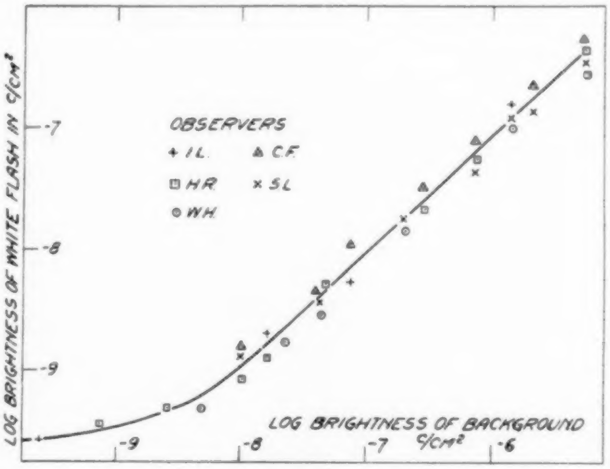

FIG. 9

(Effect of steady background brightness on the visibility of diffused flashes of white light. The ordinates represent the intensities needed for the detection of one-half the flashes.)

The range of visibility of signals of this kind depends primarily on the ability of the observer to distinguish the diffused flash from the steady background illumination. Many experimental investigations have been made of the minimum change of brightness required to produce a perceptible effect. The results are summarized in Weber's law that the smallest detectable change is a constant fraction of the total illumination. Most observers find that a 2-per cent change in brightness is observable. These measurements, however, have practically all been made with far higher background intensities than those that interest us, and the brightness of only part of the field was changed, leaving the remainder steady.

In order to study this problem from the point of view of the aviator, Mr. C. C. Steffens has conducted a series of measurements in this laboratory. His results are summarized in Figs. 9 and 10.

A white sheet 2 m. square was hung up in a dark room 1.8 m. from the observer. The sheet was uniformly illuminated by four tungsten lamps placed behind the observer opposite the four quarters of the screen. Each lamp was mounted inside a small box, which was open at one end and which contained two ground-glass diffusing screens, between which diaphragms of various openings could be interposed. The intensity of the screen illumination was varied by changing the current through the lamp filaments, but the lamp was never operated at below one-tenth normal candlepower in order not to change the color too greatly. Greater candle power variations than 10 to 1 were obtained by using the diaphragms whose diameters ranged from 4 down to 0.03 cm. The lamps and larger diaphragms were calibrated by photometering the screen, using reasonably high brightness obtained by placing the lamps at suitable distances from the screen. Tests showed that the variation of color by the 10 to 1 change in filament brightness did not cause appreciable effects, for the same results were obtained by changing the brightness by means of the diaphragms.

Flashes of light were superimposed upon the steady screen illumination by turning on and off lamps in four other similar boxes. Shutters were avoided, for the sound produced by them could lead to psychological errors in detecting the flash. The currents were actually turned on and off silently by means of a thyratron circuit in which the time interval could be adjusted.

After the observer had remained in the dark room long enough for dark adaptation, the steady-screen brightness was adjusted to any desired value from zero up to that of full moonlight (7×10^{-6} cp. per sq. cm.).

Flashes were then made at irregular intervals, starting at intensities high enough to be easily seen, decreasing rapidly until no flashes were seen, and then increasing the intensity slowly until about 50 per cent of the flashes were seen. This kind of effective threshold proved to be surprisingly definite and reproducible.

Fig. 9 gives data obtained by five observers with 1-sec. flashes of white light. The full line on the logarithmic plot which best represents the data is practically straight and of a slope 0.95 in the range of background brightnesses between 10^{-8} and 7×10^{-6} cp. per sq. cm. Below 10^{-8} the threshold flash rapidly becomes a larger fraction of the background brightness, until with a background of 2.7×10^{-10} the flash must be equal to the background in intensity.

The relation of the intensity of the flash to the background is thus given in Table 5. At brightnesses ranging from 10^{-4} to 1, Weber's law holds, and the ratio remains constant at about 0.02.

TABLE 5

(Relation between brightness of a 1-sec. flash of white light which is 50 per cent visible and the white background brightness)

Background (cp. per sq. cm.)	Flash to background
2.7×10^{-10}	1.000
10^{-9}	0.240
10^{-8}	0.112
10^{-7}	0.095
10^{-6}	0.080
7×10^{-6}	0.073

These flash intensities are such that on the average one-half are noted by the observer. With flashes close to these threshold values the observer often expresses doubt as to whether a flash that is noted is real, but actually, with white flashes, it is an extremely rare occurrence for the observer to report a flash if one did not actually occur. On the other hand, with threshold flashes of red light, 30 or even 40 per cent of the reported flashes were imaginary.

When the intensity of the flashes is made twice that of the threshold, the flashes are unmistakable, even though the observer is not particularly attentive. Every flash is seen under these conditions.

With a background intensity as high as moonlight (7×10^{-6}), a 1-sec. threshold flash is of such duration that its beginning and end are separately recognizable. With background brightnesses greater than 1.6×10^{-8} (0.4 of starlight), the flash brightness needed for threshold visibility is the same for 1-sec. and for 5-sec. flashes. With a background brightness less than about 6×10^{-9} (0.1 starlight), threshold flashes produce the sensation that the light gradually increases in brightness and slowly fades away. With a background at 2.7×10^{-10} cp. per sq. cm., a 1-sec. threshold flash is seen only after a period of from 2 to 4 sec. after its beginning, and the flash seems to persist for 6 to 10 sec. after it has really ended. With a flash of twice threshold intensity, both of these time lags drop to about 1 sec.

With these low background intensities (less than 0.1 starlight), it was observed that a 5-sec. flash needed to be only 0.5 as bright as a 1-sec. flash for 50-per cent visibility. This seems to indicate that at these low intensities the numerical constant in the Blondel-Rey Equation [4] should be 1.7 sec. instead of 0.21. At intensities above starlight, however, one is probably justified in using the unchanged Equation [4] to calculate the visibility of flashes of very short duration. Thus the cp-sec. per sq. cm. required for a threshold instantaneous flash may be obtained by multiplying the flash brightness, as given by Fig. 9 or Table 5, by 0.17 sec. (i.e., 0.21 ÷ 1.21). For very low intensities, however, this factor should be 0.63 (i.e., 1.7 ÷ 2.7).

Very interesting changes in the appearance of the illuminated screen were observed as its brightness was gradually decreased. At brightnesses from 1 to 3×10^{-8} cp. per sq. cm., the screen appeared to be remarkably uniform in intensity and perfectly steady, and seemed to be of a gray-green color, resembling the appearance of a window opening out on a vast open space on a starlit night. At intensities above 3×10^{-8} the resemblance to an open window disappeared, and it appeared to be a screen.

As the intensity was decreased, a remarkable change in quality occurred quite critically, usually at about 8×10^{-9} cp. per sq. cm. The appearance of the open window vanished and was replaced by an area of non-uniform intensity of yellowish color. If the eyes were directed at the center of the screen, the central part appeared to be darker than the edges. The central part showed fluctuations of intensity, both in time and space, while the edges appeared steady. The edges seemed to be even brighter than when the actual brightness was greater. Thus as the light intensity was deliberately decreased through the critical regions, the center of the screen appeared to grow darker, but the edges seemed to grow brighter. The fluctuations became slower and of larger size as the intensity decreased in the range below the critical value. Undoubtedly these effects result from fluctuations in the number of quanta of light striking the cones in the central part of the retina. At a background brightness of 3×10^{-10} cp. per sq. cm., areas subtending 5 to 10 deg. appeared to increase rapidly in brightness and gradually (in about 5 sec.) to fade away. The apparent size seemed to correspond roughly with that of the smallest black object that could be recognized against the black screen (visual acuity).

Since the aviator will rarely have to deal with background intensities less than 0.1 starlight (6×10^{-9} cp. per sq. cm.), effects of these kinds will not often be observed.

In connection with these experiments a study was made of the ability of the observer to detect gradual changes in light intensity such as might occur when an aviator flies at night in fog toward a city. Slow, steady changes in brightness, increasing or decreasing at about 3 per cent per second, were produced, beginning at unknown times, and the observer was asked to report any change and also to describe the brightness in terms of the original brightness.

With moonlight background an increase was first noticed when the brightness has increased an average of 45 per cent. With 0.1 moonlight 33 per cent is seen, while with starlight a 20-per cent change is needed. The results were, however, extremely irregular. For example, in some cases an increase in brightness was not noted until the brightness had changed in the ratio 1 to 2. Often an increase or decrease was reported to continue for a considerable time after it had stopped. Estimates of absolute intensities were approximately proportional to the $^3/_2$-power of the true intensities with an average error of ± 40 per cent.

Roughly, therefore, we can conclude that gradual changes in light intensity are not noticeable with certainty until the intensity has changed in the ratio 1 to 2 or even 1 to 3.

Studies also were made of the visibility of colored flashes. These data are summarized in Fig. 10, on which, for comparison, the curve for white light from Fig. 9 is reproduced. The red light examined by a spectroscope showed a band lying mostly between 5900 and 6900, the green lamp gave a band mostly between 5000 and 5700, while the blue gave 4500 to 4900. The lamps were photometered only at high intensities to avoid the Purkinje effect.

The data of Fig. 11 were obtained with a neon lamp. The lower curve agrees well with the curve for red light of Fig. 10.

With red flashes, the threshold value remains nearly constant at about 10^{-7} cp. per sq. cm., while the white-background brightness decreases from moonlight down to about 0.5 starlight (2×10^{-8} cp. per sq. cm.). In this range the threshold flash was observed as a change in color, but not as a change in intensity, of the light on the screen. With background intensities less than this, the brightness of a 1-sec. red flash needs to be about 30 times that of the white background, and the flash then does not produce any appreciable change in color of the background, but appears as a change in its brightness.

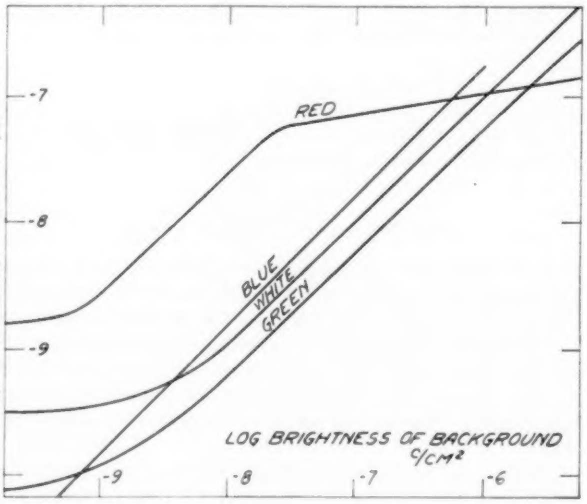

FIG. 10

(Visibility of diffused flashes of colored light as affected by the brightness of steady illumination by white light. The ordinates are similar to those of Fig. 9.)

Flashes of diffused red light are thus far less advantageous for the transmission of visible signals than are flashes of white or green. At high background intensities, such as moonlight, however, less red light than white light would be needed.

The foregoing data may be used to calculate the visibility of the flashes produced on a white diffusing surface, such as that of a cloud, by the light from a flashing point source at a distance D from the surface.

The data given in Table 6 have been calculated by means of Equations [1] and [3], using the factors in Table 5, but multiplying them by 2 in order to have flashes that can be seen with certainty. It has been assumed that the light from the source falls at normal incidence on the white surface which reflects 100 per cent of the light according to Lambert's cosine law. If we have a surface which reflects the fraction R and if the incident light beam makes an angle θ with the normal to the reflecting surface, then the candlepowers in Table 6 are to be divided by $R \cos \theta$.

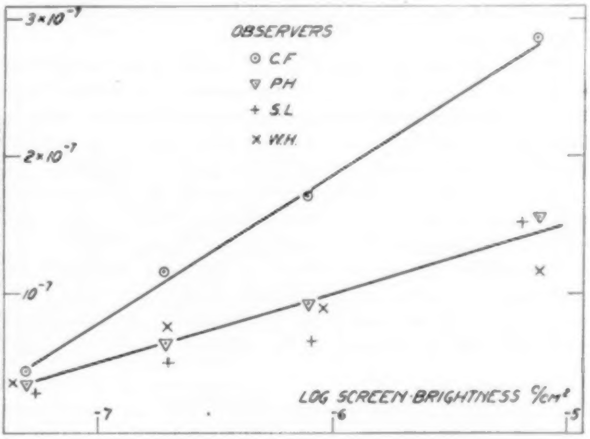

FIG. 11

(Visibility of flashes of light from a neon arc as affected by white-background brightness.)

On a dark, cloudy night when $H = 10^{-8}$ (0.17 starlight), it is thus possible to see the light flashes reflected down from clouds at a height of 1000 m. from a flashing point source of only 71 cp. on the ground; but if the cloud surface were illuminated by full moonlight, it would be necessary to increase the point source from 71 to 32,000 cp. to produce an equally visible flash at the same distance.

With flashes of very short duration, we have seen that the candle-seconds needed are only about $^1/_6$th of the candles of the steady light needed to produce 1-sec. flashes. The rotating beacon which we have considered gives 1.2×10^6 beam candles for 0.1 sec. in each flash, and thus by Table 6 visible diffused flashes should be observed when its beam at a distance of 4.7 km. from the beacon falls at normal incidence on a cloud illuminated by full moonlight. On a dark night, with absolutely clear air and $H = 10^{-9}$, such flashes should be visible at 100 km.

The flashing arc beacon giving 50,000 lumen-sec. (or 8000 candle-seconds in upper hemisphere) should thus produce visible flashes at 1.25 km. on clouds exposed to bright moonlight or at 26 km. when the steady light on the clouds is 10^{-8}.

Comparative Visibility of Diffused Light and Light From Point Sources. In the second column of Table 7 are given, for a series of steady background brightnesses, the values of light flux den-

TABLE 6

(The candlepower of a point source needed to give a distinctly visible 1-sec. flash [2 × threshold] on a white diffusing surface [cloud or snow] at distance D. H = steady illumination of the surface in cp. per sq. cm.)

H	D = 1 km. (cp.)	D = 2 km. (cp.)	D = 5 km. (cp.)
10^{-9}	15	60	375
10^{-8}	71	284	1,770
10^{-7}	600	2,400	15,000
10^{-6}	5,000	20,000	125,000
7×10^{-6}	32,000	128,000	800,000

TABLE 7

(Comparative visibility of diffused light and light from point sources, both giving 1-sec. flashes)

Background brightness H (cp. per sq. cm.)	Light flux density F for threshold visibility of point source	Light flux density F for threshold visibility after diffusion from white surface	—Ratio of sensitivity— Point source versus diffused source	Photocell versus visual for diffused light
10^{-9}	1.1×10^{-13}	7.5×10^{-10}	6,800	6
10^{-8}	3.5×10^{-13}	3.5×10^{-9}	10,000	28
10^{-7}	1.1×10^{-12}	3.0×10^{-8}	27,000	240
10^{-6}	3.5×10^{-12}	2.5×10^{-7}	72,000	2,000
7×10^{-6}	9.2×10^{-12}	1.6×10^{-6}	170,000	13,000

sity F from a flashing point source needed for threshold visibility, as calculated by Equation [5]. For comparison with these data we have, in the third column, the values of F which are visible according to the data of Table 5 when rendered diffuse by falling on a perfectly white diffuse reflector. Here we have made use of the relation between F and H given by Equation [3].

It is seen that the power of the eye to focus the light from a point source upon a small part of the retina makes it from 7000 to 170,000 times more sensitive to light from point sources than to diffused light which cannot be so concentrated. This advantage increases roughly in proportion to the square root of the background brightness, probably largely as a result of the increasing acuity of vision.

In considering the values of the ratios given in the fourth column of Table 7, it should be recognized that the time needed to find a flashing point source is an important factor, while with flashing diffused lights the average time needed to detect the signals will not exceed one-half of the period of flashing. Thus, as we have seen, the flashing point sources for practical reasons need to be 10 or 20 times the threshold, while a factor of 2 is sufficient to make diffused flashes immediately visible.

Photoelectric Cell as a Detector of Diffused Modulated Light. Although the human eye is extremely sensitive to the light from point sources, it becomes many thousands of times less sensitive when the light is diffused, as for example by fog. The photoelectric cell on the other hand, gives a response which is determined by the total light that falls upon it, and therefore it should possess particular advantages as compared to the eye for detecting diffused light.

FIG. 12
(Photoelectric receiver for modulated light.)

We have seen how the flashing of diffused light signals for visual observation gives them the characteristics needed to distinguish them from the steady diffused light such as moonlight or the light from cities. In using the photoelectric cell, however, it is better to modulate the light at a definite frequency, such as 1000 per sec., and thus be able to distinguish the signal light from all others by using a tuned amplifier for the photo-cell current.

In order to determine how well such a system may be used to detect diffused light, the authors have constructed a special photo-cell and amplifier equipment shown diagrammatically in Fig. 12.

The photoelectric cell should be of large light-gathering power. The authors used a PJ-19 argon-filled caesium photo cell which has been developed for television outfits. The spherical bulb was 19 cm. diameter and had a window opening 15 cm. in diameter, or 175 sq. cm. area. It was operated with 45 volts on the anode and gave a sensitivity of 10 microamperes per lumen for white light and for the light from a mercury arc and about 8 microamperes per lumen for light from a neon lamp.

In front of the window of the photo cell was a mirror which could be rotated slowly (200 to 300 r.p.m.) about an axis inclined at 45 deg. to the mirror surface. In this way the diffused light from the right and left sides (of the airplane) could be thrown alternately and periodically into the photo cell.

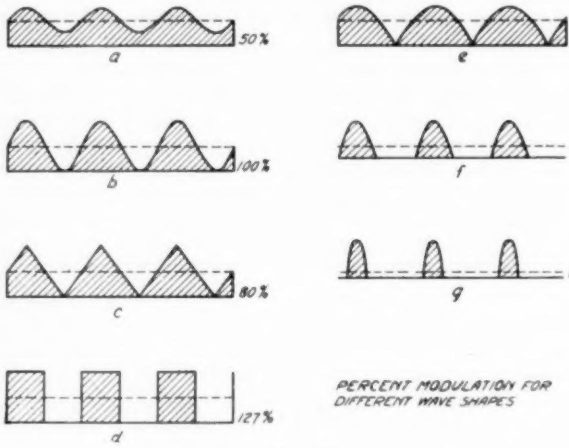

FIG. 13
(Effectiveness of various types of modulation.)

The alternating-current component from the photo cell passed to an amplifier consisting of three stages of screen-grid amplification (UY-224 tubes), the first two stages being tuned for 1000 cycles. The amplifier was thus highly selective for the modulated light signals. The voltage amplification factor was about 2,000,000.

On the shaft of the rotating mirror was a commutator through which output of the amplifier was passed. This acted as a single-pole double-throw switch which threw the amplified 1000-cycle current alternately to two detector tubes (UX-112A) in push-pull arrangement, as shown at the right-hand side of Fig. 12.

In this way the modulated light that entered the photo cell from the right tended to produce a deflection to the right of the needle of the direct-current indicating instrument, which had a sensitiveness of 150 microamperes for full scale.

The indicator reading thus gave a measure of the difference in the diffused light intensities on the two sides of the photo cell. The frequency of rotation of the mirror was immaterial so long as it was more rapid than the indicator needle could follow.

This differential arrangement was adopted so that the direction of the light source could be determined even in the presence of fog.

When desired, the light intensity in either direction could be determined by properly fixing the position of the mirror after stopping its rotation, or more conveniently by rendering one or the other of the detecting circuits inoperative.

When using the differential arrangement, it is usually desirable to have an indication which measures the relative rather than the absolute difference in the intensities in the two directions.

This was accomplished by utilizing the automatic volume control illustrated in Fig. 12. In this device the 1000-cycle component of the output of the detector-tube circuit was rectified by a

UX-112A tube, and this rectified voltage was used to bias the grid of the first tube in the amplifier. A filter circuit eliminated the fluctuations caused by the mirror rotation so that the average of the intensities of the amplified 1000-cycle current produced by the light from the two sides was kept nearly constant as the actual light intensity increased. The difference in the intensities from the two sides was, however, given by the indicating instrument.

To test the sensitivity of this apparatus a source of modulated light of known intensity was constructed by using a shutter operated by a synchronous motor. The light intensity was made to increase and decrease linearly with time (as shown by diagram C in Fig. 13) with a frequency of 1000 per sec. The intensity varied from zero at the minimum to 0.5 cp. at the maximum so that the average candlepower was 0.25. The amplitude A_1 of the 1000-cycle component in a Fourier series expansion, $I = A_1 \sin \omega t$, corresponds to 0.2 cp. (i.e., 80 per cent of the average 0.25).

Two large sheets of white cardboard were mounted in vertical planes at right angles to one another and placed at a distance of 40 m. from the described source of modulated light, so that the light fell on each plane at an angle of incidence of 45 deg. The brightness of illumination of these sheets was thus 2.8×10^{-9} cp. per sq. cm. (i.e., $0.2 \times 0.71/\pi(4000)^2$) in terms of the amplitude of the 1000-cycle component.

The photo-cell outfit was mounted symmetrically between the sheets, so that when the mirror was rotated the cell was exposed alternately to the diffused light from the two sheets.

By making a slight adjustment in the inclination of one of the sheets, with respect to the light rays from the source, the needle of the indicator instrument was brought to zero (see Fig. 12). A change of the inclination of either sheet by as little as 0.9 deg. then produced a distinct deflection of the needle (about 15 microamperes). This corresponds to a change in brightness of 1.5 per cent of the average brightness (2.8×10^{-9}). Thus the photo-cell-amplifier outfit was sensitive to a change in the absolute brightness of only 4×10^{-11} cp. per sq. cm., which is only about one-sixth of the threshold of the eye for flashing lights with a completely dark background (see the data of Fig. 9).

A particular advantage of the photo-cell equipment is its complete insensitiveness to the steady background illumination. Thus the sensitiveness to modulated light was not appreciably altered by letting light from incandescent lamps fall on the sheets up to a brightness of 10^{-8} cp. per sq. cm. (about 100 times moonlight). With full daylight or sunlight, however, the photo cell was overloaded, and the sensitiveness to modulated light decreased greatly. Undoubtedly special cells and circuits can be devised that would make it possible to detect very weak signals of diffused modulated light even in the presence of sunlight.

It is interesting to compare this observed sensitiveness of the photo-cell apparatus with the corresponding visual data given in Tables 6 and 7.

As before, we may assume that a reliable signal must produce a brightness of twice threshold value. Thus for the photoelectric detector we need a light flux density $F = 2.5 \times 10^{-10}$ lumens per sq. cm. This corresponds to 2.5 cp. at 1 km. The last column in Table 7 gives a factor which measures the relative advantage of the photo-cell detector over visual observation for diffused light signals. This factor is obtained by dividing the values of F in the third column by the threshold value for the photoelectric detector (1.26×10^{-10}). In full moonlight the photo cell can detect a diffused modulated light of an intensity only 1/13,000 of that of a diffused flashing light just visible to the eye.

Sources of Modulated Light. The instantaneous intensity I of modulated light may be expressed as a function of time t by a Fourier expansion:

$$I = A_o + A_1 \sin \omega(t - t_1) + A_2 \sin 2\omega(t - t_2) + \text{etc.}$$

The effectiveness of modulated light when used with a tuned receiver such as has been described depends upon the amplitude A_1 of the fundamental component, and therefore this component should be made as large as possible compared to A_o, A_2, etc.

One may define the degree of modulation as the ratio A_1 to A_o—that is, the ratio of the amplitude of the fundamental component to that of the average light. This ratio for a series of different wave shapes is given in Fig. 13. The maximum possible degree of modulation is 200 per cent, which is approached if the light consists of separate flashes of very short duration.

An efficient source of modulated light has been developed[8] in the form of a self-modulating neon lamp which operates on the thyratron principle and which produces the light flashes illustrated in diagram g of Fig. 13, giving a degree of modulation as high as 188 per cent.

DIFFUSION OF LIGHT IN FOG

The aviator encounters several conditions that cause poor visibility. Haze and smoke usually are due to the presence of extremely small particles in the air—particles of diameters less than the wave length of light. According to Rayleigh's law, the amount of light scattered by such particles is inversely proportional to the 4th power of the wave length of the light. Thus, white light transmitted through haze or smoke becomes red, while the light scattered is mainly blue. Scattering of this kind accounts for the blue color of the sky and of distant mountains and for the red color of the setting sun.

Besides scattering light, smoke, and smoky fog obviously absorb a considerable amount of light.

In districts far from the sources of industrial smoke, however, the aviator encounters clean white fog, either as ground fog or as clouds. Such fog consists of small water drops which range in diameter[9] from about 2.2×10^{-3} to about 10^{-2} cm., so that they are 40 to 200 times larger than the wave length of ordinary light. The color effects characteristic of haze and smoke are thus absent in clean fog and in clouds.

The question is often raised whether certain colors of light such as red or blue are not transmitted through fog far better than white light.[10] The large size of the drops indicates that the scattering of light by fog should be the same throughout the visible and ultra-violet spectrum, and in the infra-red a decrease in scattering should occur only when wave lengths of about 20 microns are reached. In the visible spectrum this conclusion is confirmed by the fact that the disk of the sun when faintly discernible through clean fog or cloud appears colorless; also by the fact that the illumination on cloudy days is not of distinctly different color from that on clear days.

The scattering of light by fog and clouds is thus due to the interception of the light rays by the spherical droplets of water. Let n be the number of droplets per unit volume, each of diameter d; then w, the weight of the drops per unit volume, is:

$$w = (\pi/6)nd^3 \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

If a beam of light of intensity I passes a distance dx through the cloud, the decrease in the intensity of the direct beam is $-dI = I(\pi/4)nd^2\, dx$, since $(\pi/4)d^2$ is the area intercepted by each drop. The scattering coefficient is thus $(\pi/4)nd.^2$ The reciprocal of this, or

$$\lambda_o = 4/(\pi nd^2) = \frac{2}{3}\frac{d}{w} \ldots\ldots\ldots\ldots\ldots\ldots [23]$$

---

[8] This modulated light source will be described in a forthcoming paper by W. F. Westendorp.

[9] "Handbuch d. Expl. Physik," 25 (1), p. 51, 1928.

[10] See "Fog Penetration," by L. H. Anderson, U. S. Air Services, July, 1931, pp. 20 to 25. (This is to appear in Trans. A.S.M.E., Aeronautical Engineering.)

is the "free path" of the light rays through the cloud; i.e., the average distance that the rays can travel before the intensity of the direct beam falls to $1/e$th value. This free path is entirely analogous to that employed in the kinetic theory of gases.

Experimental determinations of w in rain clouds have given 1×10^{-6} to 2×10^{-6} grams per cu. cm. An estimate of the maximum possible values of w can be made from the water-vapor content of air.

The air rising into a rain cloud is saturated when it reaches the level of the bottom of the cloud. Under summer conditions the temperature at this point (1000 m. elevation) may be taken to be 20 deg. cent. The total water-vapor content is then 17.2×10^{-6} grams per cu. cm. If this saturated air rises another 1000 m., it would cool by adiabatic expansion (allowing for the heat of condensation of the water vapor to 15.8 deg., and the water-vapor content would then be 13.3×10^{-6} grams per cu. cm. The difference between these quantities, i.e., $w = 3.9 \times 10^{-6}$, must be the volume of the droplets per cubic centimeter in the cloud at an altitude of 2000 m. A similar calculation for winter conditions with a temperature of —5 deg. cent., for the base of the cloud gives a temperature of —11.6 deg. at an altitude of 2000 m., which gives at this level $w = 1.4 \times 10^{-6}$. These values of w are in good agreement with the experimentally found values.

The shortest free paths which may occur in clouds or clean fogs thus correspond roughly to $w = 2 \times 10^{-6}$ and $d = 3 \times 10^{-3}$ which give by Equation [23] $\lambda_e = 1000$ cm., or 10 m. According to Equation [22], there are only 140 droplets per cu. cm. in a fog of this character.

In the less dense clouds and fogs usually encountered by the aviator, the free paths λ_e will range from 30 to 100 m.

The light which is intercepted by a droplet is scattered in various directions, but not uniformly, for the larger part is scattered in a forward direction. This means that the forward component of the light originally in a parallel beam does not decrease as rapidly as does the intensity of the unscattered component of the beam. This phenomenon corresponds exactly to that of the persistence of velocities treated in the kinetic theory of gases.[11]

The distance at which the sharp outlines of an object can be seen through a fog depends primarily upon the distance that a ray of light can travel without appreciable change in direction. Thus the free path λ_e that we have calculated from the diameter of the droplets is applicable to such problems.

However, if we are to consider the amount of diffused light transmitted through or reflected from a cloud layer of given thickness, we need to consider a different kind of free path λ—i.e., the average distance which the light from a parallel beam can travel before its forward component has fallen to $1/e$th value. This free path will probably be two or three times as great as λ_e.

The transmission of light through fog is governed by laws similar to those of the diffusion of one gas into another and is analogous to the flow of heat or electricity in a conducting solid. The intensity of the light at any point in a fog is approximately the same in all directions and is measured by H, the brightness of illumination in candles per square centimeter.

Corresponding to this average brightness H, there is a random flux density $F = \pi H$ of light flowing across an imaginary plane inclined in any direction. However, because H is not uniform throughout the fog, there will be a drift flux density F_d which represents the net flow across an imaginary plane surface. This is essentially a vector quantity, and its component in any direction is proportional to the gradient of H in that direction.

The coefficient of self-diffusion D in a gas may be calculated from the mean free path λ and the average molecular velocity v, giving the result $D = (1/3)\lambda v$. An analogous calculation for the diffusion of light leads to the following expression for F_x, the component of the drift flux in the direction parallel to the x-axis:

$$F_x = -(4\pi/3)\lambda \frac{\partial H}{\partial x} \ldots\ldots\ldots\ldots\ldots\ldots [24]$$

Thus the quantity $4\lambda\pi/3$ may be termed the luminous conductivity of the fog. The brightness H is a scalar quantity which may be regarded as the luminous potential and is entirely analogous to electric potential, to temperature in heat conduction problems, or to concentration in diffusion problems.

In deriving Equation [24] it was assumed that the free path λ was small compared to the dimensions of the cloud.

With this point of view, let us now calculate the distribution of brightness in certain typical simple idealized cases.

1 *Point Source at Center of Spherical Cloud:*

Consider a source of L lumens at the center O of a cloud of radius r_o. Since we are assuming that the light is scattered, but not absorbed, the total flux across any spherical surface having its center at O is L. Thus the light flux density F_r in a radial direction at any distance r from the center is:

$$F_r = L/4\pi r^2 \ldots\ldots\ldots\ldots\ldots\ldots [25]$$

Combining this with Equation [24] and integrating, we find

$$H = \frac{3\,L}{16\pi^2\lambda}\left(\frac{1}{r} + K\right)$$

where K is the integration constant. Since we have assumed that λ is small compared to r_o, we may put $H = 0$ when $r = r_o$ (the outer surface of the cloud), and thus find $K = -1/r_o$, so that

$$H = \frac{3\,L}{16\pi^2\lambda}\left(\frac{1}{r} - \frac{1}{r_o}\right) \ldots\ldots\ldots\ldots\ldots [26]$$

Let us examine more closely these boundary conditions. As seen from a distance, the outside surface of the cloud will appear to have a brightness H_o which may be calculated by Equation [3] from the flux density F given by Equation [25] when $r = r_o$. Thus:

$$H_o = L/4\pi^2 r_o^2 \ldots\ldots\ldots\ldots\ldots\ldots [27]$$

An observer located at the outside surface of the cloud would see this brightness H_o if he faces the interior of the cloud, but finds the brightness $H = 0$ if he faces away from the center. Thus at this surface H is no longer a scalar quantity, as it is in the interior of the cloud, but depends on the direction of observation. If we put in Equation [26] $H = H_o$, as given by Equation [27], we find that

$$r_o - r = (4/3)\lambda \ldots\ldots\ldots\ldots\ldots\ldots [28]$$

In other words, the brightness at a distance $(4/3)\lambda$ inside of the outer surface of the cloud has a value H_o which will account for the light flux emanating from the cloud. This result appears reasonable when we remember that the light that escapes from the cloud passes through a layer comparable with λ in thickness without appreciable scattering.

In general, therefore, in calculating the brightness distribution within any cloud mass, we may place $H = 0$ at the outer surface. The apparent brightness as seen from a point outside is then the brightness which is calculated for a surface lying at a depth $(4/3)\lambda$ inside of the true surface.

It is interesting to compare the brightness H inside of an illuminated cloud with the brightness which would be obtained at the same distance in the absence of the fog if the light source should shine directly on a white diffusing surface. Comparing

---

[11] See Jeans, "Dynamical Theory of Gases."

H as given by Equation [26] with $H = L/4\pi^2r^2$, which would apply in the absence of fog, we see that the effect of the fog is to increase the brightness in the ratio

$$3r(r_o - r) : 4\lambda r_o \ldots\ldots\ldots\ldots [29]$$

As r increases, this ratio reaches a maximum value $3r_o/160\lambda$ when $r = 0.5\ r_o$. Thus in a spherical cloud having a radius of 1000 m. and a free path $\lambda = 30$ m., a 5000-cp. light ($L = 60{,}000$ lumens) at the center would give a brightness $H = 3.8 \times 10^{-6}$ cp. per sq. cm. at a distance of 500 m. from the source. This is over 6 times the brightness (0.63×10^{-6}) that would be obtained if the light from the source at this distance fell directly with normal incidence on a white diffusing surface. The fog, because of its poor luminous conductivity, thus tends to prevent the escape of the light and so increases the brightness within the cloud. The brightness of the outside surface of the cloud, by Equation [27], would be $H_o = 1.5 \times 10^{-7}$ cp. per sq. cm., which is about 4000 times the threshold sensitiveness of the photoelectric receiver.

Except by means of rockets or flares we are not ordinarily able to produce light sources at the centers of large clouds, so the foregoing case may seem to be rather academic. However, if the ground reflects nearly all the light that falls on it, as for example when it is snow-covered, then with a thick layer of fog over the ground and a light source on the ground the drift flux distribution is twice that given by Equation [25], and therefore Equation [26] gives the brightness distribution if its right side is multiplied by 2. We shall see that imperfect reflection from the ground modifies these conditions.

Directional Effect in Fog. The drift-flux density F_x in a fog as given by Equation [24] may be regarded as the difference of two fluxes flowing in opposite directions. Any small plane white surface (of dimensions small compared to λ) placed in the fog in a plane perpendicular to the x-axis will be illuminated differently on its two sides, the difference of brightness ΔH_x being

$$\Delta H_x = \frac{F_x}{\pi} \ldots\ldots\ldots\ldots [30]$$

Substituting into this the value of F_r from Equation [25] and dividing by H as given in Equation [26], we find for the directional ratio

$$\frac{\Delta H_r}{H} = 4\lambda/3r(1 - r/r_o) \ldots\ldots\ldots\ldots [31]$$

The minimum value of this quotient, $16\lambda/3r_o$, occurs when $r = 0.5\ r_o$. Thus in the example we have just considered the smallest value of $\Delta H_r/H$ is 0.16. The differential photoelectric receiver, which has been described, can detect differences of only 1.5 per cent, and should therefore be able to indicate the direction from which the light comes.

If such a device were used in an airplane, the plane could be turned toward the light of greatest intensity until the two intensities balance; straight flight would then bring the plane to the source.

2 *Layer of Cloud Uniformly Illuminated From Above or Below:* Let us consider a layer of cloud of uniform thickness h, the upper surface of which is illuminated by sunlight or moonlight. If F_s is the flux density produced by the source, as given for example in Table 1, then if the upper surface of the cloud were a perfect diffuse reflector, its brightness would be

$$H_s = (F_s/\pi)\sin\alpha \ldots\ldots\ldots\ldots [32]$$

where α is the angular altitude of the source above the horizon. Let H_T be the actual brightness of the top of the cloud layer, which is less than H_s because of light lost by transmission through the cloud; let H_B be the brightness of the bottom of the cloud layer as seen from the ground; and let R be the average reflection coefficient of the ground. The corresponding flux densities ($F = \pi H$) across horizontal planes are F_T and F_B. The light flux reaching the ground is thus F_B, while that returning from the ground is RF_B, and the loss of light caused by absorption by the ground is $F_B(1 - R)$. This loss must be equal to the drift flux F_x through the cloud layer and must also be equal to $F_s \sin\alpha - F_T$, the net light input at the top of the cloud layer. Thus by Equations [24] and [32] we have

$$H_B(1 - R) = \frac{4\lambda}{3h}(H_T - H_B) \ldots\ldots\ldots\ldots [33]$$

and

$$H_B(1 - R) = H_s - H_T \ldots\ldots\ldots\ldots [34]$$

Separating the two variables H_T and H_B, we obtain the equations

$$\frac{3h}{4\lambda} = \frac{H_T}{H_s - H_T} - \frac{1}{1 - R} \ldots\ldots\ldots\ldots [35]$$

and

$$\frac{3h}{4\lambda} = \frac{H_s - H_B}{H_B(1 - R)} - 1 \ldots\ldots\ldots\ldots [36]$$

Photometric measurements of H_T and H_B could readily be made from an airplane, and by simultaneous determinations of h, the values of λ for various types of cloud layers could be found. Measurements from the ground alone, however, give some useful data. Published tables of photographic exposure show that on days described as "very dull" the exposure needs to be increased only about tenfold. If under these conditions the upper surface of the cloud layer reflects 90 per cent of the incident light, there can be no appreciable loss by absorption within the cloud layer. The effect of a cloud layer sufficient to make a very dull day, which we may assume is 1000 to 2000 m. thick, is thus to change the light flux on the ground in the ratio $H_B : H_s = 1 : 10$. From Equation [36] this gives

$$\frac{3h}{4\lambda} = \frac{8 + R}{1 - R}$$

Photometer measurements which the authors have made from a tower at an airport have shown that the reflectivity R of the ground is ordinarily very low; for example, the airport surface varied from 9 to 21 per cent reflectivity. Tree-covered land (without leaves) gave only 5 per cent. The foregoing expression gives values of h/λ which are not very sensitive to R; thus for $R = 0.1$ and $R = 0.2$, we find h/λ is 12 and 13.7, respectively. This gives $\lambda = 80$ m. with a 1000-m. layer or $\lambda = 160$ m. with a 2000-m. layer.

If we have a layer of cloud uniformly illuminated from below, as for example by a series of regularly spaced lights, the problem differs from that just considered in that the light reflected downward F_B from the bottom of the cloud layer is partly reflected back by the ground and contributes to the illumination of the cloud. Equation [34] is still applicable, but in place of Equation [33] we have

$$H_T = \frac{4\lambda}{3h}(H_B - H_T) \ldots\ldots\ldots\ldots [33a]$$

and instead of Equations [35] and [36] we obtain

$$1 + \frac{3h}{4\lambda} = \frac{H_s - H_T}{H_T(1 - R)} \ldots\ldots\ldots\ldots [35]a$$

and

$$\frac{3h}{4\lambda} = \frac{H_B(2 - R) - H_s}{H_s - H_B\,(1 - R)} \ldots\ldots\ldots\ldots [36a]$$

where H_s is the brightness which the bottom of the cloud would have if it were perfectly reflecting and the ground were completely non-reflecting. If F_s is the average vertical flux density from the light sources on the ground, then $H_s = F_s/\pi$. It should be noted (by Equation [36a]) that if the cloud layer is thick or λ is very small, so that $3h/4\lambda$ becomes very large, H_B approaches the value

$$H_B = H_s/(1 - R)$$

and thus may become much greater than H_s if the ground has high reflectivity.

3 *Point Source in Fog Close to Ground With Poor Reflectivity:* We have already considered in case 1 an example where the ground is a good reflector. Let us now consider a case where the ground is completely black ($R = 0$) and the light source is located at a point B at a height b above the ground.

Since the ground absorbs all the light that falls on it, $H = 0$ at this surface, just as at the outside surface of the fog. We can simplify the problem by assuming that the fog is infinitely thick. The problem is then similar to that of the potential distribution around a point charge at a distance b from a plane conducting surface, and may be readily solved by the method of images. In the present case the distribution is the same as if the black ground were replaced by a completely transparent plane and in addition to the light source at B we postulate a light sink (negative source) at B' which is the image of B in the plane. The brightness H at any point at a distance r from the light source ($r \gg \lambda$) and at an angular height α above the horizon (as seen from the source) is

$$H = \frac{3L_u b}{4\pi^2 \lambda r^2} \sin\alpha \ldots\ldots\ldots\ldots\ldots [37]$$

In this equation L_u represents the light flux in lumens emitted by the source in an upward direction, i.e., in the upper hemisphere. This distinction is necessary, since rays emitted downward would be absorbed directly by the ground. In practice the efficiency of the light source can be nearly doubled by placing a hemispherical reflector below the lamp to convert the downward rays into the useful upward light. In this case L_u is approximately equal to L, the total luminous output of the lamp.

If the light source were actually at the level of the ground ($b = 0$), Equation [37] would give $H = 0$. When we consider that the light radiating from the source reaches on the average a hemispherical surface of radius λ before being scattered, we see that the effective height of a point source on the ground is roughly $(^2/_3)\lambda$. If the light were focused vertically upward, its effective height[12] would more probably be λ.

Thus b in Equation [37] may be taken to be $b_o + (^2/_3)\lambda$ (or $b_o + \lambda$), if b_o is the actual height of the light source.

With $b_o = 0$, so that $b = (^2/_3)\lambda$, Equation [37] thus becomes

$$H = L_u \sin\alpha/2\pi^2 r^2 \ldots\ldots\ldots\ldots\ldots [38]$$

If there were no fog and the light source should shine directly with normal incidence on a white surface at distance r, the brightness would be

$$H = L_u/2\pi^2 r^2 \ldots\ldots\ldots\ldots\ldots\ldots [38a]$$

which is thus the same as the brightness within the fog at points directly over the source. For other values of α the brightness would be less.

Fig. 14 gives data on the range at which a modulated light of intensity $L_u = 60{,}000$ lumens (5000 spherical candles with hemispherical reflector) would produce in an infinite fog a brightness $H = 3 \times 10^{-9}$ cp. per sq. cm., this being about 75 times the threshold value of the photoelectric receiver.

Curve I is for the case that the beacon is at the ground level (effective height $(^2/_3)\lambda$). The range is then independent of the density of the fog. Curves II and III illustrate the effect of placing the beacon on a tower 50 m. high. The range is greatly increased and is now dependent on the density of the fog, being much greater for a dense fog than for one less dense. With no fog at all the range (for $H = 3 \times 10^{-9}$) is represented by curve IV, which by Equation [38a] is a semicircle of radius equal to the maximum height of curve I. Comparison of curves III and IV shows how greatly fog can extend the range of diffused light signals.

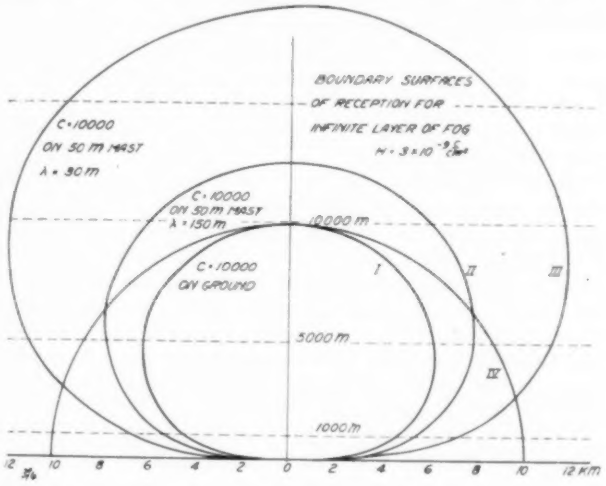

FIG. 14

(Surfaces of equal brightness [$H = 3 \times 10^{-9}$ cp. per sq. cm.] in an infinite fog overlying dark-colored ground [$R = 0$] near which is a light source projecting 60,000 lumens into the upper hemisphere; C is the candlepower in the upward direction, i.e., of the lamp with its hemispherical reflector.)

If we take x as the horizontal distance from the light source ($x = r \cos\alpha$), then by partial differentiation of Equation [37] and combination with Equation [24] we find that the horizontal component of the drift-flux density, at any point, is

$$F_x = \frac{3L_u b}{\pi r^3} \,.\, \sin\alpha \cos\alpha \ldots\ldots\ldots\ldots [39]$$

and thus by Equation [30] the directional ratio is

$$\frac{\Delta H_x}{H} = (4\lambda/r) \cos\alpha \ldots\ldots\ldots\ldots\ldots [40]$$

which is independent of b, the height of the light source.

If the receiver can detect a difference of 1.5 per cent between opposite directions, it should be capable of giving directional effects at distances of about 200λ, or 10 km. (if H is as great as 3×10^{-9}).

4 *Point Sources Within Uniform Layer of Fog or Cloud: Case a: White Ground* ($R = 1$). Consider a point source of light on perfectly reflecting ground which is covered by a layer of fog of thickness h. At the upper surface of the fog $H = 0$. By the method of images the problem is then equivalent to the determination of the potential distribution produced by a series of

---

[12] A still greater effective height might be obtained in quiet, foggy weather by building a fire on the ground so as to produce a rising vertical column of clear air up through which a searchlight beam could be projected to a height much greater than λ.

alternate positive and negative charges arranged along a vertical line with a distance $2h$ between adjacent charges. Madelung has solved[13] this and many similar problems in his studies of the electric forces in crystals built up of ions.

The complete solutions are expressible only in terms of Hankel functions, for which, however, tables are available. We are interested mainly in the distribution of brightness at distances from the source which are fairly large compared to h, the thickness of the cloud layer. Under these conditions the equations take much simpler forms. The following equations are modifications of Madelung's results adapted to our calculation of distribution of brightness.

At any point within the fog layer at a height y above the ground and a horizontal distance x from the beacon, the brightness H is

$$H = \frac{3\,L \exp(-\,\pi x/2h)\cdot\cos(\pi y/2h)}{4\pi^2\lambda h^{1/2}x^{1/2}} \quad \text{[41]}$$

Here L is the total lumens output from the light source. Because of the perfect reflection from the ground all of this light escapes from the upper surface of the cloud layer. This equation is accurate for all values of x which are large compared to h. However, for values of x even as small as $(^1/_3)h$ the errors are not greater than about 10 per cent.

A calculation of the directional ratio similar to that which led to Equation [40] gives in the present case for $x \gg h$:

$$\frac{\Delta H_s}{H} = 2\pi\lambda/3h \quad \text{[42]}$$

The brightness H_s of the upper surface of the fog, at a point directly over the beacon, $x = 0$, $y = h$, is (exactly):

$$H_s = 0.09280\,L/h^2 \quad \text{[43]}$$

At points on the upper surface for which $x > h$, the brightness H_s is

$$H_s = \frac{L \exp(-\,\pi x/2h)}{2\pi\, h^{3/2}\, x^{1/2}} \quad \text{[44]}$$

Examination of these results shows that the brightness in the fog and on its upper surface decreases exponentially as the horizontal distance x increases, falling to $1/e$th value in each increment of $0.63h$ in the distance.

As an example of the range at which modulated light signals can be detected, we may assume the following conditions. An airplane flies at a height y of 250 m. in a fog layer $h = 500$ m. thick, with a free path $\lambda = 50$ m. The ground is snow-covered, and on the ground is a modulated light beacon of 5000 cp., $L = 60{,}000$. By Equation [41] we find that the brightness in candlepower per square centimeter at various horizontal distances x from the beacon is 1.2×10^{-6} at 1 km., 3.7×10^{-8} at 2 km., 1.3×10^{-9} at 3 km., and 5×10^{-11} at 4 km. Thus since 4×10^{-11} cp. per sq. cm. can be detected, the signal could be picked up at a distance of 3 to 4 km. from the source. The directional ratio of about 20 per cent should give good directional effects at distances less than 3 km. The brightness H_s at the top of the cloud layer is $3\lambda/h$, or 0.3 of that at the height of 250 m., so that the ranges of detection just found are approximately independent of the height of the plane within the layer.

Case b: Black Ground ($R = 0$). By the method of images, this problem is equivalent to that of finding the potential of a series of dipoles arranged in a vertical line with uniform spacing of $2h$. Each dipole consists of an upper positive source L and a lower negative source $-L$, with a distance $2b$ between them.

If the height of the source above ground is small compared to h, the thickness of the fog layer, then the brightness H at any point (x, y) is:

$$H = \frac{3L_u b}{2^{3/2}\pi\lambda h^{3/2}x^{1/2}} \sin\left(\frac{\pi y}{h}\right) \exp(-\,\pi x/h) \quad \text{[45]}$$

L_u is again the total light thrown upward by the beacon.

As in Equation [37], b is the effective height $b_o + (^2/_3)\lambda$ of the beacon.

Thus if the beacon is practically at the ground level, so that $b = (^2/_3)\lambda$, we have:

$$H = \frac{L_u \sin(\pi\, y/h)\,.\,\exp\,(-\pi\, x/h)}{2^{1/2}\,\pi h^{3/2}\, x^{1/2}} \quad \text{[46]}$$

A calculation of the directional ratio gives for $x \gg h$:

$$\frac{\Delta H_s}{H} = 4\pi\lambda/3h \quad \text{[47]}$$

which is twice as great as that given by Equation [42] for $R = 0$.

The brightness H_s at the top surface of the fog directly over the beacon is:

$$H_s = 0.4262 b L_u/h^3 \quad \text{[48]}$$

At horizontal distances x, large compared to h, the brightness of the top surface is:

$$H_s = \frac{2^{1/2}\, L_u\lambda\, \exp\,(-\,\pi x/h)}{3\; h^{5/2}x^{1/2}} \quad \text{[49]}$$

A rough integration of the total light flux L_s in lumens from the upper surface of the fog gives:

$$L_s = 2\,L_u b/h \quad \text{[50]}$$

It should be noted that the logarithmic decrement in the brightness as x increases is twice as great as in the case that the ground is white.

As an example let us take as before a modulated light beacon of 5000 cp. ($L_u = 60{,}000$). For various values of h and x we have calculated H at the height $y = 0.5\,h$ by Equation [46] for the case that the beacon is close to the ground. Table 8 gives the distances at which the brightness H has the values specified in the first column. With the photoelectric receiver capable of detecting 4×10^{-11} cp. per sq. cm., ranges of 1 to 3 km. are possible. At heights other than $0.5h$ the results are not greatly different.

TABLE 8

(Distances in meters at which the light from a 5000-cp. beacon, with reflector, will produce given brightness of illumination in the interior of a fog layer of thickness h covering dark-colored ground)

H (cp. per sq. cm.)	$h = 250$ m.	$h = 500$ m.	$h = 1000$ m.
10^{-8}	580	950	1500
10^{-9}	760	1300	2180
10^{-10}	930	1640	2870
4×10^{-11}	1000	1780	3140

A tenfold increase in the output of the beacon or a tenfold increase in the effective height b would produce only a 20 or 30 per cent increase in the range at which the light from the beacon could be detected by the photoelectric receiver.

Comparing these data with those calculated for the perfectly reflecting ground, we see that the effect of making the ground black is to reduce the range to about 42 per cent of its value for perfectly reflecting ground.

5 *Reflection From and Transmission Through a Cloud Layer:* The case that we have just considered of a thin layer of fog in contact with the ground is probably the most unfavorable that can be found for light transmission inside of the fog layer. If, however, the aviator flies above the fog layer, he can make use of

---

[13] E. Madelung, *Phys. Zeitsch.*, vol. 19, pp. 524–532 (1918).

the spot of light which is transmitted up through the fog according to Equation [50]. If the upper surface of the fog is horizontal, the light flux emitted from this spot in a direction inclined at an angle α above the horizon will be proportional to sin α. The light flux density F at any point which is at the distance r (along inclined line) from the center of the spot and at the height y above the top of the fog layer is, thus:

$$F = L_o y/\pi r^3 = 2\,L_u by/\pi hr^3 \ldots\ldots\ldots\ldots [51]$$

The range of the signals that may be transmitted in this way is far greater than those within the fog layer itself. For example, putting $L_u = 60{,}000$, $b = (^2/_3)\lambda$, $\lambda = 50$ m., $h = 250$ m., we have $F = 5100\ y/r^3$. If we take $y = 2.5 \times 10^4$, (250 m.) and $F = 1.2 \times 10^{-10}$ corresponding to the threshold ($H = 4 \times 10^{-11}$) of the photoelectric receiver, we see that we should be able to detect the modulated light transmitted up through the fog at a distance of 10.2 km. as compared to the distance of only 1 km. within the fog layers, as given in Table 8.

If there are other layers of cloud above the fog on the ground, the light reflected down from them will greatly increase the range and will also make it possible to detect the modulated light within the fog layer at distances far greater than those given in Table 8.

If the bottom of the fog layer is at a height y_o above the ground, then the light L_u from the beacon forms a spot of light on the bottom of the cloud which reflects the greater part of the total light. Thus if the plane flies below the cloud layer, the range may be calculated by the first two members of Equation [51], where L_o is now to be replaced by L_u and y is the height of the ceiling above the plane.

When the cloud layer is definitely off the ground, the transmission of light through it is given by Equations [35*a*] and [36*a*]. The fraction of the light output of the beacon which escapes from the top of the cloud layer is equal to H_T/H_s. By Equation [35*a*] this is:

$$H_T/H_s = 1/\left[1 + (1 - R)\,(1 + 3h/4\lambda)\right] \ldots\ldots [52]$$

When $R = 0$ and h/λ is large, this reduces to the same value as the ratio L_o/L_u given by Equation [50] for the case of the fog lying on black ground. Equation [51] is thus still applicable for the detection of light transmitted through a cloud layer which is at a considerable height above ground.

In this case the brightness within the cloud layer will extend for relatively large horizontal distances from the source. The brightness H at any point may be calculated by linear interpolation between H_B and H_T, which are given by Equations [35*a*] and [36*a*]. The brightness H_s, which is to be used for this purpose, is equal to

$$H_s = L_u\, y_o/2\,\pi^2 r^3 \ldots\ldots\ldots\ldots [53]$$

where r is the inclined distance from the light source to the given point at the bottom of the cloud. In most applications where $r \gg y$, we may put $r = x$, the horizontal distance from the source.

Under these conditions we find by partial differentiation of Equation [53] and combining with Equations [24] and [30] that the directional ratio is

$$\frac{\Delta H_x}{H} = \frac{4\lambda}{x} \ldots\ldots\ldots\ldots [54]$$

which is $3h/\pi x$ times as great as that given by Equation [47] for the ratio inside of a fog layer on the ground.

As an example let us consider a cloud layer of a thickness of $h = 500$ m. whose bottom surface is $y_o = 500$ m. above the ground, which has the reflectivity $R = 0.2$. Let $\lambda = 50$ m. and $L_u = 60{,}000$ lumens. By Equation [53] we find $H_s = 1.5 \times 10^8/r^3$ cp. per sq. cm., and then by Equations [35*a*] and [36*a*] we get $H_T = 1.3 \times 10^7/r^3$ and $H_B = 1.09H_s = 1.65 \times 10^8/r^3$. The directional ratio is $\Delta H_x/H = 2 \times 10^4/x$. Placing $H_T = 4 \times 10^{-11}$, we find that a plane flying near the top of the cloud layer should be able to detect the modulated light at a distance $x = r = 6.9$ km. Near the bottom of the cloud layer the range would be 16.1 km. At distances of 1.65 and 3.8 km. (top and bottom, respectively) the brightness would be 3×10^{-9} (75 times threshold) and the directional ratios would be 0.121 and 0.053, respectively, whereas 0.015 can be observed with this brightness.

Effect of True Absorption of Light Within a Fog. So far we have considered the scattering of light within a clean white fog in which absorption is negligible. It may be of interest to deal briefly with the modifications that occur if there is also an absorption of light such as exists, for example, in a smoky fog.

In this case, in each unit of volume, an amount of light will be absorbed (destroyed as distinguished from scattered) which will be proportional to the light intensity H at that point. The absorption may be measured in terms of a volume-absorption coefficient A, which is the light absorbed per unit volume per unit light intensity. Thus AH lumens of light are absorbed per unit of volume.

The absorbing power of the fog may also be described in terms of a mean free path λ_A. Perhaps the best way of defining this quantity is by means of the relation

$$-\frac{dF}{F} = \frac{dx}{\lambda_A} \ldots\ldots\ldots\ldots [55]$$

where $-dF$ is the decrease in the intensity of a beam of light of flux density F, resulting from absorption, while traveling a distance dx.

It can be shown that

$$\lambda_A = 4\pi/A \ldots\ldots\ldots\ldots [56]$$

Let us now consider three special cases in which H depends only on a single coordinate; thus H depends upon:

(1) the distance r from a fixed plane, $\beta = 0$
(2) the distance r from a fixed line, $\beta = 1$
(3) the distance r from a fixed point, $\beta = 2$.

Here β is a number that has the value 1, 2, or 3 for the three cases.

Then by Poisson's equation we have for all three cases:

$$\frac{d^2H}{dr^2} + \frac{\beta}{r}\frac{dH}{dr} = \frac{3H}{\lambda_A\lambda_s} \ldots\ldots\ldots\ldots [57]$$

where λ_s is the free path for scattering, i.e., the quantity which we have previously designated by λ.

If we impose the boundary condition that $H = 0$ at $r = \infty$, the integration of Equation [57] gives for:

(1) *Plane Case* $\beta = 0$:

$$H = H_o \exp\left[-(3/\lambda_A\lambda_s)^{1/2}\,r\right] \ldots\ldots\ldots [58]$$

where H_o is the brightness of illumination at the fixed plane $r = 0$. Differentiation and substitution into Equation [24] gives the flux density F_o at $r = 0$

$$F_o = 4\pi(\lambda_s/3\lambda_A)^{1/2}\,H_o \ldots\ldots\ldots\ldots [59]$$

(2) *Cylindrical Case* $\beta = 1$:

The exact expression for this case involves Bessel functions. However, in practical cases where $(3/\lambda_s\lambda_A)^{1/2}\,r$ is larger than unity, a sufficiently close approximation is given by

$$H = 0.03618\,\lambda_A^{1/4}\lambda_s^{-3/4}\,r^{-1/2}\,L_1 \exp\left[-(3/\lambda_A\lambda_s)^{1/2}r\right] \ldots [60]$$

where L_1 is the light output from the line source in lumens per unit length.

(3) *Spherical Case* $\beta = 2$:

$$H = (3L/16\pi^2\lambda_s r) \exp [-(3/\lambda_A\lambda_s)^{1/2}r] \qquad [61]$$

where L is the total output from the point source in lumens.

In the absence of absorption, Equation [26] gives

$$H = 3L/16\pi^2\lambda_s r \qquad [62]$$

Comparing Equations [58], [60], and [61] with [62], the combined effect of scattering and absorption is seen to give an effective free path equal to $0.577\ (\lambda_A\lambda_s)^{1/2}$. Because of the presence of the exponential factor in these equations, it is obvious that useful signals can never be transmitted to distances greater than about $10 \times (\lambda_A\lambda_s)^{1/2}$.

We have now considered the various factors which seem to be of greatest importance in determining the transmission of diffused light signals from ground to an airplane. It seems possible to draw the definite conclusion that, with sources of reasonable intensity and with photoelectric detectors which can now be built, signals may be transmitted through dense white fog. The presence of smoke may greatly decrease the range.

Discussion

S. Herbert Anderson.[14] This paper is a very important contribution—if not the most important one yet made—to the use of light signals in aviation. As a result of research and compilation there is gathered here a fund of information which should be of greatest value to the engineer and physicist interested in the problems of signaling through a thick atmosphere. Furthermore, the results obtained are of great value wherever signal lamps are used—in ocean navigation, street traffic, railway signaling, and military and naval signaling. So far as the writer knows, this is the first time that an attempt has been made to determine the illumination or flux density required for threshold visibility of lights of various types (point sources, white and colored, and diffuse sources) over such a wide range of background brightness. Data of this nature are of fundamental importance in the design of beacons for both clear and foggy atmospheres. Of equal importance is the investigation with flashing signals of the threshold illumination as a function of the period of the flash and the time interval of the flash.

In all investigations in which the results are dependent on the reaction of individuals to stimuli to the sense organs, as large a number of observations by as large a number of normal individuals as is feasible should be made, in order to establish relationships which may be used with reasonable assurance of their applicability. It would seem that the importance of some of the conclusions given in the paper warrants a larger number of observations than were possible in this single investigation. Such relations as:

a The threshold flux density from a steady point source as a function of background brightness, Equation [5],

b Relative visibility of various colors with various background brightnesses, Fig. 6,

c The threshold flux density of a flashing point source as a function of the period and duration of the flash, Equation [7],

d The optimum period and duration of the flash for given flux densities and background brightnesses, and

e The visibility of flashes of diffused light, Fig. 9.

are worthy of further investigation and might well be taken up by some such organization as the Bureau of Standards.

From their study of threshold flux density and the effect of duration and period of the flash upon visibility, the authors have computed the effective range of the standard of rotating beacon as a function of the absorption coefficient of the atmosphere and the period of the beacon, as given in Table 3. In order that such data should serve their purpose we must know how the absorption coefficients correspond to the various states of the atmosphere: haze, light fog, moderate fog, and dense fog. An attempt has been made to supply this information by giving the "visibility" for each value of λ used, as 2.3λ. If "visibility" is used in the sense employed by observers of the Weather Bureau, viz., the distance at which dark-colored objects can just be distinguished, it seems to the writer that the factor 2.3 is much too small. This opinion is based on some observations made in an attempt to determine the transmission of a beam of light through a fog when a dark-colored object is just visible. Of course the visibility of an object in a fog depends upon the illumination on the object as well as the absorption of light by the fog. Photometric measurements of daylight illumination on a vertical surface in natural fogs give values ranging from 60 to 1300 foot-candles with an average of about 500 foot-candles. Observations in a laboratory fog chamber using this illumination showed that an object was just visible when the transmission was $^1/_{1000}$th. This gives a value of visibility $= 6.91\lambda$ rather than 2.3λ.

In the airways work of the Weather Bureau the following classification is used.

a Light fog—visibility greater than $^3/_4$ mile

b Moderate fog—visibility greater than $^1/_5$ mile, less than $^3/_4$ mile

c Dense fog—visibility not greater than $^1/_5$ mile.

Using these distances for visibility, the corresponding values of λ can be computed.

Quality of fog	Visibility	λ
Light	1.2 km.	1.74×10^4 cm.
Moderate	0.8 km.	1.15×10^4 cm.
Dense	0.32 km.	4.6×10^3 cm.

According to these calculations, a value of $\lambda = 2 \times 10^4$ cm. indicates a light fog in which the visibility is somewhat greater than 1 km.; and $\lambda = 5 \times 10^3$ cm. indicates a dense fog in which the visibility is about $^1/_3$ km. The corresponding effective ranges of the standard beacon with a 10-sec. period are 1.92 km. for a light fog and 0.42 km. for a dense one. It would be interesting to know how these computed values correspond to those observed by experienced pilots. Visibility $= 6.91\lambda$ may be too large. A value in between this and 2.3λ may be better.

It would be worth while to carry out a series of observations involving simultaneous measurements of transmission of light through fog and distances of visibility, from which a relation between mean free path of light rays and visibility could be established. With this relation Table 3 could be used with considerable confidence.

The most interesting feature of this investigation, and probably the most important, is the development of an extremely sensitive photoelectric receiver for light. A light-sensitive instrument which is from 6 to 13,000 times as sensitive as the eye (depending on the background brightness) is truly remarkable. This should prove a valuable addition to the equipment for fog navigation. Whether or not it will have the range which is claimed for it depends not only on its sensitivity, but upon the way light is diffusely propagated through fog.

This brings us to the most surprising feature of the paper—the theory of diffusion of light in fog. It is well recognized that light is readily propagated in a diffused manner through fog. But it is no less than startling to have it pointed out that under certain conditions (a light source at the center of a large cloud of fog) the flux density may be *six* times as great in a fog as in clear air. Even the practical case of a light on a 50-meter mast and assuming zero reflection from the ground is very surprising, showing a greater flux density than in clear air.

---

[14] Signal Corps Laboratories, Fort Monmouth, Oceanport, N. J.

If the fundamental assumptions on which this theory is based are sound, the theory must be correct. As the writer understands the presentation, it is assumed that in a clean water fog there is no loss of light energy in the diffusion by the fog droplets. If a certain quantity of light falls on a droplet, the same quantity leaves it, the only change being in the direction of the light ray.

It seems to the writer that this assumption is questionable. The scattering of light by a fog droplet is by reflection and refraction. In refraction some light passes through the water drop, and this is accompanied by a small absorption. A loss in reflection is more difficult to check on. But there may be a loss here too. If there is a loss of light energy in this diffusion process, the propagation through fog is accompanied by a true absorption. If this is the case, the theory as presented needs some modification. This theory can be and should be tested as pointed out on page 15 ante.

On page 13 the following statement is made: "The large size of the drops (fog drops) indicates that the scattering of light by fog should be the same throughout the visible and ultra-violet spectrum, and in the infra-red a decrease in scattering should occur only when wave lengths of about 20 microns are reached." The work which the writer did on the transmission of radiation through fog[15] indicates that a marked decrease in scattering occurs for wave lengths much shorter than 20 microns. This is shown in Figs. 6 and 7 of the paper referred to. This is also shown well by using the concept of the "mean free path," λ_0, of radiation through fog. Take a fog of such density that $\lambda_0 = 6.1$ m. for light of wave length 0.55μ. For a wave length of 2.6μ the value of λ_0 is 108 m., showing a much larger free path and, hence, less scattering. This work corroborates the statement on page 13 for visible radiation, but not for infra-red.

Authors' Closure

By Mr. Langmuir. A point source of intensity C candles if seen through a thickness x of fog will appear to be of an intensity $C \exp(-x/\lambda)$. Whether or not it is visible at a given distance depends mainly upon the "background brightness," which in this case means the intensity of illumination of the fog either by the given source or by other sources which may be present. Such problems can be readily worked out quantitatively from the principles outlined in this paper.

A *small* white diffused reflecting surface in a fog uniformly illuminated to brightness H will also have the brightness H and is thus invisible, although the light that comes to the observer from the surface corresponds to a brightness $H \exp(-x/\lambda)$. This means that the brightness $H\,[1 - \exp(-x/\lambda)]$ is supplied by diffusion from the fog particles that lie between the observer and the source.

If now the white surface is replaced by a black surface of the same size and position, the *apparent* brightness of its surface is $H\,[1 - \exp(-x/\lambda)]$. It is well known that surface brightnesses which differ less than 1 per cent cannot be distinguished by the eye under favorable conditions, as for example in a Lumner-Brodhun photometer. Thus the black object in a *uniformly illuminated fog* cannot be seen if $\exp(-x/\lambda)$ is less than 0.01 or if $x > 4.6\,\lambda$. It is more likely under ordinary conditions that the intensity difference needed for "visibility" will correspond rather to 10 per cent difference, giving $x < 2.3\,\lambda$.

A white card with a black cross in uniformly illuminated fog will evidently be visible at the same distance as the black cross alone. But if the card is illuminated by a separate source so that its white parts are brighter than the fog, the visibility may be greatly increased.

It is understood that in Mr. Anderson's fog-chamber experiments the object was illuminated, but the fog was not, and therefore the visibility that he observed was far greater than would be observed under more nearly normal conditions.

When light travels in a fog between two points at a distance x apart, the number of "collisions" of the light ray with fog particles is approximately $(x/\lambda)^2$, and if d is the diameter of a droplet, the total distance which the light travels through liquid water will not exceed $(x/\lambda)^2 d$. If we take $\lambda = 30$ m. or 3×10^3 cm. and $d = 3 \times 10^{-3}$ cm. and $x = 1$ km. (10^5 cm.), we find that even in this extreme case the light travels through only 3 cm. of water. Thus if the water of the droplets is *clean*, no appreciable absorption is to be expected.

Airship Factory and Dock of the Goodyear Zeppelin Corporation

By WILBUR J. WATSON,[1] CLEVELAND, OHIO

The paper describes the airship factory and dock at Akron of the Goodyear Zeppelin Corporation, covering its design and construction, a study of wind pressures, a comparison with other hangars, the docking problem, the design of the doors and the roof covering, with the details of the preparation of the site, the substructure, the structural-steel fabrication and the erection methods employed, the mechanical and the electrical equipment, and the floors, the fire protection, and the helium storage.

THE airship factory and dock of the Goodyear Zeppelin Corporation at Akron, Ohio, completed in 1929, was designed and built to construct and house two new airships for the United States Navy, the *ZRS-4* and *ZRS-5*, since named *Akron* and *Macon*. These airships have a length of 785 ft and a diameter of 133 ft and a gas capacity of 6,500,000 cu ft of helium gas, and are much the largest airships ever built. The building, however, has been planned to house an airship considerably larger than these. It can easily accommodate an airship of 10,000,000 cu ft capacity.

The principal purpose of this building is to serve as a factory for airship construction, and it is therefore thoroughly equipped with cranes, runways, elevators, etc. While essentially a factory building, it may be used in the future as a dock for ships in service, and this possibility has been borne in mind by the designers.

Airship Design and Construction

The name Zeppelin is synonymous, in the public mind, with the airship, for to Count Ferdinand von Zeppelin is due the greatest credit for the development of lighter-than-air craft. Zeppelin began the construction of rigid airships about 1900 at Friedrichshafen, on Lake Constance, and at the outbreak of the World War in 1914 had already built many such crafts. Count Zeppelin's first ship was 410 ft long by 38 ft maximum diameter and contained 400,000 cu ft of hydrogen. Compare this with the *Graf Zeppelin*, 776 ft in length by 100 ft diameter and 3,700,000 cu ft capacity.

The war gave a tremendous impetus to the development of these ships, due to their value for scouting and bombing operations. Although about 115 zeppelins had been built at Friedrichshafen at the close of the war, most of them had met various fates largely due to the hazards of warfare. Until Zeppelin undertook the development of the rigid airship, but little advance had been made in lighter-than-air craft since the invention of the hot-air balloon by the brothers Montgolfier and the hydrogen-inflated balloon by Charles in the later years of the 18th century. It was in a montgolfiere that Benjamin Franklin made an ascent in France. The free, or non-rigid, balloon is simply a bag of gas, usually hydrogen, carrying a wicker basket supported from the bag by a network of ropes. A semi-rigid airship has a structural keel which carries the cabin, the gas cells above being enclosed in an envelope which has no supporting framework.

The rigid airship has a complete metallic framework of rigid construction, consisting in the zeppelin essentially of longitudinal girders holding vertical rings, between which are placed the separate gas cells. The structural material used for most of these rigid airships is duralumin, an alloy of aluminum with copper, manganese, and magnesium that possesses approximately the strength of structural steel, but has the advantage of much lighter weight. In the design of structural members every possible way of decreasing weight without sacrifice of strength is resorted to, all unnecessary metal is removed by punching, and all shapes are carefully designed for minimum weight. The fabric for the gas cells used in the earlier ships was gold-beater's skin, mounted upon a cotton base. No gold-beater's skin is used in the *Akron*, the cells being constructed of a strong cotton fabric especially treated to make it gas tight.

The gas used in all countries except the United States is hydrogen, which is an inflammable gas. In this country, however, helium is used. Helium is an inert gas, non-explosive and nonburnable, possessing only about 83 per cent the buoyancy of hydrogen, but is much more safe. It is found at several places in the Western states, in combination with nitrogen. The lifting capacity of helium gas is 0.0656 lb per cu ft, assuming the gas to be 94 per cent pure, 60 deg air humidity, 29.95 in. barometric pressure, and 32 F air temperature.

The method of assembling an airship of the zeppelin type at Akron is, first, to erect the rings in a horizontal position on the floor of the hangar, raising them into vertical position by hanging them from the structural framework of the building, and then assembling the longitudinal girders and other members by means of platforms carried by overhead cranes and supported by movable scaffolding on the hangar floor.

It is not the intention to describe in detail the principles of airship construction in this paper, but only to give a general picture, as it affects the design of the factory and dock. In Table 1 are compared the main features of the larger airships.

Development of the Building Plan

The general shape and plan of the building is the development

---

[1] Engineer, Wilbur Watson & Associates. Dr. Watson was born at Berea, Ohio, on April 5, 1871. He received the degrees of B.S. and C.E. from the Case School of Applied Science, Cleveland, Ohio. He was in the engineering department of the Lake Shore & Michigan Southern Railway, 1889–94; design and supervision of construction, Osborn Engineering Company, Cleveland, 1898–1907; private practice as consulting, designing, and supervising engineer for bridges and buildings, Cleveland, including the Cleveland Freight Terminal for the New York Central Railroad. Dr. Watson was one of five engineers selected by the American Institute of Steel Construction to formulate a standard code for structural-steel buildings and was elected an honorary member of the institute in recognition of this service. Recent work executed by the firm includes the airship factory and dock at Akron, Ohio, for the Goodyear Zeppelin Corporation, the Northern Ohio Food Terminal at Cleveland, and the Lorain-Carnegie Bridge (now nearly completed). Dr. Watson is the author of "Bridge Architecture." The honorary degree of Doctor of Engineering was conferred upon him by the Case School of Applied Science in April, 1930.

Presented before the Ontario Section of The American Society of Mechanical Engineers at its meeting, Toronto, Ontario, Canada, December 10, 1930. (Revised up to June 16, 1932.)

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 1 PRINCIPAL CHARACTERISTICS OF "LOS ANGELES," "GRAF ZEPPELIN" AND "ZRS-4"

	"Los Angeles"	"Graf Zeppelin"	"ZRS-4"
Nominal gas volume, cu ft	2,470,000	3,710,000	6,500,000
Length overall, ft	658.3	776	785
Maximum diameter, ft	90.7	100	133
Height overall, ft	104.4	113	147
Gross lift, lb	153,000	258,000	403,000
Useful lift, lb	60,000	.....	182,000
Number of engines	5	5	8
Total horsepower	2,000	2,750	4,480
Maximum speed, mi per hr	73	80	84
Range without refueling at 50 knots cruising speed, nautical miles	4,000	6,125	10,580
Fineness ratio	1:7.2	1:7.7	1:5.9

of many years of study on the part of Dr. Karl Arnstein[2] and his assistants, in the endeavor to determine upon the most efficient type of building to meet exacting aeronautical requirements at a minimum cost.

The most difficult part of airship operation at present is the launching and docking of the ship, and it is essential that the building which serves as its shelter should cause the least practicable interference with the normal wind current, in order that the launching and docking operations may not be complicated by cross-currents created by the building itself or by the open doors. It is this consideration that suggested the shape of this building to Dr. Arnstein.

Hangars of similar design, although much smaller, had been built and operated at Dresden and Liegnitz in Germany.

The shape of this building is described in mathematical terms as two semi-paraboloids connected by a parabolic cylinder; that is to say, sections taken across it form parabolas, and its longitudinal section also forms two half-parabolas connected by a straight line.

Its shape has been described as a half of an egg, but a better simile would be a half of a silkworm's cocoon, cut in two the long way.

The length is 1175 ft between center lines of door tracks, width 325 ft center to center of arch pins, and its height $197^1/_2$ ft from center of lower to center of top pins. The height from the floor to the platform at the top is 211 ft.

The floor area is 364,000 sq ft, much the largest single uninterrupted floor area yet built. The volume is approximately 55,000,000 cu ft.

A Study of Wind Pressures

The correct distribution of wind pressures on a given structure, as well as its intensities, is not as definitely determined as one could wish. The usual American practice calls for a wind pressure on buildings of 30 lb per sq ft, although values ranging from 20 lb to 60 lb are often used.

When designs were started for the Akron hangar, early in 1928, no American experiments on buildings of comparable shape had been made to determine the amount of suction forces or negative pressures due to the creation of partial vacuums caused by the deflection of the air currents.

In the design of sheds, or hangars, for airships, the wind pressures become of paramount importance, due to the fact that the stresses produced in the structure by wind pressures are relatively greater than is the case of most buildings and also to the unusual height and exposure of the structures. It becomes, therefore, of great importance to determine as accurately as possible just what these pressures may be.

In order to obtain some experimental data relative to the action of wind on a building of the shape proposed for the Akron hangar, Dr. Arnstein caused a model to be made about 5 ft in length and had a series of tests conducted in the 9-ft wind tunnel of the Daniel Guggenheim School of Aeronautics at New York University. These tests were made early in 1928 by Dr. Klemperer, of the Goodyear Zeppelin Corporation, and Prof. A. Klemin, of the university staff. A velocity of 50 mph was used for most tests. The shell was perforated with 87 orifices 0.09 in. in diameter, and 22 similar holes were drilled into two of the door segments. To these holes were attached rubber tubes which led to the manometers. The model was tested at various angles to the direction of the wind.

In general, the region where the overpressure changed to suction was found to be about 50 to 60 per cent of the height of the building, and at the region of the doors this became as high as 72 per cent. The suction reached its maximum at a point slightly windward of the apex.

It was found that the opening of the doors affects only the pressure distribution on the doors themselves and in their vicinity, but the central regions or those at the other end are influenced but little, if at all.

In general terms, these experiments showed that a current of air impinging upon an obstacle caused positive pressures in front and suction at the sides and rear, and in most cases the maximum pressures are not positive but negative.

The experiments indicated that the outward force should be assumed at greater than one-half the inward, with provision for securing roofing against local outward forces equal to the full direct pressure. American practice in designing buildings to resist wind pressures has heretofore neglected the importance of these suction or outward pressures.

Observations on air currents at the Lakehurst hangar have demonstrated that the currents around the open doors (sliding type) may obtain a velocity twice that of the prevailing wind. As the launching or docking of an airship cannot safely be carried out against a wind greater than a certain maximum for each case, the great importance of eliminating these locally increased currents can readily be seen.

As one writer has expressed it, "What ever flies, roosts;" and up to this time no roosting place has yet been evolved for the airship to take the place of a covered building, called a "hangar" in Germany and France, a "shed" in England, and either a "hangar" or, preferably, a "dock" in America. It is vitally important, therefore, that the ship should have access to its roosting place in the worst possible navigating weather.

Orientation. As it is desirable that airships should head into the wind when landing, the longitudinal axis of the hangar should coincide with the direction of the winds prevailing during flying weather. For the location selected at Akron it has been found that the proper orientation is north 30 deg east by south 30 deg west, approximately.

Comparison With Other Hangars

The original zeppelin shed at Friedrichshafen, built in 1908–1909, is $603^1/_2$ ft (184 m) long, 150.8 ft (46 m) wide, and 65.6 ft (20 m) high. Later a larger hangar was built, having a length of 787.2 ft (240 m), a width of 150.8 ft (46 m), and a height of 114.8 ft (35 m). These hangars, and most others built in Europe, are of structural steel arches, with sliding doors at the ends. The Luftschiffbau Zeppelin Corporation has recently completed a new hangar at Friedrichshafen equipped with cylindrical doors instead of straight sliding doors, a brief description of which is given later.

At Orly, France, two reenforced concrete hangars have been built, having a length of 984 ft, a span of 298 ft, and a height of 194 ft 6 in. These hangars have not yet been equipped with doors. The cross-section is parabolic, similar to the Akron building, and the structure is made up of reenforced concrete ribs connected with reenforced concrete curtains between the rings. The design is by M. Freysennet, a noted structural engineer.

---

[2] Vice-President and Chief Engineer, Goodyear Zeppelin Corporation.

All of these hangars have vertical doors that open horizontally, from the center outward. The "orange-peel," or quadri-spherical door, a distinctive feature of the Akron dock, never had been used except for a few much smaller buildings in Germany.

New Friedrichshafen Hangar. As the original sheds at Friedrichshafen, built by the Luftschiffbau Zeppelin, were comparatively small, the latest building constructed (1929) may be taken as representative of the best thought of the original German designers of the dirigible airship.

The length of this latest addition to the Friedrichshafen plant is 815 ft inside, the width 165 ft $3^{3}/_{4}$ in., and the height 157 ft. The floor area is 150,000 sq ft and the cubical contents about 18,000,000 cu ft working space, or a total of 22,000,000 cu ft.

In design, this structure is composed of a series of three hinged arches, with the lower pins only slightly raised above the ground, about 12 ft. The arches, 22 in number, are equally spaced at 10 m (32.8 ft). The windows are about 3 m (10 ft) wide by 10 m (32.8 ft) high and are spaced two to each panel in the vertical sides, which are carried up to a height of about 100 ft. The roof profile is broken.

The distinctive feature of this design is the curved end doors, not spherical, as at Akron, or straight, as at Lakehurst, but circular with straight vertical sides. The great advantage of these doors over the straight doors is in the lessened obstruction to wind. The roofing is of pumice-stone concrete, reenforced, with asphalt-composition roofing. Two stairways and one elevator are installed. Sidewalls are of brick to a height of about 100 ft. Floors are wood and concrete.

Karachi Airship Shed. The airship shed at Karachi, India, completed in 1927, may be taken to represent the latest British practice in the design of airship hangars, as the shed at Cardington, England, is quite similar.

The Karachi shed has a clear length, inside, of 850 ft, a clear width of 200 ft, and a clear height of 170 ft. The trusses are three-hinged arches of 230-ft span and 200-ft rise, with the lower pins at the floor level instead of being supported upon low towers, as are those at Lakehurst and at Scott Field. These arches are spaced 27 ft 5 in. on centers. The overall width is 230 ft.

There is a rolling door at one end only, the other end being closed by a blank wall, and this door differs materially from those at Lakehurst and Scott Field in that the two leaves are supported at the top as well as at the base, the upper support being, however, independent of the building structure. This door has a base 60 ft wide center to center tracks and is counterweighted. The time of opening doors is from 8 to 10 min.

The floor areas is 195,500 sq ft, and the shed is designed to house an airship of 5,000,000 cu ft capacity. It was intended to be used purely as a docking hangar, not for manufacturing purposes.

Scott Field Hangar. The United States Army hangar at Scott Field, near St. Louis, was built in 1922.

This hangar is 810 ft long, 150 ft span, and 150 ft high at center, all clear inside dimensions. It is composed of 28 three-hinged arches and contains 3200 tons of steel.

The covering is asbestos-protected metal for the sides and concrete tiles for the roof. The doors are of the straight type. Each leaf of the doors contains 135 tons of steel and about 500 tons counterweight. About 3 min is required to open the doors, which are operated by four 220-hp, 220-v, d-c motors.

Lakehurst Hangar. The United States Navy hangar at Lakehurst was built in 1920 to house the navy dirigibles. It is 803 ft long, 262 ft wide, and 172 ft high, clear inside dimensions. The end doors are of the counterbalanced sliding type, 350 ft wide and 200 ft high. The frame is of structural steel, and the covering is asbestos sheets for the sides and treated timber for the roof. The framework is composed of three-hinged arches, having a span of 264 ft and rise of 131 ft center to center of the pins. The upper pin is 195 ft above the floor.

The Docking Problem

One of the most serious problems encountered in the development of large rigid airships is that of landing and of handling the ship from the ground.

The hangars at Friedrichshafen are equipped with docking rails, which carry dollies, or "hand-operated trucks, arranged to resist the quite considerable upward and sideward pull on the cables that are attached to the ship's sides and held in quick-release clutches on the dollies.

These docking rails are spaced a distance apart equal to about $1^{1}/_{2}$ times the maximum diameter of the ship, running the entire length of the building, through the doors, and out into the landing field a distance of about twice the ship's length, at both ends of the dock.

As it is very desirable that there be no projections of any kind above the floor of the dock or above the ground level of the landing field, on account of the danger of men tripping, obstruction to airplane maneuvers outside, and interference with manufacturing operations within the building, the accepted form of docking rail has been of the slotted type, the construction being somewhat similar to the center slot of a street tramway. The dollies have wheels both above and below the slot. The objections to this slotted rail are obvious—the difficulty of obtaining a uniform slot, difficulty of maintaining it so, and the accumulation of dirt and ice or snow which must be removed prior to each operation, often with considerable difficulty.

The United States Navy hangar at Lakehurst is equipped with slotted rails of this type. The British airship sheds have no docking rails, dependence being placed upon the use of greater man power for handling the ships.

In the construction of the Akron dock, provision has been made for docking rails of the slotted type, but before the floor was completed, the designers decided to omit the slots for the present, and that part of the floor was finished in such a way that the slots could be put in later, or their place could be taken by standard-gage railroad tracks, which have since been installed.

Mobile stub masts have been built and successfully used at Lakehurst and at Akron, and it seems assured that mechanical methods are destined to supersede man power in handling airships on the ground.

Design of Doors

The most unusual feature of this building is doubtless the spherical doors, with their hinges and supporting trucks, and the operating mechanism for opening and closing them.

If one can visualize a quarter of a half of an orange peel set up on a flat surface, held with a pin at its pointed top and resting on a set of rollers distributed under the bottom edge, and imagine this one-eighth of an orange peel as 202 ft high and 214 ft wide at the bottom, fastened or hinged at the top point with a huge hollow forged pin and resting on 40 wheels at its base, he would have an idea of what one leaf of the two that close one end of the hangar will be like.

Not considering the snow that may accumulate on the doors or the wind pressure against them, the doors alone weigh about 600 tons for each leaf, or 1200 tons for each end of the building.

Obviously the simplest way to mount this heavy leaf so that it can be moved back and forth is on wheels running on a track, similar to railroad equipment. In this case, 40 forged-steel, double-flanged wheels, 27 in. in diameter, running on the two rails, weighing 100 lb per yd each, set like a railroad track and to the standard railroad gage, are used under each leaf of the doors.

The wheels are spaced uniformly in pairs under the long curved structural-steel sill which constitutes the base of the door. Each pair of wheels is set radially so as not to bind against the curved rails which form the track, but each wheel is mounted on a separate short axle, because if the pairs were arranged like car wheels, there would be great loss of force and excessive wear due to the necessity of slipping one wheel continually, as the outer wheel would have to travel a greater distance than the inner wheel to pass around the circular runway.

Because it is not practicable to so build a large structure of this nature that the weight will be equally divided on the 40 wheels, each wheel is separately mounted under bearing boxes which rest against heavy springs. If one wheel, then, receives more weight than its neighbor, its springs will give more until the weight is more evenly distributed.

The radius of the curved standard-gage track on which the doors are carried is 187.69 ft to the center between the rails from a point projected down from the hinge pin above.

To carry this heavy weight on the ground a curved runway built of reenforced concrete, 10 ft wide and deep enough to go below the frost line, is provided, and under this runway is a series of concrete piles driven to solid rock.

The hinge pins to fasten the top points of the doors to the main shell of the building are secured by heavy steel frames to the roof girders, and a separate pin is provided for each leaf of the door, spaced 4 ft apart, side by side.

The pin is required to resist the side pressure against it caused by the door tending to fall inward, but it does not need to carry any vertical weight whatever, because the door is horizontal at the top where it bears against the pin, except when a strong wind blowing through the building (with doors on the other end open) is of sufficient strength to tip it backward, at which time the pin is required to hold the door from being blown out.

It is estimated that the pressure against the pin may reach a maximum of about 550,000 lb inward or 450,000 lb outward, depending on the snow and winds.

The pin cannot be regarded as being always fixed in the same spot, although tons of metal are used to make it fast, because in a building so large as this the sun's heat will cause expansion and contraction that will move the entire roof and wabble the pin around several inches. To provide for this movement of the hinge pins, the horizontal thrust bearing is made a ball-and-socket joint, free to move in any direction within moderate limits. The pin is 17 in. in diameter and about 6 ft long, and the bearing ball is about 30 in. in diameter. The bearing can move up and down on the pin 4 in. each way to provide for the change in height of the door due to expansion and contraction.

It is especially desirable that the floor of the dock and the yard in front of it should be nearly level, as men handle the ships by hand ropes as they are docked or launched. Anything projecting above the yard level would be in the way of the men. This requirement also makes it necessary to keep the circular track that supports the doors flush with the surface.

To still further maintain a level yard, the runways for the doors are buried so that just the tops of the rails are on the yard level, and the bases of the rails and the ties are all concreted in below the floor line.

For these reasons and, further, because of the important fact that these doors must be under control at all times and not subject to starting off by themselves to swing around and cause wreckage in a heavy wind, it was decided to use a rack-drive system for operating them.

These devices consist of a very large gear, called a "bull gear," with heavy, coarse teeth, mounted horizontally on a fixed concrete base just outside of the dock (one at each corner of the building) and set far enough to the side to be in the clear of the open yard in front. This gear is revolved by a train of gears connected to a 125-hp motor through a worm-gear reduction. The worm-gear reduction was selected because of its characteristic of being "self locking," so that as soon as the power of the motor is shut off, the gear stops and cannot be started again in either direction through pressure of the wind.

The large "bull gear" engages a rack built to surround the base of the door at the bottom, just above the wheels near the ground. This rack is rigidly attached to the door in a vertical position. As the motor revolves the "bull gear" slowly, the rack is driven back and forth and pushes the door along with it.

All of the reduction gears, including the worm gear, are of substantial construction and flexibly set up in a cast-steel frame mounted on a reenforced concrete foundation which is built as a part of the circular runway foundations.

The motor is special in that it is capable of being used at two speeds with a constant torque effort. It can be connected up to drive the doors at a maximum speed of travel of 20 ft per min or at 40, as desired. The brake for holding is on the armature shaft of the motor and is a so-called hydroelectric brake, capable of being set with a time limit so that a second or so can be allowed for the motor to finally slow down before the brake begins to stop it too suddenly.

Electric cutout switches are mounted on the runway adjacent to the driving units, so that as projections from the door operate them, the door comes to a slow-down and creeping speed, automatically as the two leaves come together at the center, or as the doors come to the extreme open position. This makes it only necessary for the operator to push a button to start the door, after which it will open and stop, or close and stop, as the case may be, automatically.

It may be noted that the speed of movement of the doors is rather higher than that of the two other similar hangars in this country, which are geared for about 12 to 25 ft per min as against this construction with 20 to 40 ft per min. This device is protected, however, by the automatic-control feature which compels the doors to slow down to a creeping speed as they approach the ends of their travel, and, further, the wind cannot increase the speed materially by its pressure due to the worm gear and the constant-speed motor. They also can be driven at any desirable speed up to 40 ft per min by manual control.

The driving units are set under separate roofs outside the hangar, for the reason that the pressure of the gear against the rack resists the outward pressure against the wheels due to the door weight, and so that there can be no danger of sparks from the control switches in case hydrogen gas is used in the bags of the dirigibles.

Mention of the outward thrust against the track wheels under the door should perhaps be made and also of its tendency to largely increase the effort needed to start the doors in motion. The wheels are made with a contour similar to that of railroad car wheels to counteract this side thrust, and the motor provided with a heavy torque "pull out" capacity for starting. It is estimated that it may require, at times of extreme snow and wind, a pressure of as much as 50 tons to start the doors in motion, but ordinarily much less.

This at once raises the question as to why roller bearings were not used to materially reduce this effort. While roller bearings would without doubt reduce the starting effort to a fraction of the amount required for the plain bearings, they would similarly increase the more serious problem of control in slowing down and stopping. With roller bearings, one would be inclined to figure for a much less travel speed because of the fact that impact varies as the square of the velocity. The friction assists materially to slow down and stop.

For those interested in the details, it might be well to state that the bull wheel is of cast steel with 22 cut teeth, 9-in. face, 9-in.

circular pitch. The driving pinion is shrouded, has 8 teeth, not cut (chipped smooth). The intermediate gear (cast steel) has 60 teeth, cut 60-in., diametral pitch, 9-in. face. The pinion on the worm-gear shaft has 16 teeth. The worm gear has 46 teeth, $2^{1}/_{2}$-in., circular pitch, $5^{1}/_{2}$ in. face; the worm is $6^{1}/_{4}$ in., diametral pitch, $2^{1}/_{2}$-in. face, double thread, and has a 14° 17″ lead angle. The motor is connected by a flexible coupling and is of 125/62 hp, with a synchronous speed of 600/300 and is arranged for a 440-v, three-phase, 60-cycle current with a capacity of 200/100 hp on a 15-min rating. The entire unit is set up on a continuous bedplate.

Adjustment is provided for setting the "bull gear" in the pitch line of the rack by jackscrews and a spring, allowing limited variation for moderate unevenness in construction of the rack.

The rack in which the "bull gear" is engaged is made from a curved (192′ 10″ radii) 14-in. H-beam with 4-in.-diameter pins set on 9-in. pitch. The rack is rigidly attached to the bottom of the doors.

It is estimated that the door can be opened or closed in 5 min.

Expansion and Contraction

One of the features of this design is the entire absence of expansion joints. The three center arches are fixed in position, while all others are carried upon rollers, placed transversely to the axis of the structure, allowing it to expand freely as a whole, from the center to each end. This allows the end arches, supporting the upper door pintles or hinges, to move laterally about 4 in. under the maximum range of temperature, a motion which is taken up partly on the pins themselves and partly transmitted to the doors, and absorbed by the door frames in bending.

It should be borne in mind that the main-arch shoes are horizontal, and subjected to horizontal forces as well as vertical. The horizontal forces are transmitted to the footings through flat plates on the upper and lower shoeplates that engage deep slots in the rollers.

The vertical reaction on each typical arch shoe due to dead load only is 677,000 lb and the horizontal reaction 200,000, a ratio of 1 to 3.38. The horizontal reaction may, under certain conditions of wind load, be reversed and amount to 119,000 lb inward instead of outward.

An interesting detail in connection with the expansion and contraction of the structure is the arrangement of the pins supporting the doors. These pins are 8 in. longer than the bearing of the castings surrounding them, allowing the top of the door to slide up and down on the hinges, in order to take up part of the movement of the pin in this way. Observations made thus far indicate a range of movement of about 2 in.

The computed rise and fall of the upper arch pins under wind may be 1.68 in., while the horizontal movement may be as great as 9.47 in. The corresponding vertical movements of the arch ribs are 5.46 in., and clearances between the main shell of the building and the doors had to be very carefully computed for all conditions of loading in order to make certain that there would be no interference.

Roof Covering

In selecting the external surface for the factory and dock at Akron, the material required was one that would be fire resistant, comparatively light weight, and of such a nature that it would not rupture under the strains caused by the slight motion anticipated in the structure due to high wind velocities. To accomplish this it was decided to use some form of sheet metal attached directly to the steel girts and purlins. The entire external covering was divided into three types, according to location, which for convenience will be called type A, or "exposed surface roofing," type B, or "steep surface roofing," and type C, or "flat surface roofing."

Type A covering was intended for the surface beginning at the grade line and extending up to the top edge of the skylights, on the sides of the structure, and to a line projected therefrom horizontally around the spherical doors at ends of structure. This covering was to consist of metal sheets, pretreated with a protective covering and designed to withstand an ultimate load of 100 lb per sq ft, either from the outside or inside of the structure with limiting deflection of 2 per cent of the span. This area to have no further covering after erecting except painting.

Type B covering was intended for the surface between the line at the top edge of the skylights, as described, and a line located approximately 40 ft from the center line of the structure, on the sides and projected therefrom horizontally around the doors. This covering was to consist of the metal sheets, except that they were to be designed for an ultimate load of 200 lb per sq ft, either from the outside or inside of the structure, with a limiting deflection of 2 per cent of the span. In order to overcome condensation, this type of covering was to be covered with an insulating material 1 in. thick, securely attached to the metal sheets, and then waterproofed with a standard "steep surface" roof covering, guaranteed for 10 years. As built, this section was not insulated.

Type C covering was intended for the surface on the top of the structure, a width of approximately 80 ft. This roof deck and covering, including insulating, is the same as type B except that the waterproofing is standard "flat surface" roof covering, guaranteed for 10 years.

In order to create high visibility of the structure from the air a color scheme was determined upon. The entire area of type C covering is dead black. Type B area is divided into three horizontal strips of equal width: the upper strip to be chrome yellow; the next Goodyear blue, with the words "Goodyear Zeppelin" and the "Wingfoot" trademark painted in chrome yellow with approximately 22-ft-high letters; and the third strip chrome yellow.

A strip of surface bounded by the top and bottom edges of the skylights, a width of approximately 24 ft and extending around the ends of the shell and the spherical doors, was to be dead black. Below the lower edge of the skylights, the surface to be dead black or light gray in color, depending on the kind of type A covering selected. As built, only the sign with its background has been painted.

The entire area was covered with Robertson V-beam roof deck sheets, No. 22 gage core metal for type A surface and No. 20 gage metal for type B and type C surfaces. These sheets are of sheet steel formed into deep angular corrugations with a flat surface where the corrugation comes in contact with structural supporting members (see Fig. 1). This steel core is hermetically enclosed and sealed in three impervious protective coatings—asphalt, asphalt-impregnated asbestos felt, and a heavy waterproofing envelope. The sheets are all fabricated to the size and shape required for the work, before tar protective covering is applied, and delivered at the work ready for erection.

This sheet was developed by the Robertson Company for this work, and due to the V-beam shape has a greater load-carrying capacity and will span wider spacings of purlins than the standard corrugated sheets heretofore used.

The under side of the deck sheets was painted aluminum gray, full finish, at the factory.

Preparation of the Site

The building is located in a level plain between low hills about 4 miles southeast of the business center of Akron. The site is part of the Municipal Airport of the City of Akron, which owns the surrounding property. About 60 acres, on which is located the dock, is the property of the Goodyear Zeppelin Corporation,

but the latter has the right to use the surrounding ground for maneuvering and docking purposes.

The preparation of this site required the removal of about 1,500,000 cu yd of earth from the adjacent hills, which was used to fill in the low parts of the site.

The general level of the ground at the building site was about 1038, referred to sea level. The soil consisted of about 2 ft of muck and 28 feet of sand, gravel, and clay, underlaid by a solid sandstone, presenting a fairly level surface. The water level was about 1036, with little chance for drainage below this level. It was deemed best to remove the 2 ft of muck from the site of the building and fill in with about 6 ft of selected gravel and clay from the adjacent hillside, which was deposited in 9-in. layers and rolled. The finished grade of the dock is Elevation 1044.

It is intended to build a mooring mast later as a part of this development. The City of Akron undertook the general preparation of the site, including grading, relocation of the line of the Baltimore & Ohio Railroad through the site, clearing of all buildings, trees, and other obstructions, relocation of highways, providing water and sewers, and carrying out a general drainage scheme.

Substructure of Airship Factory and Dock

The substructure work consists of concrete footings for the arches, carried on vertical and inclined concrete piles driven to rock, concrete ties across the building laid on the sand and clay after removing the muck and heavily reenforced to take the thrust from the arches, concrete door foundations for supporting the rails carrying the doors, which are also carried on concrete piles, a concrete service tunnel the full length and one-half the width of the building, and two lines of concrete docking rail supports. The piles are of the MacArthur type, carrying maximum loads of 30 tons each.

The typical arch foundations are subjected to dead-load reactions of 340 tons vertical and 100 tons horizontal, while the maximum reactions under the worst possible combinations of dead, snow, and wind loads are 472 tons vertical and 168 tons horizontal.

These reactions are taken by reenforced concrete footings 15 ft square and 5 ft 6 in. deep, each of which is carried by 25 piles, of which 10 are battered, the battered piles being the inside and outside lines. The battered piles are inclined about 4 in. to the foot. The footings are tied together by reenforced concrete ties carried entirely across the building, underneath the floor. These ties are 2 ft 3 in. deep by 4 ft wide, and are reenforced with 12 bars $1^1/_4$ in. square.

The tracks for supporting the spherical doors are 10 ft wide by 5 ft 6 in. deep, reenforced with 22 bars $1^1/_4$ in. square and supported on two rows of concrete piles 7 ft apart and 9 ft center to center of piles. The segmental door foundations are tied into the center tunnel and into the docking rail supports at all intersections.

The field control method of proportioning the concrete was used, the contract being based on using six sacks of cement per yard, with provision for adjustment of cost, plus or minus, as the case might be, for more or less cement per yard.

The contractor was instructed to produce a concrete developing a crushing strength of not less than 3000 lb per sq in. in 28 days, using 6 gal of water to the sack of cement. On this basis, a theoretical mix of 1 part cement to 2.96 parts fine aggregate to 3.37 parts of coarse aggregate was established, maintaining these basic proportions of fine and coarse aggregates. Cement content was varied to suit the particular requirements of the different parts of the work. In massive members, slumps as low as 2 in. were used, while in thin members, calling for a very plastic material to properly flow around reenforcement and into forms, slumps as high as 7 in. were used, water control being rigidly maintained in all cases.

Structural-Steel Fabrication

Shopwork on this structure was begun about January 1, 1929, at the Ambridge Plant drawing room of the American Bridge Company, where layouts were prepared and material lists were made. Practically all material was ordered from the mill cut to length. Special care had to be taken in regard to ordering the material for the chord members of the arches, as these were silicon steel, making rectification of mistakes difficult and costly, as silicon steel shapes are rolled only on special orders. After the material was ordered, details were prepared and sent to the shop for fabrication.

In fabricating the arches, these were split up in sections that

were as large as shipping restrictions would permit. All necessary milling, punching, cutting, reaming, assembling, and riveting of these sections was done in the shop and then they were hauled out to the assembly yard. Particular care had to be taken in the matter of the milling of joints in the chord members. To prevent any error the various set-ups were checked several times before milling operation was begun, as any error in the set-up of the milling machine would have affected all arches. No difficulty was experienced with the work on the silicon steel, which is harder than carbon steel. The milling of the silicon-steel members required more time than for carbon steel. The punching, while not requiring more time, is limited to less thickness of material than in carbon steel, the limit of thickness being about $^1/_4$ in. less than the diameter of the punch. Silicon steel, due to its hardness, wears out punches and dies quicker than carbon steel. Reaming requires slightly more time and is also harder on the tools. The shop cost of fabricating silicon steel is estimated to be about $2.50 to $3 per ton higher than for carbon steel. The fabrication of the vertical and horizontal purlins, rafters, etc. was usual shop practice. These parts were assembled and riveted at the shop in as large sections as possible to avoid unnecessary field assembly and riveting.

As the sections composing the arches were received in the yard, they were assembled into half-arches in a horizontal position, about 3 ft above the ground and supported on timber blocking. After the assembly of the half-arches in each case, a wire was stretched from the center of the bottom pinhole to the center of the top pinhole and the distance was measured, which in all cases except one checked within $^1/_2$ in. of the computed distance, which was a little over 255 ft. In the exceptional case, the distance varied $^3/_4$ in. from the computation. Offsets or ordinates from certain panel points on the chords to the wire were measured, and these varied not more than $^5/_{16}$ in. from the computed measurements. The small variations between measured and computed distances was an excellent check and proof of the accuracy of the shopwork. After measurements were taken, the field holes in the connections of the sections, which had been sub-punched in the shop, were reamed to size while in the assembled position, assuring good fit-up in the field. The ease with which the material went together in erection and the extremely small number of holes requiring reaming in the field was splendid proof of the soundness of the shop methods used in the fabrication of this work. After reaming of holes in the connections was completed, the arch ribs were taken apart, painted, and loaded on cars for shipment. The same procedure was followed in the fabrication of the door rib arches.

Shop Paint. "Metalastic," manufactured by the Sherwin-Williams Company, was used for all painting.

All shopwork was fabricated in accordance with the standard specifications of the American Institute of Steel Construction for structural steel for buildings.

Sub-punching and reaming was required for the arch ribs only.

Erection Methods Employed

The designers of this structure had contemplated erecting the steel frame by the use of a traveler which would be supported upon three standard-gage railroad tracks, one on the center line of the building, and one on each side, spaced 100 ft therefrom, on the center line of the proposed docking rails. This traveler would be designed to pass under the trusses with its derricks removed.

The engineers of the erection department of the American Bridge Company deemed this method of erection to be too slow, and developed an alternate plan which was submitted to the designers and approved by them.

This method consisted in erecting the lower sections of a pair of arches about 100 ft in height and 80 ft apart, upon temporary bents, placing all bracing between the arch ribs to this height; then assembling the center portion of the arches on the ground, upon a cradle, and lifting them into position by means of counterweights carried upon the side sections already erected and the drums of the locomotive cranes.

Erection started with the southerly two arches of the three fixed center arches, and proceeded southward to the south doors, which were erected in open position, supported upon the exterior of the main structure, and assembled by using locomotive cranes as high as these could reach and then utilizing a derrick traveler located on top of the arches.

The erection plan involved the use of eight lines of railroad tracks, two outside the building and six inside. Altogether about $1^1/_2$ miles of standard-gage railroad tracks was used at one time, over which were operated seven locomotive cranes, five with 50-ft booms and two with 105-ft booms and goose-necks which gave them a total reach of about 125 ft.

The erection bents for supporting the side sections of the arches consisted of two steel columns, each supported upon a 300-ton jack at its base, the function of the jack being to spread the tops of the lower sections enough to allow the center section to pass by and then to bring them together again in order to effect the closure between the two sections.

At the top of these columns were placed the sheaves for carrying the counterweight boxes, weighing about 72 tons each pair loaded

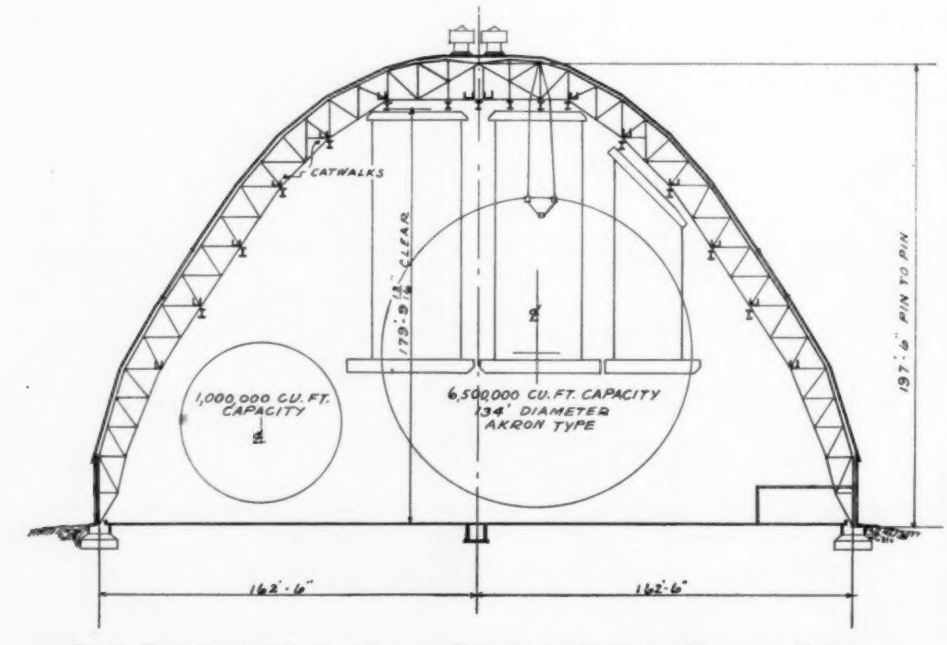

Fig. 3 Typical Cross-Section Showing Position of Airships of Different Capacities

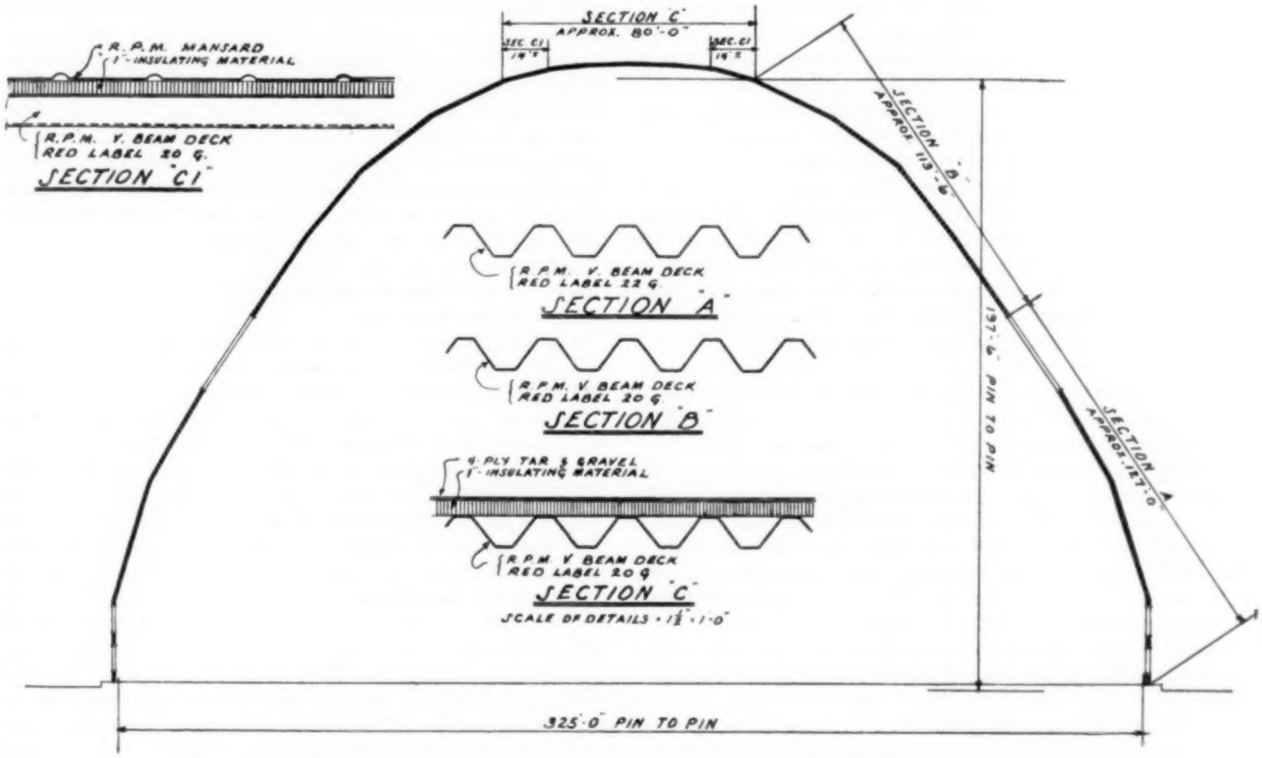

Fig. 4 Sections of Hangar Roof, With Roofing Materials

and equivalent to about 80 per cent of the weight of the center portion of the span, leaving about 20 per cent to be lifted by the cranes. Each center section erected weighed about 360 tons.

The center sections were assembled by the cranes upon cradles which comprised longitudinal girders carrying the ends of the arches and transverse ties to take up the thrust.

During the lifting of the center section of the arch truss, the four corners were kept level by means of weighted piano wires and graduated boards, which served very well as height gages, or telltales.

The traveler used on top of the arches for erecting bracing and the end arches was of the usual type of horizontal frame about 80 ft wide and 80 ft long, carrying two stiff-leg derricks with 90-ft booms. The travelers were mounted on temporary I-beams and moved by hand winches. The derricks were operated from the ground.

For erecting the end diagonal arches and the upper parts of the doors and the cantilever trusses, two additional stiff-leg derricks with 90-ft booms were used, mounted on top of the end arches near the center.

Speed of Erection. Erection of steel was started on April 29, 1929, the entire operation consisting of assembling the arch sections in a horizontal position, ready for hoisting into position by the locomotive cranes. This method was followed for all the arch erection. The first set of arches was raised into position on May 22, 1929, the operation of hoisting and connecting up taking about 6 hours. The second set of arches was raised June 12; the third, July 6; the fourth, August 27; and the fifth, set September 19. The hoisting of the last set was accomplished in 4 hours.

The south-end diagonals were completed July 20, and the erection of the south door was started August 3 and completed September 1. This was moved into closed position on September 16 after being completely riveted up.

The north diagonals were completed October 18, and the north doors were closed November 25.

Mechanical Equipment

Mechanical Equipment of Buildings. As this building is primarily a factory for the construction of airships, it is equipped with a considerable amount of mechanical handling devices. At the center of the building, overhead, there are two crane runways consisting of 12-in. I-beams supported on the trusses. These runways will carry 6-ton electric hoists for handling material.

At each side of the crane tracks are two 12-in. I-beams designed to carry working platforms which can be lowered and raised to any desired height, and on which the workmen engaged in assembling the ship's structure are employed.

Farther down the curved sides of the structure are more I-beams for carrying additional working platforms.

At the center of the structure there are provided fixed working platforms the full length of the building overhead, and at various levels, six on each side, are catwalks 2 ft wide, also running the full length of the structure and located between the chords of the arches. Access to the upper platform is provided by two stairways, one on each side of the building near the center, and by a specially designed inclined railway, intended to transport men and materials to the upper levels.

This inclined railway consists of two counterbalanced cars running on a curved track, but so built that the car itself remains horizontal at all times. The motors and drums for operating this elevator are located on the upper platform, and the car can be operated by a man at the top or from either car, as desired.

At the center of the building, just under the floor, there is a service tunnel, extending the full length of the building and containing electric outlets for both lights and power, water lines, compressed air lines, and the gas lines for inflating the gas cells.

Shops and Offices. The building is 325 ft wide between arch pins, but the necessary width for assembly of the ships is only 240 ft. This leaves a space for shops and offices on each side of the building about 42 ft wide by 640 ft long. Eventually it is expected that shops and offices will occupy all of this space, but at present they are confined to the east side of the building.

On account of the expansion and contraction of the main building frame, it was necessary to build these offices and shops entirely independent of the main building, and it also was necessary to use fireproof construction for them to meet insurance requirements.

Heat. The engineers consider it useless to attempt to heat this structure. The offices and shops are heated by independent gas-steam radiator units, and electric heaters are used on the floor and on the working platforms in cold weather.

Light and Power. Only a small amount of natural light is provided, the designers intending that most operations should require artificial light. There were three reasons for doing this: First, the fact that assembly would probably require continuous work, day and night; second, the difficulty of making skylights watertight and the cost of good skylights; third, the fact that even with ample windows, much of the work would need to be done by artificial light owing to the interference of the assembled ship with the light from the outside.

The interior lighting has proved to be quite satisfactory, due largely to painting the under side of the covering with aluminum paint and the use of a light gray paint for the structural steel, and a large part of the work is actually carried out with only natural lighting.

Electrical Equipment

Electric current is brought to the site at 22,000 volts to a transformer building located adjacent to the main building at about the center, at the east side. This current, as well as all other utilities, is brought to the building underground, as no wires can be tolerated above the ground surface. At the transformers, the current is converted into 460-volt, 60-cycle, three-phase for power, which is delivered to the main switchboard housed in the same building with the transformers. Six secondary transformers are located at convenient distributing points just outside the building walls, designed to receive primary current at 460 volts and distribute at 115 to 230 volts for lighting purposes. Distribution is accomplished through six weathertight main distributing panels located outside of the building, so that switching, with any accompanying arcs, can at no time be the cause of a gas explosion.

The general lighting consists of adjustable projectors of 1000 watt capacity each, located along the catwalks, from 65 to 150 ft above the floor, and seven lines of outlets along the catwalks and upper platform. Additional lighting is also provided at all stair and hoist landings.

Outlets for extension cables are provided at all trusses, 80-ft centers, at both sides of the building and in the tunnel at the center. Most of the manufacturing operations are carried on by lights taken from these outlets. Each of these outlets at trusses consists of a gang of six heavy-duty receptacles, each capable of handling 10 to 12 kw. Those in the tunnel are of approximately 20 kw capacity each. All of these heavy-duty receptacles are housed in gasketed cast-iron boxes so as to be absolutely gas-tight.

Power at 460 volts is carried to a point near the center of the building on the top platform, from where it is distributed to the crane and hoist motors. Separate power feeders are carried to each of the door motors direct from the main switchboard. Each main feeder is protected by an automatic circuit breaker, no fuses of any description being used on the main switchboard. This is a precaution adopted to prevent any extended shutdown due to unreliability of fuses. All main feeders from the switchboard are run underground, using lead-covered cables in fiber ducts laid in concrete, preventing any damage to insulation from water. All other wiring is run in rigid galvanized conduits secured to the building structure.

The usual shop lighting is installed throughout the shop portion of the building, and provisions have been made for ample power supply in the shops.

The door operation is as follows: Pressing the "open" or "close" button will start the equipment on the high-speed motor winding and accelerate the same to full speed. Travel will continue at full speed until the first slow-down limit switch is encountered in that direction. This will insert secondary resistance in the high-speed winding, causing the motor to slow down. When the second slow-down switch is encountered, the motor will become disconnected from the high-speed winding and thrown into slow-speed connections with secondary resistance. This will cause the motor to decelerate to half-speed and below, depending upon the amount of secondary resistance left in the circuit on the low-speed winding. It is expected that, with 80 to 100 per cent normal torque on motor, the final slow speed will be approximately one-third of the top speed. The door will then continue at such slow speed until the final stop, at which time power will be entirely disconnected from the equipment, including the hydraulic-operated brake. It is intended to so arrange the hydraulic-operated brake that, after cutting off power, there will be an inherent time lag of $1^1/_2$ to $2^1/_2$ sec before the brake is finally set. It should be noticed that the setting of the brake is a gradual application. The operation in the reverse direction is the same.

The motors are four type MT-566-Y-BL 200-100-hp General Electric motors, 15-min rating, 600-300-rpm, 440-v, three-phase, 60-cycle, having special long shaft and third outboard bearing and with shaft extension and brake pads at the opposite end for the motor-mounted brake.

The motor-mounted brakes are General Electric type CR-9516-466 hydraulic-operated. These brakes are provided with operators of such capacity that they will provide a retarding torque of approximately 1200 lb-ft, and at the same time will have an inherent time delay of from $1^1/_2$ to $2^1/_2$ sec.

The electrical equipment also includes the necessary panels, switches, contactors, accelerating relays, terminals, interlocks, starting-duty resistors, operating pushbuttons and 24 double-circuit limit switches with spring return and roller lever; 16 of these switches are for slowdown and 8 for opening both sides of line on final stop.

Floors

As the floor of this dock is used as a working platform for laying out delicate work, it was essential that there should be no obstructions, that facilities should be provided for fastening-down jigs, and that as level a surface as practicable should be provided.

It seemed to the designers that a heavy tongue-groove or splined wood floor met these conditions best, and designs were made and bids were received on a floor consisting of 4-in. by 4-in. yellow pine, toe-nailed to 6-in. by 6-in. sleepers laid to 3-ft centers. All flooring was to be No. 1 common dense grade, long-leaf yellow pine, quartered from 8-in. by 8-in. timbers, in order to obtain a near edge-grain face. Sleepers were to be creosoted. All finished floor was to have two heavy coats of linseed oil. The base for this floor was to consist of 6 in. of rolled slag, on which the 6-in. by 6-in. sleepers were to be laid and granulated slag used to fill between them.

There were two serious objections to this timber floor: First, whether such a floor would hold its shape under the severe weather conditions to which it would be subjected, it being impracticable to avoid alternate wetting and drying under the doors when open to admit or to let out ships, and the probability of water dropping from condensation on the steel structure, and second, the much greater cost of such a floor as compared to a concrete floor.

The concrete floor as actually constructed consists of 6 in. of rolled slag, 5 in. of concrete, and 1 in. of finish, placed integral with the 5-in. base. All finish is rough troweled and hardened with Master Builders hardener, 40 lb per 100 sq ft. A wire-mesh reenforcing consisting of No. 6 wires, spaced 6 in. both ways, is used for all concrete floor.

Special floor inserts, designed and made by Donley Bros. Co. of Cleveland, were used throughout the building. These inserts are spaced on 10-ft centers each way. Special holding-down bolts, designed to resist an upward or sideways pull of 5 tons each, were installed in the floor along the center and 50 ft each side of the center, one to each 80-ft panel. These are set in blocks of concrete and are for use in holding down the ship and as anchors for hoisting ropes.

Fire Protection

As no precedent had been presented to the fire underwriters, new rulings were required for this building. The underwriters requested that only incombustible materials be used in the construction of the building, which eliminated wood roofing.

It also was requested that a system of outside and inside fire hydrants be installed and connected to an automatic fire pump located outside the building and capable of boosting the normal pressure of 50 to 60 lb per sq in. to 125 lb per sq in.

Water is brought to the pump house just east of the building by a 12-in. main, and from that point a 10-in. loop is carried entirely around the building. This 10-in. loop supplies 12 outside fire hydrants and 24 inside hydrants.

In addition to these water lines, chemical fire extinguishers are distributed liberally throughout the building, on the main floor, on catwalks, and on the upper platform.

Helium Storage

Gas-Handling and Storage Facilities. As the airships now being built at this plant will use only helium gas, provision for this gas only is being made. Helium gas is found in certain natural-gas fields the gas of which contains 2 to 4 per cent of helium, the remainder of the gas in most cases being nitrogen.

The gas is shipped from the field in small steel containers, called bottles, about 4 ft long and 9 in. in diameter, each bottle containing about 170 cu ft of free gas, under a pressure of about 2000 lb. As helium gas follows rather closely Boyle's law of gases, which states the volume is inversely proportional to the pressure, each cubic foot of gas under 2000 lb pressure is equivalent to approximately 133 cu ft of free gas at atmospheric pressure.

As the ships now being built will require about 6,500,000 cu ft of gas each, it will be seen that 38,000 bottles would be required. The Navy has built special tank cars for transporting helium, each car to carry about 600,000 ft of gas.

To receive this gas, there is installed a permanent railroad track parallel to the building and about 100 ft therefrom. Alongside this track, at about the center of the building, is the pump house, containing a compressor and a purification plant, and adjacent to this are provided underground storage cylinders having a storage capacity of over 1,000,000 cu ft of gas at 750 lb pressure.

Gas is taken directly from the tank cars or bottles into the gas cells of the ship or into the storage cylinders, as desired. The gas is drawn out of the gas cells by the suction pump, which is able to deflate 1,000,000 cu ft of gas in 24 hours and place it into storage at 750 lb pressure, or which may, at a lower rate, compress gas back into the cylinders or tank cars at 2000 lb pressure for reshipment.

The purifying plant is necessary in order to remove air and other impurities which mix with the helium and decrease its lifting power, requiring removal at intervals.

These tanks, 96 in number, are built for a working pressure of 750 lb per sq in. and were tested with a pressure of 1250 lb per sq in. at the shop, corresponding to a unit stress of 28,000 lb per sq in.

The tanks are 24 in. outside diameter, 80 ft $2^1/_4$ in. long over all, with a wall thickness of shell of $^1/_2$ in. and flat heads $2^1/_4$ in. thick, joined to the shell with one girth seam each. The material is open-hearth steel, with a minimum ultimate strength of 60,000 lb and yield point of 38,000 lb.

The high-pressure test is intended to be sufficient to produce a stress equal to 75 per cent of the yield point of the material, in addition to which the vessels are subjected to a hammer test developing a stress of 60 per cent of the yield point. The high-pressure test is equal to $P = 2ts/D$, or $(2 \times {}^1/_2 \times 28{,}000)/23$, which equals 1220 lb per sq in., or 1.62 times the working pressure. The pipes are pickled and one coat of coal-tar primer is applied at the shop and two coats in the field.

These tanks are placed underground, in two layers, supported on three lines of concrete footings, and are covered with 12 in. of gravel. They are in two groups, with a concrete valve pit between. The tanks are valved in groups of five and are connected with 4-in. pipes. The main pipes to the compressor are 6 in. in diameter, as are also the deflation pipes inside the building. The inflation outlets are located in the center tunnel and are 4 in. in diameter.

The compressor is a three-stage Ingersoll-Rand machine especially designed for helium compression and will deliver 882 cu ft per min of 96 per cent pure helium gas at 750 lb per sq in. pressure. A "booster" can be added later which will deliver 441 cu ft per min at 2000 lb pressure, and this will be done when a permanent fixed purification plant is added. The compressor has a direct-connected 300-hp. 257-rpm motor.

Before adopting this method of storing helium gas, careful estimates of cost were made comparing this method with storing in a gas holder at atmospheric pressure and storing at high pressures in large forged cylinders.

The method of storing at an intermediate pressure was found to be the most economical.

AER-54-23

Racing Propellers for Light Airplanes

By FRED E. WEICK,[1] LANGLEY FIELD, VA.

To clear up the apparently puzzling situation in regard to propellers for light airplanes with high-speed engines the author has suggested a design for a racing propeller and then attempted to change its shape systematically in every possible way, noting the effect on the efficiency and the maximum speed. The effect of having the engine deliver its rated power at various revolution speeds is also investigated, as well as running a particular engine at revolution speeds above the rated.

This paper has been prepared for the purpose of clearing up an apparently puzzling situation in regard to propellers for light airplanes with high-speed engines, particularly when the highest possible air speed is sought for racing purposes. It seems that many of the fastest light airplanes have been equipped with propellers which differ considerably in form from the more or less standard propellers of the Army and Navy, which should represent the highest standard of efficiency obtainable. This has naturally led to some question as to what actually is the best form to use. Another point which has been questioned by some is the advisability of making use of such fast-turning engines as seem to be the trend of the times for light airplanes.

The best manner of throwing light on this subject, it seems, will be to design a racing propeller of conventional form for a typical light airplane, and then to change its shape systematically in every possible way and note the effect on the efficiency and on the maximum speed. The effect of having the engine deliver its rated power at various revolution speeds will also be investigated, as well as running a particular engine at revolution speeds above the rated.

It will be assumed that this light airplane has a nicely cowled four-cylinder in-line tractor engine in the nose of the fuselage, and that this engine develops 90 hp. at its rated speed of 2000 r.p.m. (These values represent the average of the most popular engines for light airplanes.) The maximum speed of this light plane fitted with the best high-speed conventional metal propeller is, say, 110 m.p.h.

The standard propeller, which is of the conventional detachable blade, adjustable-pitch, aluminum-alloy type, is defined by the form curves in Fig. 1. This particular propeller has been selected because it has been the subject of a large number of full-scale tests on various fuselages in the N.A.C.A. 20-ft. Propeller Research Tunnel, and the results have been given in convenient form for the selection of the best pitch and diameter for any given purpose. (These results, incidentally, can be found in either of the first two references at the end of the paper.) The appearance of this propeller is shown in Fig. 2, along with the fuselage on which it was tested that most nearly represents a well-cowled, in-line, air-cooled installation.

With the aid of the foregoing data a series of propellers of different pitches have been selected for the conditions of 90 hp., 2000 r.p.m., and 110 m.p.h. The propulsive efficiencies obtained with the various pitches are plotted as a curve in Fig. 3, the various pitches being represented by the blade angles at three-fourths of the tip radius. The propulsive efficiency includes the effect of the body on the propeller and the increase in body drag due to the propeller slipstream; and in obtaining the values given in Fig. 3, as well as all of those used in this paper, due consideration has been given to the effect of relative body size and propeller diameter on the propulsive efficiency. From Fig. 3 it will be noted that the propeller giving the highest propulsive efficiency and consequently the greatest maximum speed has a blade angle at three-fourths of the radius of 20 deg. and a propulsive efficiency of 78.8 per cent. This propeller has a diameter of 6.78 ft. It is also interesting to note that the pitch is not a particularly critical factor, for any propeller of this form between that having a blade angle of 17 deg. and a diameter of 7.23 ft. and that having a blade angle of 25 deg. and a diameter of 6.15 ft. will give a propulsive efficiency within 1.5 per cent and a maximum speed within about 0.7 m.p.h. of the best. Furthermore, a maximum speed within 0.1 m.p.h. of the best can be obtained with any pitch angle within a range of about 3 deg. This is partly due to the body interference for, as the pitch is reduced, the diameter becomes greater and the body interference loss becomes less, compensating to some degree for the lower propeller efficiency accompanying the lower pitches.

High revolution speeds are often associated with high tip speeds and their accompanying efficiency loss, which can be very great if the tip speeds are above the velocity of sound in air. Recent tests in the 20-ft. Propeller Research Tunnel (reference 3) show that for propellers of the standard form the efficiency is unaffected by tip speed up to a critical value of approximately 1000 ft. per sec., but beyond this value it falls off very rapidly. Since the tip speed of the 6.78-ft. propeller turning 2000 r.p.m. at 110 m.p.h. is only 730 ft. per sec., it is well below the critical value and it will have no efficiency loss from this cause. In fact, as long as light planes have engines of about 100 hp. or less there need practically never be any fear of loss of efficiency due to too high a tip speed, for regardless of the revolutions the diameters will be sufficiently small to keep the tip speed under the critical value.

It has been found that the conventional metal propeller having the best pitch and diameter for high speed on this assumed light plane with an engine delivering 90 hp. at 2000 r.p.m. and a maximum speed of 110 m.p.h. has a propulsive efficiency of 78.8 per cent. This means that 21.2 per cent of the brake horsepower being delivered to the propeller is lost, and it will be of interest to examine this in detail to see if there is a reasonable

---

[1] Aeronautical Engineer, National Advisory Committee for Aeronautics. The author has spent several years in experimenting with and designing aircraft propellers and in performing aeronautical research work. His first work of this nature was with the Bureau of Aeronautics, Navy Department, where he was propeller designer. He was then transferred to the staff of the National Advisory Committee for Aeronautics, in charge of propeller research in the 20-ft. Propeller Research Tunnel. Following this, Mr. Weick was chief engineer of the Hamilton Aero Mfg. Co., propeller manufacturers, until their consolidation with the Standard Steel Propeller Company, when he returned to do research work with the N.A.C.A. at Langley Field. Author of "Aircraft Propeller Design," McGraw-Hill Book Company, 1930.

Presented at the Fifth National Meeting of the A.S.M.E. Aeronautic Division, Baltimore, Md., May 12 to 14, 1931.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

possibility of reducing the loss. It is fundamental that with any form of fluid propulsion a mass of the fluid must be set in motion in a direction opposite to the craft propelled in order to provide a thrust or propelling force, and this rearward moving air represents energy which is lost. The proportion of lost energy depends on the mass of air handled and the velocity imparted to it, which in turn depend primarily on the propeller diameter, the speed of advance, and the thrust. For a given diameter, speed, and thrust, the foregoing loss, which may be termed an induced loss, is a minimum if the thrust is uniform and constant with time over the entire propeller disk. This minimum loss, which represents an ideal condition beyond which it is not possible to go, can be found very easily by means of the simple Froude momentum theory. For the case of the 6.78-ft. propeller absorbing 90 hp. at 110 m.p.h., the ideal efficiency is calculated as 94.2 per cent, giving an unavoidable loss of 5.8 per cent of the engine power with this diameter. Thus the power loss, which there may be some possibility of reducing to give improved performance, is only 21.2 — 5.8 = 15.4 per cent.

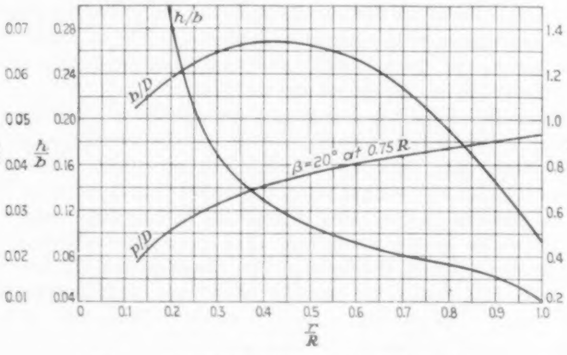

FIG. 1 PROPELLER BLADE FORM CURVES

(D = diameter; b = blade width; k = blade thickness, p = pitch; R = tip radius, $D/2$; r = radius; airfoil sections, R.A.F.-6 type.)

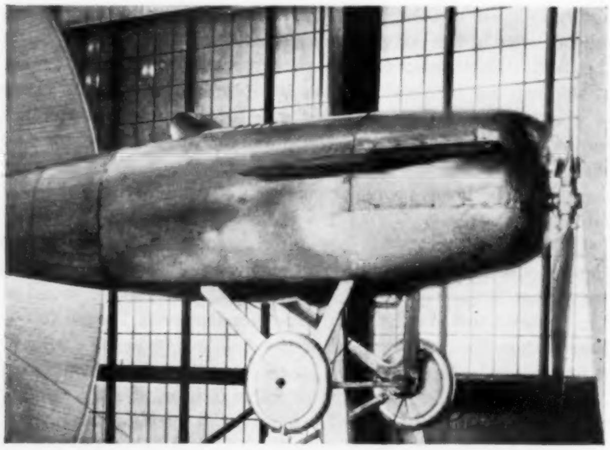

FIG. 2 PROPELLER NO. 4412 ON FUSELAGE NO. 1 IN THE N.A.C.A. PROPELLER RESEARCH TUNNEL

Due to the fact that screw propulsion in accompanied by a torque as well as a thrust, the slipstream is given a certain rotation which also represents a loss. This is usually small, however, and in this case is approximately 0.6 per cent. The rotational energy could be regained by means of guide vanes called a counter propeller, but the drag of the vanes would more than offset the gain obtained. The total loss, which may possibly be reduced somewhat, is therefore cut down to 15.4 — 0.6 = 14.8 per cent. This remaining portion is due to skin friction, turbulence, and body interference.

It is now interesting to investigate every possible variation or change in the form of the propeller which might possibly reduce these losses due to friction, turbulence, and body interference, and allow a closer approach to the ideal efficiency.

From the best experimental data available it seems that the loss due to body interference, i.e., the difference between the efficiency of the propeller alone without a body and the propulsive efficiency with the body present, is in this case approximately 4 per cent. The important items which can influence this body interference loss are the diameter of the propeller, the shape of the body, the fore-and-aft distance between the propeller and the body, and the distribution of the thrust along the propeller blade radially. The last of these, the radial-thrust distribution, is rather important, for the loss can be materially reduced by reducing the thrust near the center of the propeller where the slipstream is thrown against the body. The thrust can be reduced somewhat near the hub by making the blade there as narrow as strength and a low drag section permit, but a much greater effect is obtained by varying the pitch distribution along the radius. A propeller with its pitch reduced in toward the hub in the best possible manner will, with an ordinary body, have a propulsive efficiency about 3 per cent higher than an otherwise similar propeller with uniform pitch. According to the best experimental data available the standard propeller already has approximately the best possible pitch distribution, which eliminates the possibility of an appreciable gain in this direction. The shape of the body and the forward position of the propeller, while of appreciable importance, are out of the control of the propeller designer and so will not be taken up here.

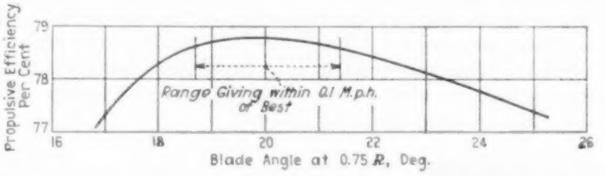

FIG. 3 PROPULSIVE EFFICIENCIES OBTAINED WITH VARIOUS PITCH SETTINGS

The effect on the propulsive efficiency of increasing the propeller diameter, within the limits possible while keeping the same power, revolutions, and air speed, is very small. Since there already has been obtained the best pitch, considering both body interference and propeller efficiency, the only way left which will permit of increasing the diameter appreciably without decreasing the propeller efficiency is to decrease the blade width or change the airfoil section. Changing the airfoil section, in so far as the effect on the diameter is concerned, is about the same as changing the pitch, and since the pitch is already the best pitch, there can be expected no appreciable body interference gain in this direction. This leaves only the possibility of narrowing the blades, and this will also give a slight increase in the efficiency of the propeller itself, not considering the body interference.

Suppose for a moment that it would be possible, considering strength, to cut the blade width in half. (The airfoil sections would not be changed, and consequently the thickness would also be cut to half of its former value, and the cross-sectional area to one-fourth.) The best propeller with these narrow blades will have a diameter of about 8.2 ft. This propeller alone, not considering the body interference, would, as determined by the vortex blade element theory and checked by experimental data, have an efficiency about 1 per cent higher than that of the standard propeller. It is interesting to note here that the ideal efficiency with the 8.2 ft. diameter is 1.7 per cent greater than that with the standard propeller. This accounts for more than the entire actual gain, indicating that the friction and the turbulence losses are slightly greater with the narrower and longer blades. The increased diameter would account for an additional increase of 1.5 per cent due to the effect on the body interference, making the total gain in efficiency 2.5 per cent with the narrow blades and 8.2 ft. diameter.

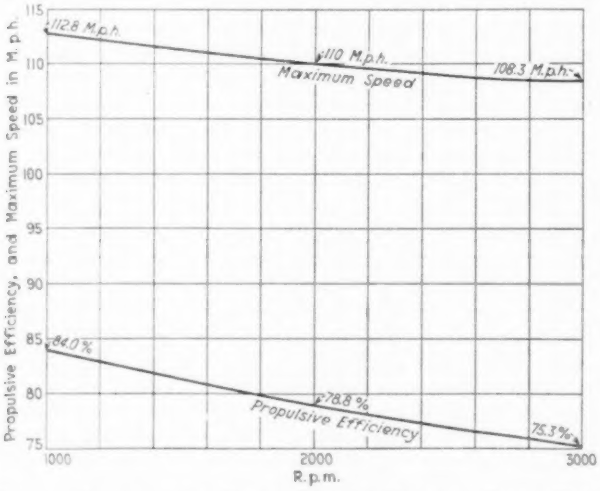

FIG. 4 VARIATION OF EFFICIENCY AND MAXIMUM SPEED WITH PROPELLER REVOLUTIONS

(The horsepower remaining constant with a value of 90.)

The radically narrow and thin propeller assumed as an extreme example is of course out of the question for actual use with present materials and forms of construction. It does not seem likely that it would ever be possible to obtain satisfactory safety, reliability, and smooth operation with an aluminum-alloy propeller having blades less than about three-fourths the width and thickness of those of the standard propeller, especially considering that the diameter with the narrower blades is greater. In this case the total efficiency gain would be just 1 per cent, and the maximum speed of the airplane would be increased by one-half mile per hour.

It has been commented upon that some rather fast light airplanes, particularly British ones, are equipped with propellers having rather wide blades. According to both theory and experiment, this gives them a loss in efficiency as compared with our narrower metal blades, but a very slight one.

The thickness of the blades, or rather the ratio of thickness to width, is directly connected with the shape of the airfoil sections, and these two should be considered together when considering the effect of thickness ratio on the efficiency. Our standard propeller has airfoil sections based on the R.A.F. 6, which have been used in propellers for years and are very good in thin sections for some performance conditions. These sections are very poor, however, in the greater thickness ratios, and their effectiveness increases as the thickness ratio decreases down to at least about 0.04, which is well below the thickness of the sections of this standard propeller. According to full-scale tests on propellers of various thicknesses having these same sections (reference 4), it would be possible for us to get an increase in efficiency of about 0.5 per cent by reducing the blade thickness to about 0.06, a reasonable value which, with the proper design, could be used with safety.

Another form of airfoil section has come into rather wide use in propellers in this country in recent years, this form being based on the Clark Y, and probably about as efficient for high-speed conditions as any likely to be developed in the future. The efficiency of these sections does not vary greatly with thickness ratio up to 0.10, all of the thicknesses giving about the same propeller efficiency as the thinnest R.A.F. 6 type. Thus, if this standard propeller was provided with Clark Y-type sections, one could expect an increase in efficiency of about 0.5 per cent, regardless of the blade thickness, within reasonable limits. It is not likely that this can be appreciably improved upon by changing the airfoil sections.

Another possible variable is the plan form of the blades. In this matter it is advantageous to have a certain amount of taper and rounded tips. The effect is not great, however, for the increase in efficiency by changing from a straight blade with a square tip to a tapered and rounded one such as that of the standard propeller is less than 2 per cent, and there is no probability of an appreciable further increase.

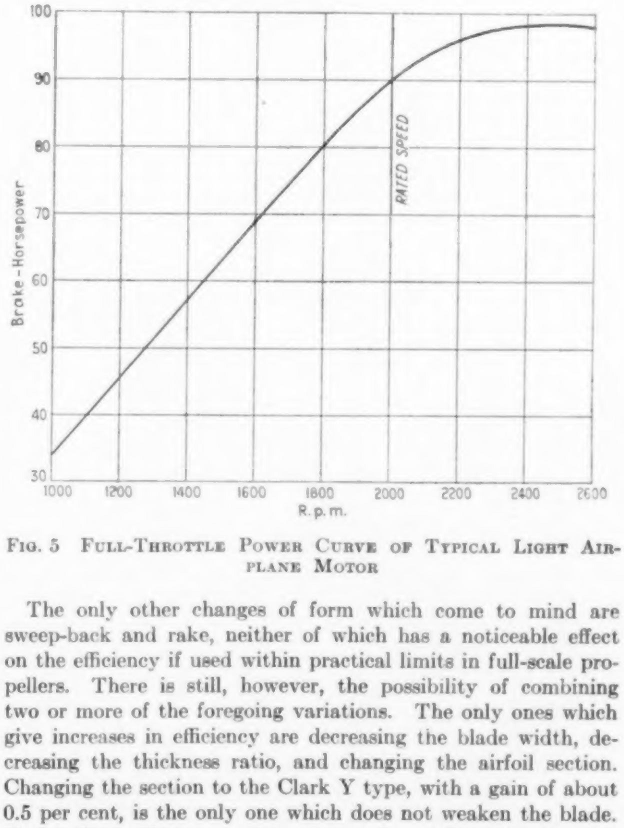

FIG. 5 FULL-THROTTLE POWER CURVE OF TYPICAL LIGHT AIRPLANE MOTOR

The only other changes of form which come to mind are sweep-back and rake, neither of which has a noticeable effect on the efficiency if used within practical limits in full-scale propellers. There is still, however, the possibility of combining two or more of the foregoing variations. The only ones which give increases in efficiency are decreasing the blade width, decreasing the thickness ratio, and changing the airfoil section. Changing the section to the Clark Y type, with a gain of about 0.5 per cent, is the only one which does not weaken the blade. If the Clark Y-type sections are used, another advantage is gained, for then there can be used thickness ratios up to 0.1 or possibly 0.12 without loss of efficiency. The blade width can therefore be decreased, which gives the greatest gain in efficiency, without decreasing the actual thickness, and this will allow a greater reduction in width for the same strength. The width-to-diameter ratio could be reduced in this manner to about two-thirds of the present value before the section thickness ratio would become great enough to produce an appreciable efficiency loss. Any changes in this direction would of course require careful regard to the strength and smooth-running qualities, with suitable overload whirling tests if possible. Assuming, as is quite likely true, that a satisfactory propeller could be developed with two-thirds of the standard blade width ratio and

Clark Y-type sections having the same actual thickness as the present blades, a propulsive efficiency of 80.5 per cent could be expected, as compared with 78.8 per cent with the standard propeller. Thus the most that one can expect to obtain by changing the shape from the standard blade in this case is an increase in efficiency of something under 2 per cent, which means an increase of maximum speed of something under 1 mile per hour.

In getting this slight increase in efficiency there were used a narrower blade and a larger diameter (7.4 ft. instead of 6.78 ft.), and this larger diameter in itself causes a higher ideal efficiency. The ideal efficiency of the "best possible" 7.4-ft. propeller is 95.1 per cent, an increase of 0.9 per cent over that with the standard propeller. Thus, the increase in ideal efficiency is responsible for fully one-half of the entire efficiency gain and, with the best propeller which can be devised, there still will be a loss of 14.2 per cent of brake horsepower to body interference, skin friction, and turbulence.

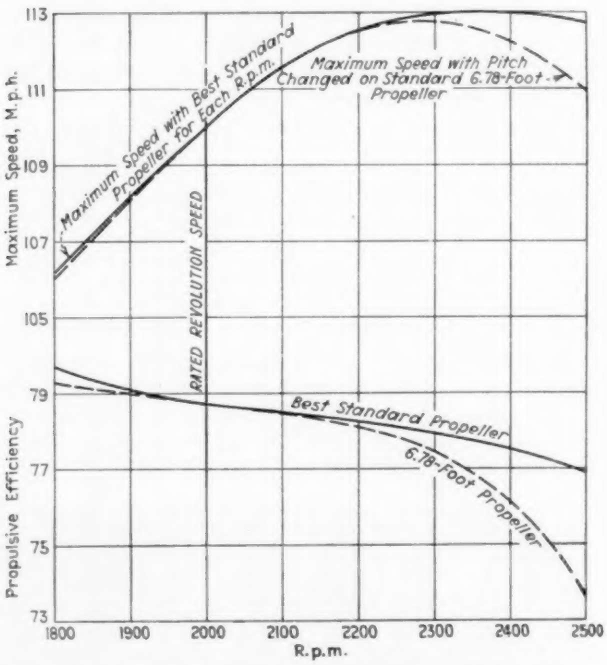

FIG. 6 EFFECT OF RUNNING A GIVEN ENGINE AT VARIOUS FULL-THROTTLE REVOLUTION SPEEDS

From the foregoing it is seen that the propeller designer, having the conditions of body form, engine power, revolutions, and approximate airplane speed all fixed outside of his control, has but a small chance of increasing the maximum speed by even 1 full mile per hour over that with the best standard propeller which can be selected in a few minutes from a chart (reference 1 or 2). It may also be of interest to see what influence the airplane and engine designers and the operators can have on the maximum speed. Apparently body interference is costing about 4 per cent, and it seems likely from test data available that this could be reduced to about 2 per cent without increasing the drag of the body by lengthening the nose and locating the propeller farther forward. This would no doubt entail disadvantages such as extra weight, but in this paper only the speed aspect is being considered.

Another factor which has a large effect on the propeller efficiency is the revolution speed at which it must operate. The efficiency obtained with the best pitch and diameter of the standard form propeller is plotted in Fig. 4 for revolution speeds ranging from 1000 to 3000, the engine in each case delivering 90 hp. The fuselage is the same as before, and with a revolution speed of 2000 r.p.m., a maximum air speed of 110 m.p.h. is obtained. It will be noticed that with 1000 r.p.m. a propulsive efficiency of 84 per cent is obtained, as compared with 78.8 per cent with 2000 r.p.m. and 75.3 per cent with 3000 r.p.m. If the 1000 r.p.m. were obtained by means of reduction gears with a power loss of about 2 per cent, the overall propulsive efficiency would be about 82 per cent, which is just about the same as that obtained with the old OX-5 motor which delivers 90 hp. at 1400 r.p.m. As can be seen from Fig. 4, this would give a gain in maximum speed of about 1.7 m.p.h.; while running the revolutions up to 3000 would cause a loss in maximum speed of the same amount. This comparison, incidentally, shows that, considering the powers and air speeds involved, present light plane motors do not run at excessive revolution speeds for reasonable propeller efficiency. Also, even with 3000 r.p.m. the tip speed would be well under the range where it would cause a loss in efficiency, for the diameter in this case would be less than $5^1/_2$ ft.

The comparisons just made show that the airplane and engine designers control factors which might effect an increase in propulsive efficiency and speed three or four times as great as that within the range of the propeller designer. It is also of some interest to show what effect the operator can have on the maximum speed with a given airplane and engine to start with, by running the engine at higher than the rated revolutions. The power curve of the typical engine, which is rated at 90 hp. at 2000 r.p.m., is shown in Fig. 5, the peak occurring at 2500 r.p.m. The solid curves in Fig. 6 show the propulsive efficiencies and maximum speeds which would be obtained with the best standard propellers if the engine were allowed to turn at full-throttle revolution speeds different from the rated one. It will be noted from Figs. 5 and 6 that, although the power becomes greater as the revolutions go up to a certain value, the propulsive efficiency drops off. The greatest speed, which is 3 m.p.h. higher than that obtained at the rated revolutions, occurs at a revolution speed about 200 r.p.m. below that for the peak of the power curve. The dotted curves in Fig. 6 show that nearly the same gain in speed can be obtained if the original standard 6.78-ft. propeller is used throughout, and the higher revolutions obtained by merely decreasing the pitch of the blades. Thus, the operator also can influence the maximum speed obtained over a short period for a race to a much larger extent than the propeller designer.

It is no doubt evident from this discussion that the propeller, assuming that the design is within reasonable limits of good practice, cannot be expected to have anything but a relatively small effect on the high speed of an ordinary light airplane. (It should be kept in mind, incidentally, that the high speed is the only performance item which has been considered here.) In the case of a racing light plane which has a maximum speed of 150 or 160 m.p.h., variations in the propeller have even less effect.

AER-54-24

The Design of Practical Light Airplanes

By KARL H. WHITE,[1] ROBERTSON, MO.

Expense has instilled the thought of low-powered airplanes in the minds of airplane manufacturers during the slump, in order that a market can be maintained for their product and an outlet seed planted for later production. The important features in the design of light airplanes are (1) price, (2) safety, and (3) appearance and performance. The manufacturing cost depends upon materials employed and simplicity of design, and also varies with the quantity produced. Curves are plotted showing the cost of materials and direct labor for different quantities of production. Safety is dependent upon (1) visibility, (2) low take-off and landing speeds, (3) controllability at low speed, and (4) fire hazard. Photos show how visibility is obtained in the pusher type of light airplane. Appearance and performance rank equally in third place, and the author speaks of the necessity for "eye appeal." Performance in light airplanes is not measured in terms of high speed and maneuverability, but should be measured in terms of take-off and landing characteristics, together with controllability at low speeds. Wing-cell design is discussed, and charts show comparison of wing weights of light airplanes and normal-powered airplanes.

WHY a light airplane? The light airplane is one logical result of the aftermath of an oversold airplane public. The word "airplane" has been too expensive for the majority to seriously consider—not too dangerous or unsafe, but too expensive. "Normal powered" airplanes have required engines costing from $1500 up. This in itself, not to consider operating expense, has been sufficient to keep the prices of airplanes out of general reach. The airplane manufacturer has therefore groped around for a means of lowering the cost of some of the new models and has resorted to the low-powered engines costing less than $500 as a good start toward the possibility of producing a real low-priced airplane.

Price, then, becomes the most essential feature in the design of a practical light airplane. No matter how safe a light airplane may be, if it is expensive the public cannot afford to buy it, and therefore no business concern will entertain the thought of its manufacture.

The second consideration is safety. Although it is embarrassing to admit that human life trails second to a price consideration, it is nevertheless an actual fact. The airplane business is similar to any other, and the American public today is forced first to look at its pocket book, and then if there is a chance of meeting the requirements financially, it enquires further regarding safety, performance, and other details that may come to mind.

Appearance and performance equally demand third place, but the first consideration of price cannot be used as an alibi to present a crude-looking object to the public. The automobile industry today is bending every effort for good looks and graceful lines, and the commercial airplane designer who omits a certain amount of "eye appeal" in his product will soon be left behind in the struggle for a place in the light-airplane market.

PRICE AS A CONSIDERATION

Experience has shown that the cheapest type of light airplane to build is the monoplane. The biplane has certain definite advantages such as (1) being more compact (2), easier to obtain large wing area per unit weight, and (3) facilitating undercarriage design, but if price heads the list, the monoplane must be selected.

Cost may easily be discerned in parts. The fewer the parts the less the cost. Table 1 gives a comparison of the number of parts required in the wing cell of a conventional open two-place one-bay biplane, the well-known Robin monoplane, and the Curtiss-Wright Junior monoplane, which is in the light airplane class.

TABLE 1 COMPARISON OF PARTS

Name	Two-place one-bay biplane	Robin	Curtiss-Wright Junior
Beams	8	4	4
Ribs	48	38	38
Compression struts	16	10	10
Internal tierods	24[a]	24[b]	24[c]
Drag-wire fittings	32	24	16
Leading edge	4	2	2
Trailing edge	4	2	2
Wing tips	4	2	2
Wing hinges	8	4	4
External fittings	18	12	4
External strut units	19	18	20
External tierods	20	4	4
Tierod terminals	88	56	20
Bolts in wing cell	120	96	50
Total number parts per plane.	413	296	200

[a] single, [b] double, [c] 50 per cent double.

Of course, the relative cost of the parts being considered enters into this analysis, but without going into too much detail, it is readily seen that the monoplanes have the advantage from a price consideration. Wherever possible the number of parts should be cut to a minimum. Separate units should be combined. Fig. 1 is an example of how two units, a fuel and oil tank, on a light

---

[1] Design Engineer, Curtiss-Wright Airplane Co. Mr. White was born in Winchester, Mass., Aug. 25, 1897. His parents moved in 1905 to Lawrence, Kan., where Mr. White received his education. He was graduated from the University of Kansas with a B.S. degree in Mechanical Engineering in June, 1921. After graduation he entered the employ of the Aeromarine Plane & Motor Company, Keyport, N. J., as draftsman. He was promoted to Project Engineer and was later Assistant Superintendent of the Airplane Division. In 1924 he went with the Chance Vought Company, Long Island, New York, as Chief Draftsman. In 1926 he became Assistant Chief Engineer, but resigned in 1927 to leave military aviation and to enter the commercial aviation field as Chief Engineer for the Bellanca Aircraft Co., then located on Staten Island, New York. In 1929 Mr. White joined the Moth Aircraft Corp., Lowell, Mass., as Chief Engineer. In 1930 this company merged with the Curtiss-Robertson Airplane Mfg. Co. and the Travel Air Co., now forming the commercial airplane unit of the Curtiss-Wright Corporation, Robertson, Mo. Mr. White is the designer of the recent Curtiss-Wright Junior light airplane.

Contributed by the Aeronautic Division and presented at the Kansas City Meeting, Kansas City, Mo., Sept. 7 to 9, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

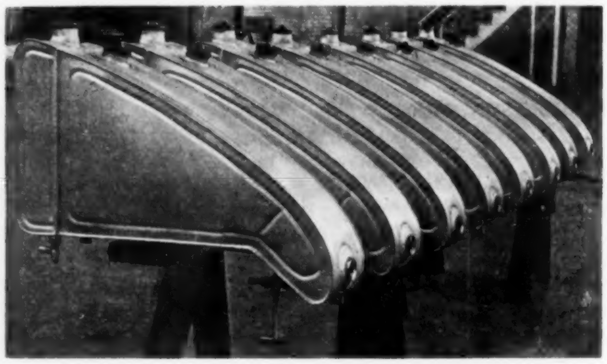

FIG. 1 TWO UNITS, AN OIL AND A FUEL TANK, COMBINED INTO ONE

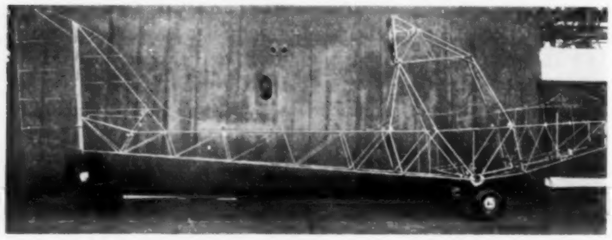

FIG. 2 A WELDED FUSELAGE UNIT

(Note that the fin, cockpit cowling, fairing, seat supports, center section, and controls have been combined into a single unit.)

airplane have been combined into one. This cuts down weight, facilitates handling through the production line, and requires only one support and tie-down arrangement instead of two. This arrangement also provides an oil-cooling medium which has proved its merit in hot-weather flying.

Regarding the type of airplane construction to be employed, some manufacturers have considered duralumin throughout, others duralumin monocoque fuselages with wood wings, and still others have used a combination of welded-steel tubular fuselage structure with wood wings and ailerons. There is a strong desire among airplane designers to go into all-metal construction, but the present-day practical low-cost light airplane, built for the present-day market, of necessity has been a combination of wood wings and steel tubular fuselage and tail structure.

The steel tubular fuselage is not only very strong and safe against injury to occupants in bad landings, but assembles readily and eliminates a great amount of handwork now required in other types of metal construction and also reduces the number of loose fittings to a minimum. This construction permits welding seat supports, surface control bearings, cable guides, engine-control fittings, and many other parts integral with the fuselage structure, and facilitates employing one unit for two or three different purposes. It is particularly well adapted to the light airplane because of the abuse to which it is subjected in the novice market, and because it is easy to repair in the field. Fig. 2 shows how the fin, center section, engine mount, seat supports, cowling, and surface control unit have been combined into one steel welded unit with the body of a light pusher type airplane.

Manufacturing cost also depends in a large degree on the quantity to be produced. Unfortunately we have not yet reached the quantity production period in airplane manufacture where expensive tools, jigs, dies, and fixtures can be afforded, which go hand in hand with sheet-metal work and pressed parts. When this time does come, our present method of assembly will indeed seem very crude, and the picture of cost presented herein will take on an entirely different aspect.

Fig. 3 shows how labor cost varies with the number of light airplanes produced per week. This cost is separated to show the labor comparison between all-steel tubular construction used in conventional fuselages and the wood construction as employed in a wing cell.

Fig. 4 shows how little the material cost is reduced when purchased for larger quantities of production. The material cost in airplane manufacture will have to be lowered considerably before we will be able to produce a real "flivver of the air."

FEATURES THAT MAKE FOR SAFETY

Under safety come the following features, which are listed in their relative importance: (1) Visibility, (2) low take-off and landing speeds, (3) controllability at slow speed, and (4) fire hazard.

Visibility can best be obtained in the pusher-type airplane. The old war-time slogan of "Sit well aft for protection in a crash," is gradually being replaced with the peace-time idea of sitting well forward to prevent a crash. As more airplanes get into the air it will become all the more important to have 100 per cent

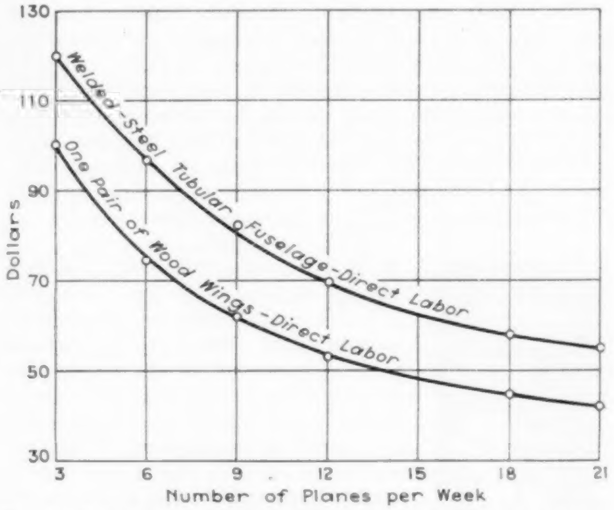

FIG. 3 VARIATION OF LABOR COST WITH NUMBER OF LIGHT AIRPLANES PRODUCED PER WEEK

(Comparison is made of the labor in all-steel construction and wood construction.)

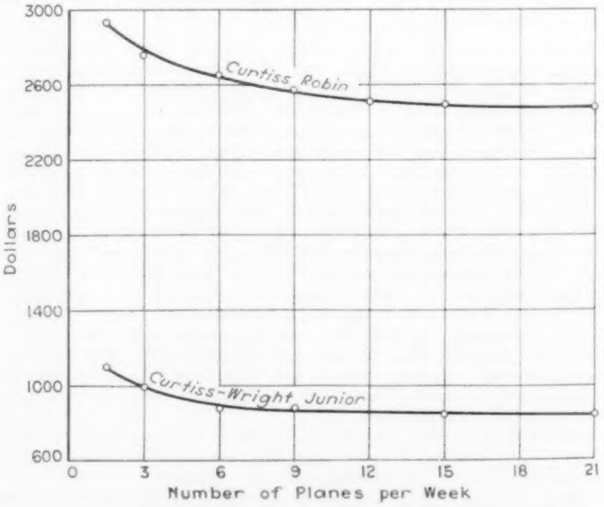

FIG. 4 MATERIAL COST COMPARED WITH NUMBER OF PLANES PRODUCED PER WEEK

visibility. Fig. 5 shows visibility possibilities in a pusher-type light airplane.

Low take-off and landing speeds give the light plane owner, who is usually an amateur, more time for thought during this maneuver. An airplane designed so that it cannot be forced off the ground is safer for a beginner than one which can get off accidentally before flying speed is reached. For this reason a low landing gear is preferable to the high one. Until flying speed is reached, the tail cannot be lowered sufficiently to force the ship into the air. Because of propeller clearance, the pusher type permits low landing gear, which also in turn makes it difficult for the plane to nose over. Nosing over still is a common occurrence among trained fliers, as well as amateurs, especially in the light plane class. Cost again crops up, and money is saved in repair bills. Fig. 6 shows an axle being formed in a press, which constitutes a low-type landing gear used on one of the present light airplanes.

Controllability at slow speed is of vital importance in any amateur airplane. The beginner is not always certain just when he has reached the stall, which often occurs when landing, and effectiveness of surface controls is paramount under these conditions. Any feature which can be incorporated in the design of airplanes to improve present-day control at stalling speeds will do much toward increasing safety of flying. Experiments are being conducted at the present time to determine the practicability of placing a stop in the up elevator control, so that all one has to do to land is to "cut gun" and pull the stick back and let the plane do the rest. A well-designed airplane will permit this maneuver without tendency to fall off in a spin.

Fire is not common in the air with present-day flying, but nevertheless this hazard should receive its share of consideration. Fuel tanks should be so located as to preclude the possibility of fire blowing back into the cockpits in case of accidental fire and forced descent. Many military planes now have the fuel tanks on the sides of the fuselage, while the majority of commercial planes carry fuel in the wings.

APPEARANCE AND PERFORMANCE

Appearance in light-airplane design should be measured in terms of gracefulness or pleasing harmony of outline. In the fighter pursuit class of airplanes, appearance is measured by the number of guns carried or the length of cowling over the engine, but the light airplane should have all the earmarks of grace and ease of contour. It should not necessarily appear light, but on the other hand should instill the thought of strength and ruggedness. The more that ruggedness is brought out in the design, the more pleasing the appearance, providing that gracefulness is still in the picture.

Biplane appearance is usually aided by sweepback, stagger, and dihedral, although all of these characteristics add to the cost. Monoplanes never appear as graceful without dihedral as they do with dihedral. The amount required for good looks is often decided upon by the actual flying characteristics of the airplane, but nevertheless anything less than about 2 deg. gives a flat appearance to the wing cell.

The fuselage need not necessarily be round, square, or triangular, to look right—it may be most any section; but it must be located and arranged in harmony with the rest of the airplane. If a fuselage is round, the tail planes should not be square or triangular in profile, but should conform to and have a general likeness to the body structure. A fuselage triangular in section looks well with a triangular tail unit. Tail units with abrupt changes in contour look well with wing tips of the same stroke. Consider for a moment how an elliptical wing tip would look with a box tail unit. If the box tail unit must be used, then use a square tip with sheared corners. The color schemes employed in the finishing of airplanes can do much to improve or harm a given outline. It does not appear that airplane manufacturers have yet taken full advantage of what the automobile industry has learned in the way of color combinations, but no doubt more time and consideration will be given to this art as the industry becomes more and more stabilized.

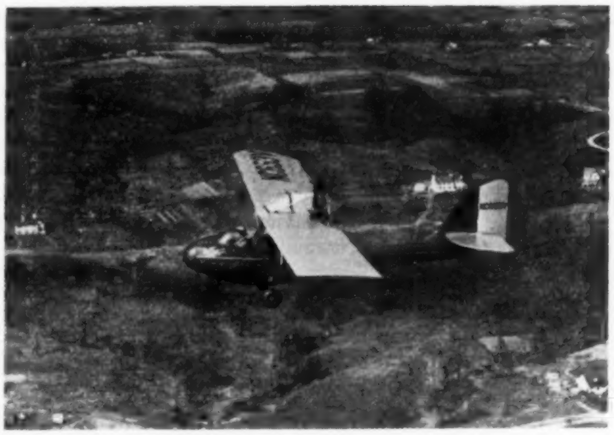

FIG. 5 VISIBILITY POSSIBILITIES IN A PUSHER TYPE OF LIGHT AIRPLANE

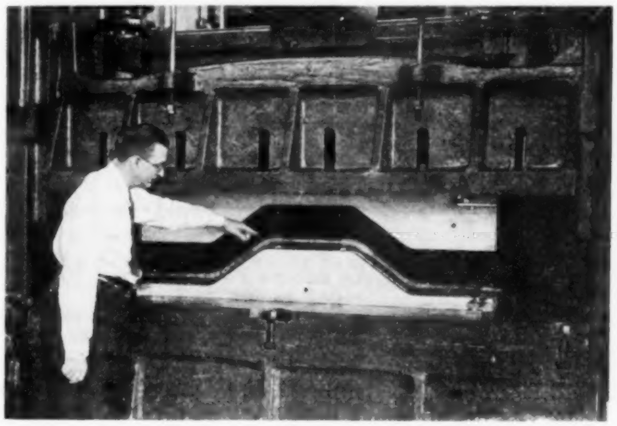

FIG. 6 ONE-PIECE AXLE IN PRESS. THIS TYPE PROVIDES LOW LANDING GEAR

Performance in light airplanes is not measured in terms of high speed and maneuverability, but should be measured in terms of take-off and landing characteristics, together with controllability at low speeds. The light airplane is the step between the glider and the "normal powered" class. Every one knows the necessity for high aspect ratio on successful gliders, and this need is also present in gaining performance with the light airplane. Wing cells with high aspect ratios require particular consideration with regard to structure, because of the weight involved in large spans. A study of high aspect ratio wing weights immediately presents itself as the designer proceeds to select his wing cell.

The first consideration is beam height, which of course is dependent upon airfoil section. The best present-day airfoils for light airplanes restrict the rear beam depth. Because of the large span, the beams should be kept well apart to assure a rigid drag truss, and this again adds to the difficulty of obtaining a satisfactory rear beam. A special airfoil was developed for the Curtiss-Wright Junior which gives a 15 per cent greater rear beam depth than could have been obtained with other airfoils of approximately the same characteristics. A 15 per cent gain in beam depth increases the moment of inertia 52 per cent, which aids materially in keeping down beam weights.

Fig. 7 shows wing weights per square foot plotted against aspect ratio for different types of wing cells. Fig. 8 shows the wing weight per square foot plotted against specified high incidence load factor, while Fig. 9 plots wing weight per square foot against wing loading. These figures show approximately what can be expected in the saving of wing weights for light airplanes as compared to "normal powered" airplanes.

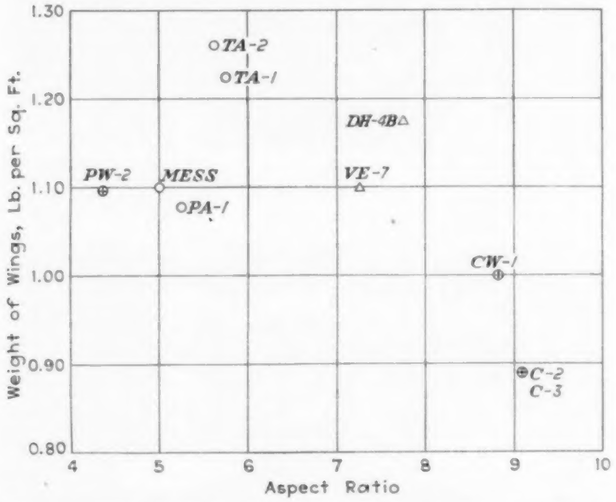

FIG. 7 WING WEIGHTS PER SQUARE FOOT COMPARED WITH ASPECT RATIO

(Legend: ○, single-bay biplane; △, double-bay biplane; ⊕, monoplane braced. Reprinted in part, by courtesy of Air Service, from Inf. Circ. No. 541.)

The names of the airplanes, listed by model designation in Figs. 7, 8, and 9, are as follows:

TA-1.....	G. Elias
TA-2.....	Huff Daland
Mess.....	Verville
DH-4B...	DeHavilland
PW-2.....	Loening Monoplane
PA-1.....	Loening Biplane
VE-7.....	Vought
C-2......	Aeronca One-Place Light Airplane
C-3......	Aeronca Two-Place Light Airplane
CW-1....	Curtiss-Wright Junior Light Airplane

It is regretted that no data are available at the present time on light airplanes other than the ones listed, as this would make a much more interesting study.

Light-airplane design is still young. Many new and interesting models are breaking forth all over the country, and there is every reason to believe that the schoolboy will take up the art of flying because of its sporting nature as soon as price, safety, and performance (within the limits outlined herein) are brought within his reach and understanding.

Discussion

MILTON C. BAUMAN.[3] Mr. White starts out with the question, "Why a light airplane?" This question must be answered before the design can be comprehensively discussed. Has the normal-powered airplane been modified at a sacrifice of speed just to meet a price or are the flying characteristics of the light airplane the real reason for it?

Mr. White leads us to believe that price is the most important factor in the design of these small planes. He then tells us how the cost is reduced. This is done only by virtue of the modified design of the normal airplane. In the first place the light airplane does not require as large a motor as the normal airplane, and in the second place it has been simplified as much as possible. The manufacturing methods are the same for both types. Is this the way the price should be reduced?

The author states that the manufacturing cost also depends on the quantity produced, but that quantity production is not justified. It seems that quantity production is the real solution for a cheap, satisfactory airplane, and that the savings resulting from changes in design of engine and plane are, after all, insignificant as compared to the reduced cost of quantity production. If this is true, then how are we going to get more people to seriously use airplanes? By making airplanes of high performance equipped with the best engines available or by making airplanes of low performance with relatively inferior engines, but selling

---

[3] Chief Engineer, Inland Aviation Company, Kansas City, Mo.

at a lower price? Remember, it is one thing to get a person into the air and still another to get that person to use it as a means of transportation, which really sells airplanes.

Wellwood Beall.[3] Mr. White's paper has brought to attention many truths about the features and design of light airplanes and has given much interesting information. The appearance of the airplane has been highly stressed. In order to merchandise any object, it must have eye appeal. Of two objects, all other things being equal, the one with the more pleasing appearance will of course be the more successful. Since most light planes have approached the same performance and since they are constructed almost identically, due to the regulations of the Department of Commerce, it stands to reason that the most important feature in the design of a plane will be its appearance.

However, in certain types of structures and designs, inherent beauty of form cannot be built into the airplane. In this case a great improvement in the appearance can be effected by the use of an intelligent and artistic paint job. The point is that much credit for a pleasing appearance can be given to the paint job. This of course includes the type of finish, whether dull or bright, whether smooth or rough, whether corrugated, or whether free from all joints or cracks; in other words, it also includes the type of covering. Then the color of the paint and the layout of the paint pattern are important. A well-thought-out pattern with an artistic color scheme will do wonders with an ordinary machine, and with a machine that has good lines inherently, a wonderful looking airplane can be produced.

Too little thought is given to this consideration in the aeronautical field. A lesson could be learned from the automobile industry; in later years the biggest battles in the automobile industry have been fought and won in the paint room.

Hugh L. Thompson.[4] Mr. White has given a very excellent résumé of the light airplane. He has stressed a very important point, and that is price. Of course there are other important points, but if people are going to buy the light airplane, it must be sold at a price that is as low as the medium-priced automobile—say, around $1500. Under present conditions this is difficult to do and make a profit. Large-scale production will help. However, there is something else lacking for the light airplane that should be brought out, particularly as so much attention is being given to power. What is needed is a good, inexpensive power plant for this type of airplane. At present aircraft engines run in price around $8 or $9 per horsepower. The larger motors have been developed to a point of great reliability, but the little motors have not reached this stage as yet—probably because they are too new. The motor for the light airplane should not be reduced in horsepower, but it needs to be reduced in weight and price and increased in reliability, and then light airplanes can be built at a price that will sell them and make a profit. Let us have more development and research work along these lines.

Frank M. Smith.[5] Mr. White is laying too much stress on the matter of price. While undoubtedly the flying public want low-priced airplanes, they do not want cheap airplanes. The building of an airplane to satisfy a class that does not consider life worth a few extra dollars is poor psychology and a questionable procedure, and the establishment of a successful business on such a basis is entirely impractical.

Such sales psychology is all wrong, and the day is past when a dumb public will buy airplanes on the recommendation of an airplane pilot or salesman, but prides itself on its knowledge of aviation and is demanding something better than a cheap crate.

A combination of speed, safety, comfort, visibility, economy of operation, and service is what the flying public demand, and when a ship combining these essentials can be produced at a reasonable figure, the responsible element of the public will buy, and not until then. Such a plane must be a cabin-type, all-metal plane of a design different from anything now in the air.

Author's Closure

Referring to Mr. Bauman's discussion, the author thinks that sales statistics will bear him out in the matter of price being at the top of the designer's guide in developing light airplanes. Of course, we cannot think of offering an unsafe airplane to the public, and even if we should, we all know the Department of Commerce would not allow it.

The author heartily agrees with Mr. Beall that no one gives sufficient attention to color schemes. Unfortunately, within the past two years the manufacturers have, of necessity, been using up inventory wherever possible.

It is true, as contended by Mr. Thompson, that the field for engines of around 50 hp. used in light airplanes is new and that experience will in time enable us to greatly improve these power plants.

Mr. Smith is making a big jump in recommending that what we need is something entirely different from anything new in the air. The author agrees that the future airplane will not look much like the old "Jenny," but progress is made slowly, and new types develop gradually from the present conventions. So let us take it easy, at least until the depression is over.

APM-54-1

The Hydraulic Jump and Related Phenomena

By BORIS A. BAKHMETEFF,[1] NEW YORK, N. Y.

In this paper the author presents certain results which were obtained by him in studying the hydraulic jump over a period of years. A general characteristic of the "state" of flow is introduced through the notion of "Kineticity of Flow," expressed numerically by a "Kinetic flow factor." The fundamental relations, referring to the jump, are presented in generalized form. A physical basis is offered to explain the different forms in which the jump occurs. The practical important cases of a jump below a sluice and at the foot of a weir are studied in detail. Formulas are devised and charts given which make it possible to solve different problems of engineering practice.

I—PRELIMINARY

Energy Diagram. In dealing with the hydraulic jump and related problems it has become customary to refer the flow to the "specific-energy diagram" (Fig. 1).[2] Given the shape of the canal and the discharge Q, flowing in parallel movement under varying depths d, the curve $\epsilon = f(d)$ pictures the energy per unit weight

$$\epsilon = d + \frac{v^2}{2g} = d + \frac{Q^2}{2ga^2} \quad\ldots\ldots[1]$$

carried by the flow at each and every depth. In this equation v is the average velocity, and a the cross-sectional area at the depth d.

Point C in the energy diagram (Fig. 1), at which the ϵ-curve passes through a minimum, determines the "critical depth" d_{cr}. Flow at $d = d_{cr}$, being flow with the minimum possible content of energy, is said to be in the "critical state." Following Boussinesq's nomenclature, flow at stages above the critical depth ($d > d_{cr}$) is said to be in the "tranquil" state, while flow at stages below the critical ($d > d_{cr}$) is in the "rapid" state.

Hydraulic Jump. In the jump (Fig. 2), the flow passes abruptly from a rapid to a tranquil state, corresponding in the energy diagram to a sharp change from point (1) on the lower branch to point (2) on the upper branch of the ϵ-curve. The horizontal difference between points (1) and (2), or

$$\epsilon_j = \epsilon_1 - \epsilon_2 \quad\ldots\ldots\ldots\ldots[2]$$

is the specific energy lost in the jump.

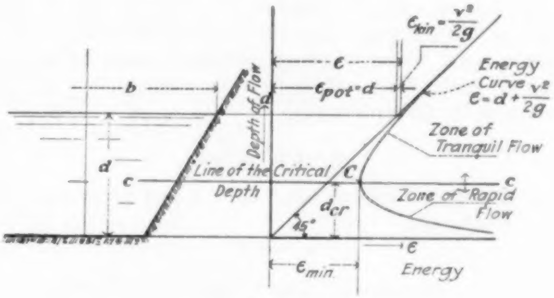

FIG. 1

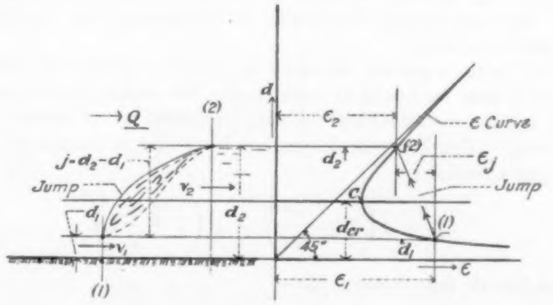

FIG. 2

The depths d_1 and d_2 before and after the jump will be called (Fig. 2) the "conjugated" depths. They are usually determined by means of the momentum principle of Bélanger.

For a canal of rectangular shape,[3] with a discharge per unit width of $q = Q/b$, the conjugated depths are related by the well-known symmetrical equations:

---

[1] Consulting Engineer. Mem. A.S.C.E. Boris A. Bakhmeteff was born in 1880 at Tiflis, Caucasus, Russia. In 1898, graduated Classical Gymnasium, Tiflis; 1903, Institute of Engineers of Ways of Communication, St. Petersburg; 1904-1905, research work at Polytechnic Institute, Zurich, Switzerland, and practical work in the United States (New York State Barge Canal and office of Colonel Bogart, consulting engineer); 1911, received degree of "Adjunct Applied Mechanics" corresponding to Doctor of Engineering; academic work at the Polytechnic Institute Emperor Peter the Great, St. Petersburg; 1905–1916, as assistant professor, docent, and professor; is the author of "Lectures on Hydraulics," St. Petersburg, 1912-1913, "Varied Flow of Liquid in Open Channels," Petrograd, 1912, and "Introduction to the Study of Variable Flow of Liquids," 1914; 1907–1915, consulting engineer in St. Petersburg, specializing on water power; was connected with the Dneiper project (300,000–1,000,000 hp.) as chief engineer, the "Volchow" and "Immatra" plants (150,000 hp.) of the "Petrograd Company for Transmission of Hydraulic Power" as chief engineer, and the Rion Plant, Caucasus (50,000 hp.), for the electrification of the Trans-Caucasus Railroad; member of Technical Board of the Russian Reclamation Service; chairman of "Board for Engineering Research" of the Reclamation Service; served as expert on governmental and municipal boards connected with irrigation, internal navigation, sewage disposal, legislation on public utilities, and water rights; with the advent of the war, volunteered first with the Red Cross, subsequently with the Central War Industrial Committee; a public voluntary organization of business and professional men; 1915–1916, Chief Plenipotentiary of the C.W.I. Committee to the United States; member of Anglo-Russian Purchasing Commission; March, 1917, after the fall of the Czar Government, was appointed Under Secretary of State (Vice Minister) for Commerce and Industry of the Provisional (Kerensky) Government; May, 1917, appointed Ambassador to Washington, remaining in that post until 1922, at which time he resigned; since 1923 established in New York as consulting engineer connected with various industrial enterprises.

[3] The general case of a canal of any cross-sectional form is dealt with in Appendix No. 1.

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

$$\left.\begin{aligned} d_2 &= \frac{d_1}{2}\left[-1+\sqrt{1+\frac{8q^2}{gd_1^3}}\right] \\ d_1 &= \frac{d_2}{2}\left[-1+\sqrt{1+\frac{8q^2}{gd_2^3}}\right] \end{aligned}\right\} \qquad [3]$$

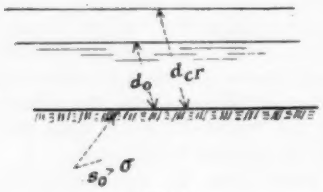

FIG. 3

Critical Depth. For a rectangular canal the critical depth is

$$d_{cr} = \sqrt[3]{q^2/g} \qquad [4]$$

For a canal of any shape with the discharge Q, the critical depth is the depth satisfying the equation

$$\frac{Q^2}{g} = \frac{a^3}{b} \qquad [5]$$

Critical Slope. In uniform flow with the depth d_0, corresponding to a discharge Q, the streaming will be *rapid* if the bottom slope is sufficiently "steep" to cause the depth of uniform movement d_0 to be smaller than the critical depth d_{cr}. (See Fig. 3.)

The slope which makes uniform flow critical ($d_0 = d_{cr}$) is called the "critical slope" and will be designated by σ.

For a canal whose width is sufficiently great to make the hydraulic radius $R = \sim d$, we have, for uniform flow, in accordance with the Chézy formula,

$$q = Cd_0\sqrt{d_0 s_0}$$

For flow in the critical state, $s_0 = \sigma$ and $q_0^2 = gd_0^3$. Thus $gd_0^3 = C^2 d_0^3 \sigma$, and

$$\sigma = g/C^2 \qquad [6]$$

II—KINETICITY. THE KINETIC FLOW FACTOR

The position of a point on the energy curve characterizes the "state" of flow. The higher the point on the upper branch [(2) in Fig. 2], the more tranquil the flow. The lower the point on the lower branch [(1) in Fig. 2], the greater the "rapidity" of the streaming.

To obtain a general standard by means of which the "state" of flow may be qualified numerically, the author makes use of the notion of "kineticity" of flow, measured by a "kinetic flow factor." The latter is designated by κ and is defined by the energy equation:

$$\epsilon = d\left(1+\frac{v^2}{2gd}\right) = d\left(1+\frac{1}{2}\kappa\right) \qquad [7]$$

The kinetic flow factor is thus

$$\kappa = 2\,\frac{v^2/2g}{d} = 2\,\frac{Q^2/2ga^2}{d} \qquad [8]$$

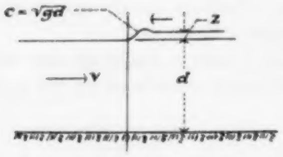

FIG. 4

or twice the ratio of the kinetic-energy head to the depth of flow. Obviously, for a given discharge κ is a function of the depth.

For a rectangular canal, remembering that $q^2/g = d^3_{cr}$ and with $Q^2/a^2 = q^2/d^2$, we have:

$$\kappa = d^3_{cr}/d^3.$$

For critical flow, with $d = d_{cr}$, $\kappa = 1$
For tranquil flow, with $d > d_{cr}$, $\kappa < 1$
For rapid flow, with $d < d_{cr}$, $\kappa > 1$

Kineticity equal to unity, corresponding to the critical depth, is thus the dividing criterion between tranquil and rapid flow. This simple and convenient characteristic explains the particular manner of designation as suggested in [7] and [8].

Celerity of Propagation. The kinetic flow factor provides also for a simple relation between the velocity of flow and the speed of propagation c of an intumescence of small height (Fig. 4).

According to the well-known St. Venant formula for a rectangular canal,

$$c = \sqrt{gd\left(1+\frac{3}{2}\frac{z}{d}\right)} \qquad [9]$$

which for small values of z/d is identical with the Lagrange formula

$$c = \sqrt{gd}$$

By comparison with [8] it is seen that

$$\kappa = \frac{v^2}{c^2} \qquad [10]$$

The velocity w with which the intumescence moves relative to the embankment is

$$w = c \pm v = c(1 \pm \sqrt{\kappa})$$

III—GENERALIZED FORMULA FOR THE JUMP IN RECTANGULAR CHANNELS

Substituting the value of κ from [8] in [3],

$$\left.\begin{aligned} \frac{d_2}{d_1} &= \frac{1}{2}\left[-1+\sqrt{1+8\kappa_1}\right] \\ \frac{d_1}{d_2} &= \frac{1}{2}\left[-1+\sqrt{1+8\kappa_2}\right] \end{aligned}\right\} \qquad [11]$$

where κ_1 and κ_2 are, respectively, the kinetic flow factors before and after the jump.

Solving Equation [11] with respect to κ_1 and κ_2,

$$\left.\begin{aligned} \kappa_1 &= \frac{1}{2}\frac{d_2}{d_1}\left(\frac{d_2}{d_1}+1\right) \\ \kappa_2 &= \frac{1}{2}\frac{d_1}{d_2}\left(\frac{d_1}{d_2}+1\right) \end{aligned}\right\} \qquad [11a]$$

Finally, substituting [11] into

$$\kappa_2 = \left(\frac{d_{cr}}{d_2}\right)^3 = \left(\frac{d_{cr}}{d_1}\right)^3 \cdot \left(\frac{d_1}{d_2}\right)^3 = \kappa_1\left(\frac{d_1}{d_2}\right)^3$$

the following symmetrical relations are obtained:

$$\left.\begin{aligned} \kappa_2 &= \frac{8\kappa_1}{(-1+\sqrt{1+8\kappa_1})^3} \\ \kappa_1 &= \frac{8\kappa_2}{(-1+\sqrt{1+8\kappa_2})^3} \end{aligned}\right\} \qquad [12]$$

The specific energies before and after the jump are, respectively:

$$\epsilon_1 = d_1\left(1+\frac{\kappa_1}{2}\right)$$

$$\epsilon_2 = d_2\left(1+\frac{\kappa_2}{2}\right)$$

Eliminating the depths by means of Equations [11] and [12],

$$\frac{\epsilon_2}{\epsilon_1} = \frac{\frac{1}{2}\left(\sqrt{1+8\kappa_1}-1\right) + \frac{2\kappa_1}{\left(\sqrt{1+8\kappa_1}-1\right)^2}}{1+\frac{1}{2}\kappa_1} \quad \ldots\ldots [13]$$

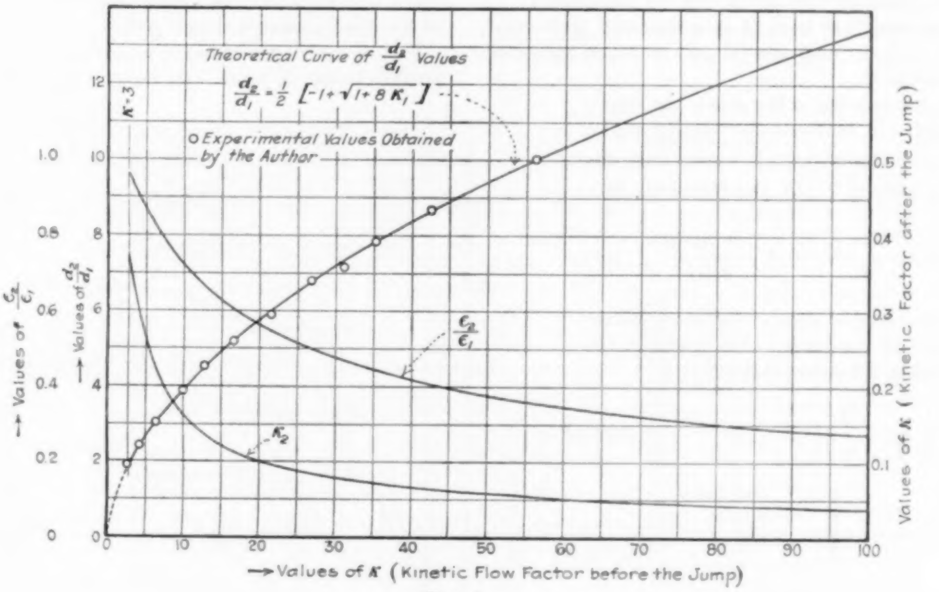

FIG. 5

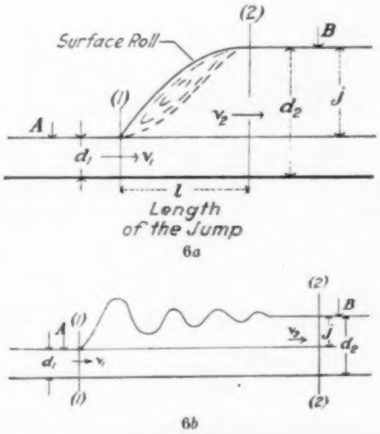

FIG. 6

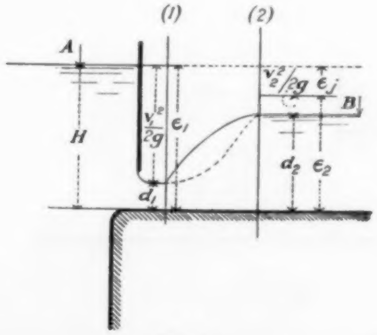

FIG. 7

Equations [11] to [13] present the fundamental relations governing the jump in dimensionless form, in terms of a single variable κ_1 or κ_2.[4] The kinetic flow factor thus constitutes a generalized coordinate. Fig. 5, drawn in accordance with Equations [11] to [13], makes it possible to solve practical problems in a very simple manner, as the following examples show:

Example 1. Assume a flow of 400 cu. ft. per sec. in a rectangular canal 20 ft. wide. Assume $d_1 = 0.8$ ft. Determine the height of the jump and the loss of energy.

With $v_1 = 400/(20 \times 0.8) = 25$ ft. per sec. and $v^2/2g = 9.7$ ft., the kinetic flow factor is $\kappa_1 = 2(9.7/0.8) = 24.2$. The initial energy $\epsilon_1 = 0.8 + 9.7 = 10.5$ ft. From Fig. 5, $d_2/d_1 = 6.45$; $\epsilon_2/\epsilon_1 = 0.52$. Hence $d_2 = 6.45 \times 0.8 = 5.16$ ft.; the height of the jump $j = 5.16 - 0.8 = 4.36$ ft. On the other hand, $\epsilon_2 = 0.52 \times 10.5 = 5.46$ ft.; and the loss of energy is 48 per cent, or $0.48 \times 10.5 = 5.04$ ft.

Example 2. With the same discharge, determine the depth d_1 which will sustain a jump resulting in $d_2 = 4$ ft. The velocity $v_2 = 400/(4 \times 20) = 5$ ft.; $v^2/2g = 0.388$; $\epsilon_2 = 4.39$; $\kappa_2 = 2(0.39/4) = 0.194$. From Fig. 5 the corresponding $\kappa_1 = 7.4$; $d_2/d_1 = 3.36$; $\epsilon_2/\epsilon_1 = 0.794$. Hence $d_1 = 4/3.36 = 1.19$ ft.; and the loss of energy = 20.6 per cent.

IV—FORMS OF THE JUMP. STABILITY

THE JUMP BELOW A SLUICE

The hydraulic jump is known to occur in two distinct forms:[5]

1 The "direct" form, in which the upper stage is reached through *one* single rise [Fig. 6(*a*)].

2 The "undulate" form, where the connection between the two stages presents a series of undulations [Fig. 6(*b*)].

The direct form is accompanied by a "surface roll" covering the underlying continuous streaming. In the "undulate" form, when the jump is small, the whole surface may be smoothly continuous.

---

[4] *Annales Inst. Polyt.*, St. Petersburg, 1911. See also Miami Conservancy District Technical Report, 1917, p. 3.

[5] The different forms of jump have been differentiated by Bazin. See also Flamant's, "*Hydraulique*," and Böss, *Forschungsarbeiten V.D.I.*, No. 284.

An explanation of the phenomenon is gained by considering the case of a jump below a sluice (Fig. 7). In what follows the canal will be assumed to have a rectangular section. The slight losses accompanying the efflux will be disregarded. In other words, assuming that level A is maintained permanent, the energy ϵ_1 at the *vena contracta* (1) will be taken to remain constant and equal to H.

By regulating the opening of the sluice, the depth d_1 will be changed. In each case the velocity will be $v_1 = \sqrt{2g(H - d_1)} = \sqrt{H}\sqrt{2g[1 - (d_1/H)]}$; the discharge $q = d_1\sqrt{2g(H - d_1)}$, and the kineticity

$$\kappa_1 = 2 \cdot \frac{v^2/2g}{d_1} = 2\,\frac{H - d_1}{d_1} = 2\,\frac{1 - (d_1/H)}{d_1/H} \quad \ldots [14]$$

By means of [11] to [13] we may further calculate the other elements of the jump. For example, the depth d_2 (substituting [14] into [11]) will be:

$$d_2 = \frac{d_1}{2}\left[\sqrt{16\,\frac{H}{d_1} - 15} - 1\right] \quad \ldots\ldots\ldots [15]$$

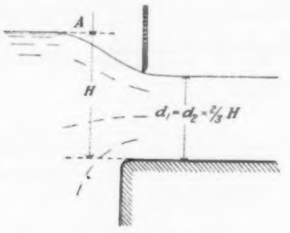

FIG. 8

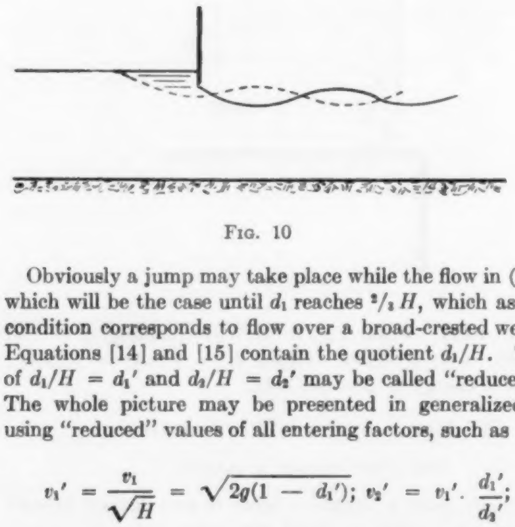

FIG. 10

Obviously a jump may take place while the flow in (1) is rapid, which will be the case until d_1 reaches ${}^2/_3\,H$, which as a limiting condition corresponds to flow over a broad-crested weir (Fig. 8). Equations [14] and [15] contain the quotient d_1/H. The values of $d_1/H = d_1'$ and $d_2/H = d_2'$ may be called "reduced" depths. The whole picture may be presented in generalized form by using "reduced" values of all entering factors, such as

$$v_1' = \frac{v_1}{\sqrt{H}} = \sqrt{2g(1 - d_1')};\ v_2' = v_1' \cdot \frac{d_1'}{d_2'};$$

$$q' = \frac{q}{H\sqrt{H}} = d_1'\sqrt{2g(1 - d_1')};\ d_{cr}' = \frac{d_{cr}}{H}$$

$$= d_1'\sqrt[3]{2\,\frac{1 - d_1'}{d_1'}};\ \epsilon_1' = 1;\ \epsilon_2' = \frac{\epsilon_2}{H};\ \epsilon_j' = 1 - \epsilon_2',\ \text{etc.}$$

The results are presented in chart form in Fig. 9. Obviously, the relations as obtained are not limited to the specific manner by which the jump was produced (Fig. 7). In fact, the chart given in Fig. 9 is a general characteristic of the jump as a function of d_1 under the condition that ϵ_1 is constant.

Referring to Fig. 9, it is seen that the d_2'-curve is ascending for values of $d_1' < 0.4$; having reached a maximum of $d_2' = 0.8$ at $d_1' = 0.4$, with $\kappa = 3$, the depth d_2 diminishes. In other words, $\partial d_2/\partial d_1$ is positive for the zone where $\kappa > 3$, and negative for kineticities smaller than $\kappa = 3$.

This circumstance appears to have a direct bearing on the possible forms of jump. In fact, experiments carried out by the author[6] indicate that in the zone where $\kappa > 3$ the jump occurs in the direct form. Moreover, the phenomenon is *stable*, and the values of d_2/d_1 are in close accord with the theoretical curve (Fig. 5).[7] On the contrary, in the zone of low kineticities ($\kappa < 3$) the surface becomes undulated; the waves increasing as κ declines. With this the whole phenomenon becomes *unstable*. The undulations shift back and forth in the direction of flow, until with a further opening of the sluice the whole efflux becomes subject to a periodical pendulatory movement. A phase such as that indicated in Fig. 10 by the solid line is succeeded by streaming, where the flow tears itself entirely from the edge of the sluice as shown by the broken line.

Within the scope of the author's experiments, with the undulatory form present there was actually no portion of flow

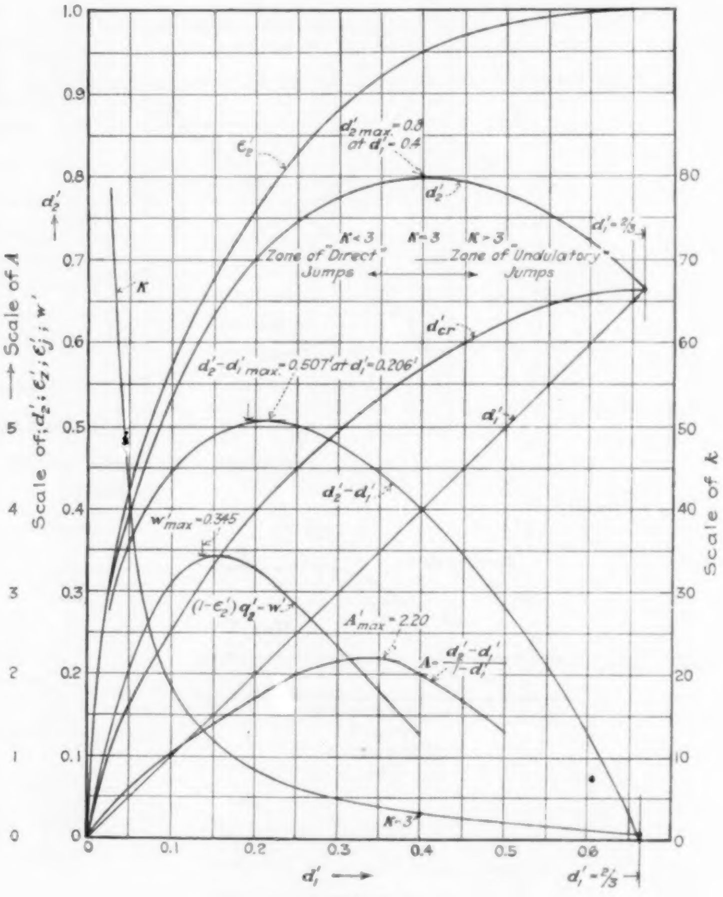

FIG. 9

---

[6] *Annales Inst. Polyt.*, St. Petersburg, 1911.

[7] The close accord between observed and theoretical values is characteristic of all experiments where the kineticity was high. (Rehbock; Gibson, Proc. Inst. C. E., 1913–14; Koch-Carstanjen "Bewegung des Wassers," 1928, etc.)

back of the jump where the movement was parallel and to which Equation [3] could be strictly applied. All that can be said is that the tops of the waves were distinctly above the "conjugated" values of d_2 obtained from [11]. The author's work was of a preliminary character, and further detailed experiments are required,[8] in particular to determine the losses in an "undulate" jump. However, attention is drawn to the fact that the loss of energy at the dividing point at $\kappa = 3$ is only 5 per cent of ϵ'. One may reasonably expect that in the undulate zone the relative losses are still smaller.

Most of the earlier experiments (those of Bidone and Bazin) were made on jumps produced by inserting a barrier in a stream flowing uniformly at a rapid rate ($d_0 < d_{cr}$, Fig. 11). One may estimate the range of kineticities obtained in such a manner by

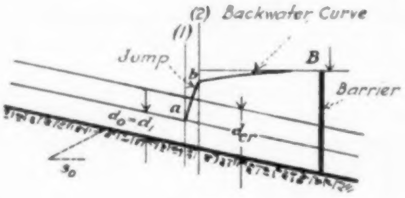

FIG. 11

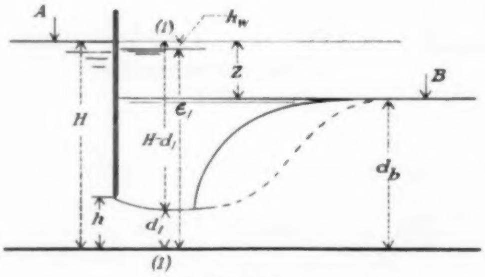

FIG. 12

considering the case of a broad canal, with $R \cong d$. For uniform movement, with $v = C\sqrt{d}\,\sqrt{s_0}$, the kinetic flow factor is

$$\kappa = \frac{v^2}{gd_1} = \frac{C^2 d s_0}{gd} = \frac{C^2}{g} s_0$$

or, referring to [6]

$$\kappa = \frac{s_0}{\sigma} \qquad [16]$$

or the ratio of the actual bottom slope to the critical slope. To obtain $\kappa \geq 3$, the slope would have to be $s_0 \geq 3\sigma$. For a case characterized by an average value of C, namely, 100, this would mean that $s_0 \geq 3 \times 0.0032 = \sim {}^1/_{100}$.

Naturally in most watercourses, where the flow is due to the slope only, the kineticity will be lower and the jump of the undulate type. This will explain the rather confusing results obtained at times through experiments; and also why certain observers (Bélanger in his earlier works, Rühlman, etc.) were led to ignore losses in the jump entirely, determining the relation between the conjugated depths from the Bernoulli equation.

V—The Jump Below a Sluice in Engineering Practice

There are a number of important cases where the chart of Fig. 9 and the related equations may be directly applied. In such practical computations, the head to which the elements of the jump are to be referred when using the chart should be the energy head $\epsilon_1 = d_1 + v_1^2/2g$ at (1) in Fig. 7. This head is less than H, determined by the level A by

$$h_w = (1 - \varphi^2)(H - d_1)$$

where φ is the velocity coefficient in the efflux formula (see Fig. 12).

(a) *Free or Submerged Efflux?* (Fig. 12.) Given the positions of levels A and B, the discharge and all other circumstances will depend on whether the outflow is submerged under a working head Z, or whether, by reason of a jump, the efflux becomes free, with a working head $H - d_1$. The discharge in free outflow is obviously greater. So is the erosive action of the outflowing water. The form of flow will depend on whether d_B as determined by level B is larger or smaller than the depth d_2, conjugated to d_1 through the jump.

(b) *The Jump as an Annihilator of Energy.* In passing excess water through a sluice or over a spillway, the problem often is to annihilate excess energy in order to reduce erosive action in the tailrace. The jump appears to be an efficient means for this purpose.[9] The quantity of energy annihilated in the jump per unit of time is equal to

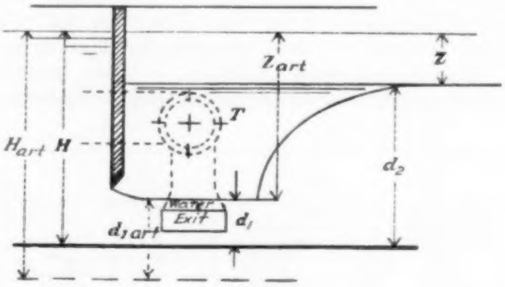

FIG. 13

$$w = \Delta . q . (\epsilon_1 - \epsilon_2) \text{ ft-lb. per sec.}$$

where Δ is the specific gravity of the liquid. By multiplying the respective values of the chart, Fig. 9, one may obtain the reduced value of

$$w' = q'(1 - \epsilon_2') \qquad [17]$$

As shown in the chart, w' maximum is equal to 0.345 and occurs at $d_1' = 0.15$, corresponding to $\kappa_1 = 11.3$. Thus the maximum possible dissipation of energy which may be effected by means of a jump per unit width of flow is $0.345 \times \Delta \times H^{3/2} = 21.5$ $H^{3/2}$ ft-lb. per sec.

(c) *The Jump as a Fall Increaser* (Fig. 13). The jump has been suggested as a "fall increaser," to cope with the reduction of head in power plants during periods of high water.[10] In Fig. 13 the natural fall Z is increased to Z_{art} by letting the turbines T discharge into the pool ahead of the jump.

With $Z = H - d_2$ given, the greatest possible increase of the head will correspond to the maximum value of

$$\frac{d_2 - d_1}{H - d^2} = \frac{d_2' - d_1'}{1 - d_2'} = A' \qquad [18]$$

Fig. 9 shows that this maximum is reached at $d_1' = 0.35$ with $A'_{max} = 2.20$. However, between $0.25 < d_1' < 0.40$, the value of A' is > 2, so that within these limits the fall may be increased at least three times. To obtain the required d_1' =

---

[8] It is due to this uncertainty that the curves of Fig. 5 are not extended below $\kappa = 3$.

[9] Technical Reports, Part III, Miami Conservancy District, 1917; Rehbock, Proc. Intl. Congress Appl. Mech., Delft, 1925; *Bau Ingenieur*, 1928; etc.

[10] Saugey, *Z.V.D.I.*, 1906.

$(d_1/H)_{\text{art}}$ with a given Z, it is usually incumbent to lower the sluice bottom.

VI—The Jump at the Foot of a Weir

Fig. 14 refers to the important practical case of a jump at the foot of a weir. Depending on the stage of level B, the tail water may either "cover" the nappe falling from the dam ($B' - b'$), or, if the depth t is small, it may be repelled by a jump $b''B''$ (toe roll). In this case the flow is free. The erosive action may become dangerous.

The question is identical with one investigated by Bazin,[11] who distinguished between "nappes covered by tail water" (*Nappes couvertes par le reflux d'aval*) and "free nappes with a removed jump" (*Nappes libres a ressaut éloigné*). Guided merely by experimental observations, the great hydraulist suggested that the presence of that or another form of flow depends on the value of Z/p, the quotient of the "step" between the levels by the height of the weir. The value of Z/p, which divides the two possible forms, was found by Bazin to be practically constant and equal to $(Z/p)_0 = 0.75$. Steps above $0.75p$ are expected to produce free nappes, independently of whether the weir is "submerged" or not in the customary sense of the word. The opposite is the case for $Z/p < 0.75$.

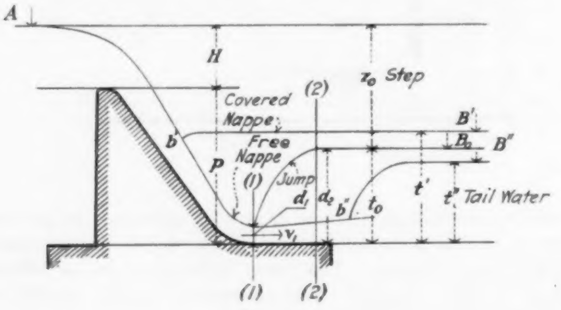

FIG. 14

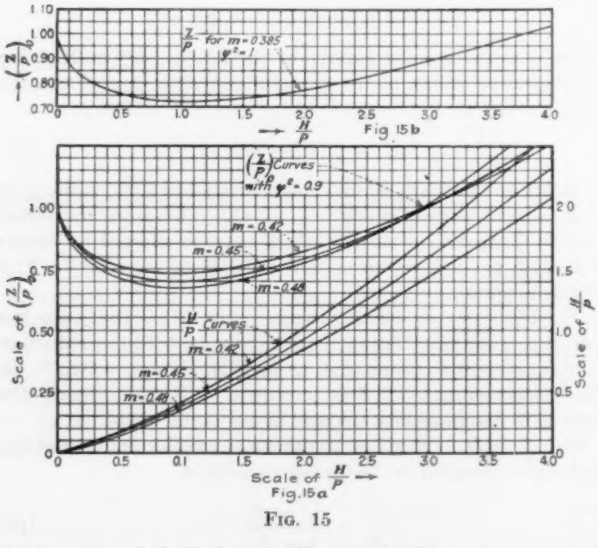

Fig 15b

Fig.15a

FIG. 15

Bazin's deductions are fully substantiated by theoretical analysis. In fact, returning to Fig. 14, it is evident that free or covered flow will depend on whether the tail-water depth t is above or below the depth d_2, conjugated through the jump to the depth d_1, which is the depth of free flow at the foot of the dam.

A more detailed analysis of the case is given in Appendix No. 2. The value of $(Z/p)_0$ is there proved to be dependent on the value of the coefficient of discharge over the weir m and the velocity coefficient φ, which takes account of the losses of energy between the pool A and section (1) at the foot of the structure.[12]

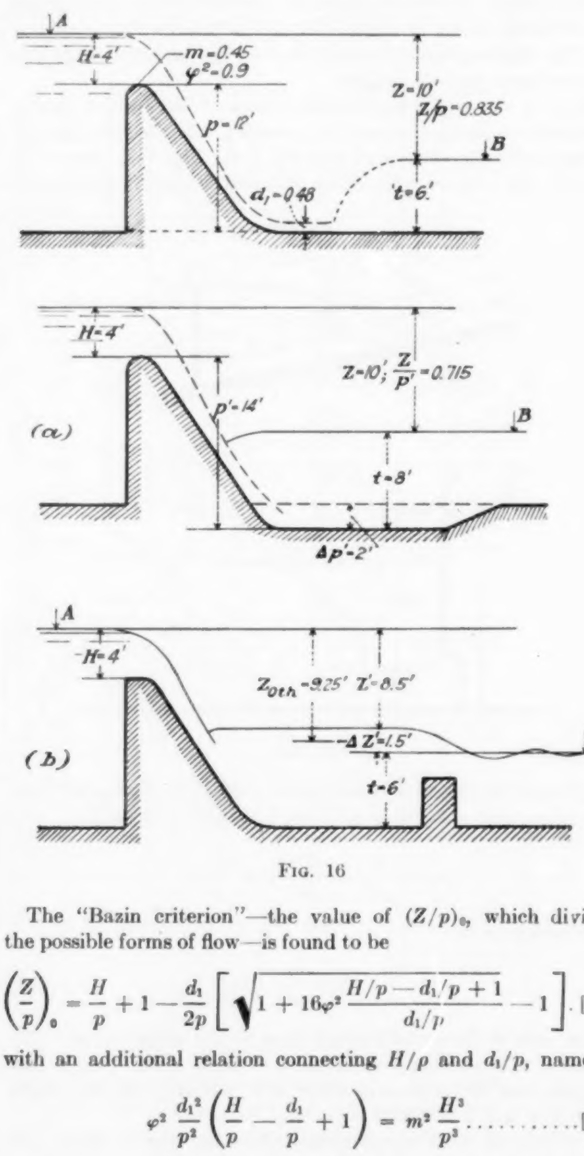

FIG. 16

The "Bazin criterion"—the value of $(Z/p)_0$, which divide the possible forms of flow—is found to be

$$\left(\frac{Z}{p}\right)_0 = \frac{H}{p} + 1 - \frac{d_1}{2p}\left[\sqrt{1 + 16\varphi^2\,\frac{H/p - d_1/p + 1}{d_1/p}} - 1\right]. \quad [19]$$

with an additional relation connecting H/p and d_1/p, namely,

$$\varphi^2\,\frac{d_1^2}{p^2}\left(\frac{H}{p} - \frac{d_1}{p} + 1\right) = m^2\,\frac{H^3}{p^3} \ldots\ldots\ldots\ldots [20]$$

Fig. 15 gives the values of $(z/p)_0$ and of d_1/p for a series of weir coefficients m with an average value of $\varphi^2 = 0.9$ ($\varphi = \sim 0.95$). The range of the m coefficients selected covers most of the cases which occur in practice. In comparing the curves of Fig. 15 with the figures of Bazin, it should be remembered that Bazin experimented with values of H/p between 0.37 and 1.74. For $m = 0.42$, corresponding to a sharp-edged weir, the respective theoretical values for $(Z/p)_0$ are between 0.73 and 0.78. Moreover, the curves in this region are flat, which explains why Bazin was led to suggest a constant value of $(Z/p)_0 = 0.75$, which is in good accord with the theoretical computations. The curves show, however, that for smaller H/p values (high dams), as well as for larger H/p (weirs of very small height), the limiting values of $(Z/p)_0$ are considerably larger.

---

[11] "Expériences nouvelles," 1898.

[12] *Annales Inst. Polyt.*, St. Petersburg, 1914.

The following example shows the nature of the problems which may be solved by means of the curves of Fig. 15.

Example. Assume in Fig. 16 that $H = 4$ ft., $m = 0.45$, $p = 12$ ft., and the tail-water depth $t = 6$ ft. The relative step $Z/p = 10/12 = 0.83$, which is much in excess of $(Z/p)_0 = 0.77$, corresponding to $H/p = 4/12 = 0.33$ on the curves. The flow, therefore, will be free with $d_1 = 0.04p = 0.48$ ft. Suppose now that in order to diminish erosion the tail water must be brought to submerge the toe; to achieve such purpose, Z/p must be reduced.

(*a*) One way of doing this is to increase p by providing a basin at the foot of the dam. [Fig. 16(*a*).] An additional depth of $\Delta p = 1$ ft. making $p' = 13$ ft. is theoretically sufficient; in fact, H/p' is now $4/13 = 0.31$, requiring that $(Z/p)_0$ be 0.78, while in the present case $Z/p' = 10/13 = 0.77$.

As an additional safeguard, making $\Delta p' = 2$ ft., we obtain $Z/p' = 10/14 = 0.715$ as against the theoretical $(Z/p)_0 = 0.79$.

(*b*) Another way is to reduce Z by inserting a barrier [Fig. 16(*b*)]. To make Z/p equal to the theoretical value of $(Z/p)_0 = 0.77$, Z must be reduced to $0.77 \times 12 = 9.25$. Raising the tail water 1.5–2 ft. and making $Z' = 8.5$–9 ft. would answer all practical purposes.

Appendix No. 1

THE JUMP IN A CANAL OF ANY CROSS-SECTIONAL FORM

THE author has found it expedient to handle this problem in the following manner. Given a prismatic canal of the cross-sectional form shown in Fig. 17 and the discharge Q. Assume the bottom of the canal to be horizontal. The momentum equation applied to the liquid body between sections (1) and (2) gives:

$$\frac{\Delta Q}{g}(v_2 - v_1) = \Delta(a_1 Z_{01} - a_2 Z_{02}) \qquad \ldots\ldots[21]$$

where a_1 and a_2 are the cross-sectional areas corresponding to the conjugated depths d_1 and d_2, while Z_{01} and Z_{02} are the distances of the respective centers of gravity of the cross-sections below the surface of the flowing liquid.

Substituting $v = Q/a$ in Equation [21], it can be written

$$\frac{Q^2}{ga_2} + a_1 Z_{01} = \frac{Q^2}{ga_2} + a_2 Z_{02} \ldots\ldots\ldots\ldots [22]$$

The symmetrical form of [22] shows that the conjugated depths correspond to two equal values $[m(d_1) = m(d_2)]$ of a single function:

$$m(d) = \frac{Q^2}{ga} + aZ_0 \ldots\ldots\ldots\ldots\ldots\ldots [23]$$

which for a given discharge is obviously a function of the depth d only. The function m has two branches, and, further, it is easily shown that it passes through a minimum at the depth corresponding to

$$\frac{Q^2}{g} = \frac{a^3}{b} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [24]$$

analogous to [5], and determining the critical depth.

In Fig. 18 the $m(d)$ curve is traced for a trapezoidal canal of the section there shown for a discharge of $Q = 300$ cu. ft. per sec.

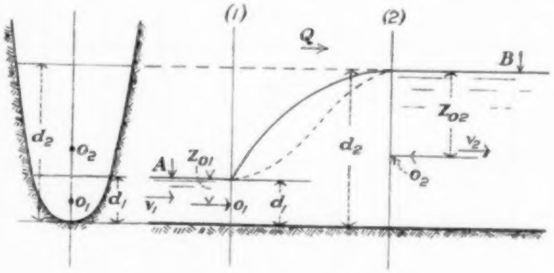

FIG. 17

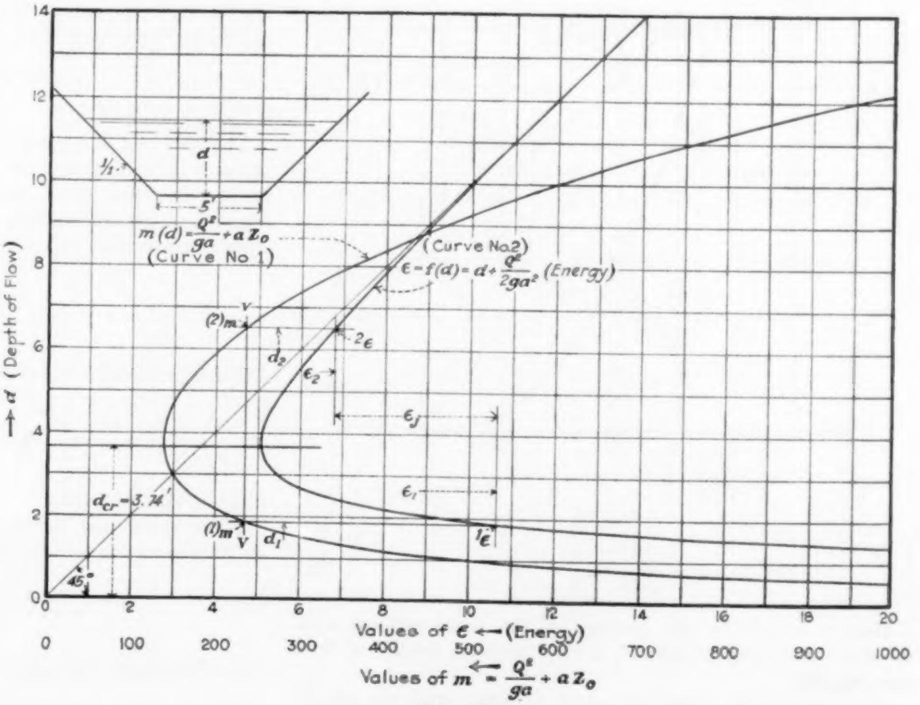

FIG. 18

The points of intersection $(1)_m$ and $(2)_m$ of any vertical v with the two branches of the m-curve determine a pair of conjugated depths d_1 and d_2. By tracing on the same chart the energy curve $\epsilon = f(d)$ (curve No. 2 in Fig. 18), one obtains an idea of the energy balance in the jump. In fact, horizontal lines drawn from $(1)_m$ and $(2)_m$ to intersect with the respective branches of the ϵ-curve determine the specific energies ϵ_1 and ϵ_2 and thus the loss ϵ_j in the jump. Applying the procedure to a series of verticals, one obtains the elements for the curve shown in Fig. 19, which expresses the jump as function of d_1.

It should be noted that the curves given in Fig. 18 and 19 describe the phenomenon for but one given discharge Q. To obtain general characteristics similar to those given for a canal of rectangular section in Figs. 5 and 9, it would be necessary to repeat the procedure for a series of discharges.

The inversion of curvature in the $\frac{\epsilon_1 - \epsilon_2}{\epsilon_1}$ curve in Fig. 19 implies the existence of two zones, similar to Fig. 9, corresponding to a direct and an undulatory form of the jump.

Kinetic Flow Factor. The value of the kinetic flow factor at the critical depth, because of [24], is

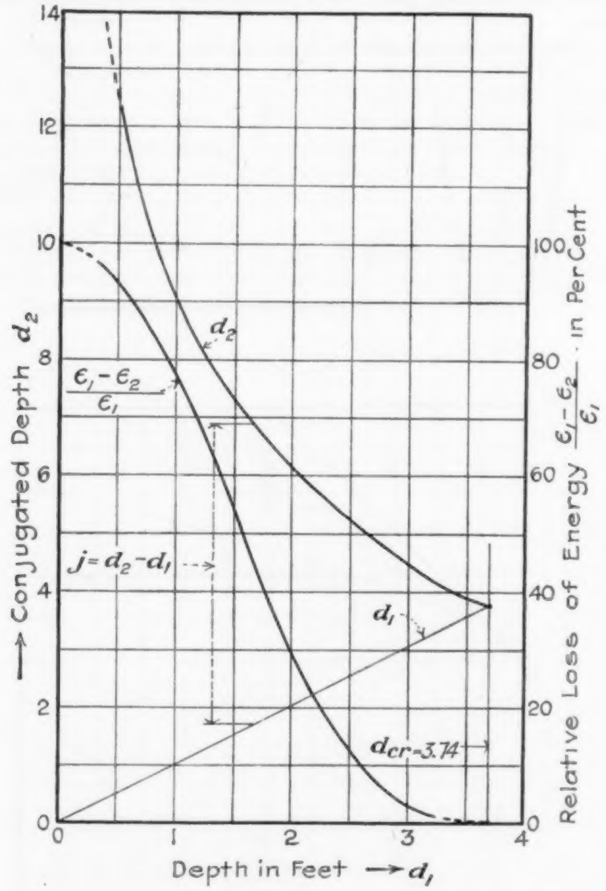

FIG. 19

$$\kappa_{cr} = \frac{Q^2}{ga^2d} = \frac{a}{b}\cdot\frac{1}{d} = \frac{\delta}{d} \quad \text{[25]}$$

Here $\delta = a/b$, or the quotient of the cross-sectional area divided by the top breadth b, is the "average depth" of flow (see Fig. 20).

For open canals, where the width increases with the depth, $\delta = a/b$ is always $< d$; hence the kinetic flow factor at the critical depth is < 1, or less than the kinetic factor in a rectangular canal.

Appendix No. 2

THE JUMP AT THE FOOT OF A WEIR

WITH reference to Fig. 14, assuming that H is the head over the weir, corrected for the velocity of approach, we have for section (1)

$$\left.\begin{aligned} &\text{Velocity:} && v_1 = \varphi\sqrt{2g(H + p - d_1)} \\ &\text{Discharge:} && q = \varphi d_1\sqrt{2g(H + p - d_1)} \end{aligned}\right\} \quad \text{[26]}$$

On the other hand, for the weir

$$q = m\sqrt{2g}\,H^{3/2} \quad \text{[27]}$$

Designating

$$\frac{H}{p} = x; \quad \frac{d_1}{p} = y \quad \text{[28]}$$

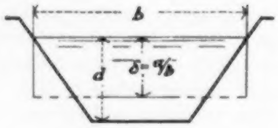

FIG. 20

and eliminating q between [26] and [27],

$$\varphi^2y^2(x - y + 1) = m^2x^3 \quad \text{[29]}$$

which is Equation [20], giving the relation between H/p and d_1/p_1.

The kineticity in section (1) is

$$\kappa_1 = 2\frac{v_1^2/2g}{d_1} = 2\varphi^2\frac{H + p - d_1}{d_1} = 2\varphi^2\frac{x - y + 1}{y} \quad \text{[30]}$$

The depth d_2 conjugated to d_1 through the jump, because of [11], is

$$d_2 = \frac{d_1}{2}\left[\sqrt{1 + 16\varphi^2\,\frac{x - y + 1}{y}} - 1\right] \quad \text{[31]}$$

Obviously the flow at section (1) will be free or covered by the tail water, depending on whether the depth

$$t = H + p - Z \quad \text{[32]}$$

is less or greater than d_2.

The lower the tail-water level (t_2'' in Fig. 14), the farther the distance to the repelled jump. As t increases, the jump moves toward the dam, until with $t_0 = d_2$ the limiting condition is reached. This corresponds to a dividing value of the step Z_0 which answers the requirements of the equation

$$t_0 = H + p - Z_0 = \frac{d_1}{2}\left[\sqrt{1 + 16\varphi^2\frac{x - y + 1}{y}} + 1\right] \quad \text{[33]}$$

Dividing by p and rearranging,

$$\left(\frac{Z}{p}\right)_0 = x + 1 - \frac{y}{2}\left[\sqrt{1 + 16\varphi^2\left(\frac{x - y + 1}{y}\right)} - 1\right] \quad \text{[34]}$$

which is Equation [19].

When computing the curves of Fig. 15, a procedure which avoids solving the cubic equation is to put

$$\frac{x}{y} = \frac{H}{d_1} = \xi \quad \text{and} \quad \frac{1}{y} = \frac{p}{d_1} = \eta$$

which transforms [30] into

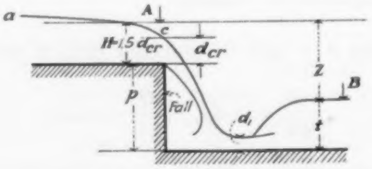

FIG. 21

$$\eta = 1 - \xi + \frac{m^2}{\varphi^2}\xi^3$$

By assuming a series of ξ values, we compute in each case η; then $y = 1/\eta$ and $x = \xi/\eta$.

The curve $m = 0.385$; $\varphi = 1$ [Fig. 15(*a*)], is specifically intended for appraising conditions at the foot of a "fall" (Fig. 21), as used in irrigation and other engineering practice. The surface in the canal approaches the fall by means of a drop curve *ac*, crossing the critical depth in the immediate vicinity of the edge. For a cross-section of rectangular shape the critical depth is $\sqrt[3]{q^2/g}$ and the energy head $\epsilon = 1.5\sqrt[3]{q^2/g}$. The flow over the fall may be treated as a streaming over a broad-crested weir, with the ideal discharge coefficient $m = 0.385$ and a head $H = 1.5\sqrt[3]{q^2/g}$.

Under such assumptions Equations [29] and [34] are directly applicable. The step Z is to be computed as

$$Z = p + H - t = p - t + 1.5\sqrt[3]{q^2/g}$$

By assuming $\varphi = 1$, we disregard the small losses in the falling nappe and add to the safety of the design.

Discussion

O. G. Tietjens.[13] For those who are not so well acquainted with the notation used in hydraulics, it may be pointed out that Equation [1] and the "specific energy diagram" presented in the paper are nothing more than the usual Bernoulli equation. However, it may be emphasized that Equation [1] and all the conclusions derived from it hold only if the curvature of the river bed and of the water surface are small enough so that the centrifugal forces of the water can be neglected; otherwise, the assumption made with respect to the uniformity of the velocity distribution over the cross-section does not hold.

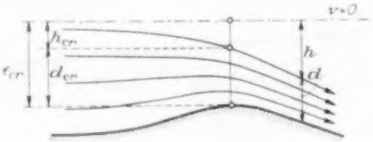

Fig. 22

Figs. 1 and 2 would possibly have been made clearer by giving a picture such as Fig. 22, showing the varying depth d and the corresponding variation of the water surface.

According to the Bernoulli equation, it is simply

$$h = \frac{v^2}{2g}$$

or

$$h + d = \epsilon = d + \frac{v^2}{2g} \quad\text{[35]}$$

This equation is identical with Equation [1] of the paper and shows at the same time the physical meaning of ϵ.

Assuming a rectangular cross-section of the channel, we have

$$Q = bd\sqrt{2gh} \quad\text{or}\quad d = \frac{Q}{b\sqrt{2gh}}$$

where b is the constant width of the channel. This, together with Equation [35], gives

$$\epsilon = h + \frac{Q}{b\sqrt{2gh}} \quad\text{[36]}$$

In the lower part of Fig. 23, ϵ is plotted as a function of h according to Equation [36].

Setting

$$\frac{\partial\epsilon}{\partial h} = 0$$

Equation [36] gives

$$\left.\begin{aligned} \epsilon_{cr} &= \frac{3}{2}\sqrt[3]{\frac{Q^2}{b^2g}} \\ \text{for}\quad h &= \frac{1}{2}\sqrt[3]{\frac{Q^2}{b^2g}} = \frac{d}{2} \end{aligned}\right\} \quad\text{[37]}$$

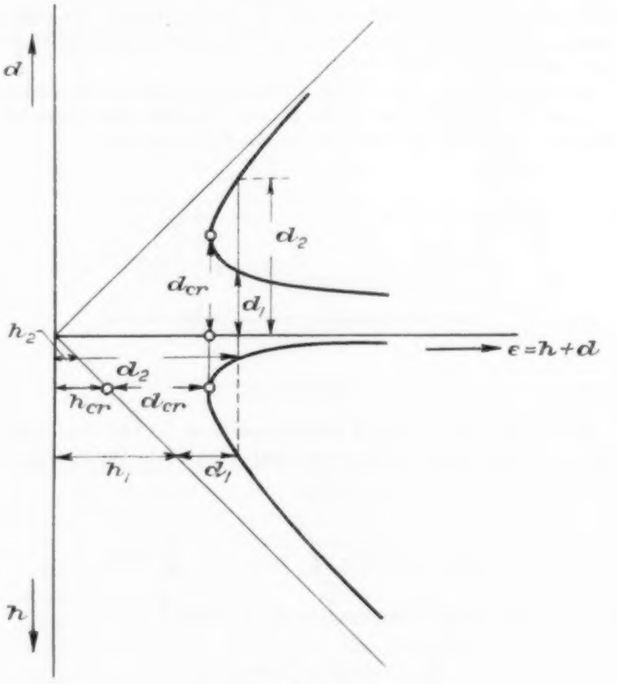

Fig. 23

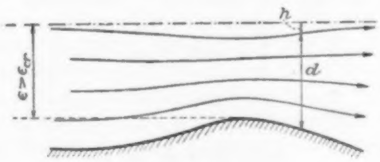

Fig. 24

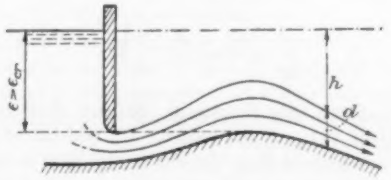

Fig. 25

This equation has the following physical significance: A certain height $\epsilon [= \epsilon_{cr}]$ of the water level over the weir is necessary to carry a certain quantity of water Q through a channel of the width b.

Fig. 1 of the paper can easily be obtained from Fig. 23 by plotting the ordinates ϵ corresponding to certain values of h as a function of $\epsilon - h = d$, as is done in the upper part of Fig. 23.

According to Fig. 23, for a water level higher than the critical as determined by Equation [37], two values of h and d are possible. Two types of flow which are possible in this case are shown in Fig. 24 and Fig. 25. In Fig. 22, the height of the water level ϵ has just the critical (i.e., minimum) value. In this case d is twice as large as h, and therefore the velocity

---

[13] Research Laboratories, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

$$v = \sqrt{2gh} = \sqrt{gd}$$

This value is equal to the velocity of propagation of tidal waves of water depth d. However, since any intumescence can penetrate against the direction of flow only if the velocity of the flow is less than the velocity of wave propagation, we see that any intumescence becomes more or less abrupt at the point where the velocity of flow reaches the wave velocity. In other words, a hydraulic jump is only possible where the velocity of flow reaches the wave velocity.

An expression for the loss of energy due to hydraulic jumps is given in Equation [13] of the paper. Another expression for this loss can easily be obtained in the following way:

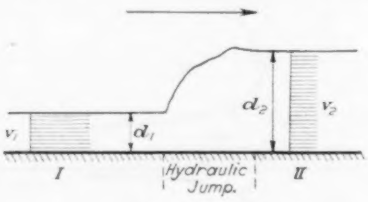

FIG. 26

In Fig. 26, the change of momentum from I to II (i.e., mass times the difference in the velocities) is equal to the resultant force:

$$Q \frac{\gamma}{g} (v_1 - v_2) = \gamma \int_0^{y = d_2} bydy - \gamma \int_0^{y = d_1} bydy$$

or for a rectangular cross-section (b = const.)

$$\frac{Q}{b} (v_1 - v_2) = \frac{g}{2} (d_2^2 - d_1^2)$$

In connection with the equation of continuity:

$$\frac{Q}{b} = v_1 d_1 = v_2 d_2$$

we therefore obtain

$$\left.\begin{aligned} \frac{v_1^2}{2g} &= \frac{d_2 + d_1}{4} \cdot \frac{d_2}{d_1} \\ \text{and} \quad \frac{v_2^2}{2g} &= \frac{d_2 + d_1}{4} \cdot \frac{d_1}{d_2} \end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots\ldots [38]$$

Incidentally, these two Equations [38] are identical with the Equations [3] or [11] of the paper. If, instead of an abrupt transition, it is assumed that the change in level is continuous, the increase of the water depth would be according to the Bernoulli equation

$$d_2' - d_1 = \frac{v_1^2 - v_2^2}{2g}$$

where d_2' is of course larger than d_2. The difference $d_2' - d_2$ thus represents the loss of energy:

$$d_2' - d_2 \equiv d_2' - d_1 - (d_2 - d_1) = \frac{v_1^2 - v_2^2}{2g} - d_2 + d_1$$

or in connection with Equation [38]

$$d_2' - d_2 = \frac{d_2 + d_1}{4} \left(\frac{d_2}{d_1} - \frac{d_1}{d_2}\right) - d_2 + d_1$$

or

$$d_2' - d_2 = \frac{(d_2 - d_1)^3}{4 d_1 d_2} = \text{loss due to hydraulic jump} \ldots [39]$$

A similar expression containing the velocities instead of the water depths can be obtained in the same way:

$$\frac{(v_1 - v_2)^3}{2g(v_1 + v_2)} = \text{loss due to hydraulic jump} \ldots\ldots [40]$$

This derivation of the loss due to hydraulic jumps is not much shorter than that given in the paper. However, this derivation has an advantage in that it expresses the *physical* aspect of the problem in a clearer manner than does the more elegant method used by the author.

In this connection it may be of interest to refer to results which can easily be obtained by a discussion of the well-known banking-curve equation.

Starting from the Eulerian equation

$$\frac{v}{g} \frac{dv}{ds} + \frac{dh}{ds} + \frac{1}{\gamma} \frac{dp}{ds} + \lambda \frac{1}{t} \frac{v^2}{2g} = 0$$

in which the last term is added to take into account the resistance of flow, the equation of the banking curve can easily be derived by assuming that the angle (α) in Fig. 27 is small enough to permit neglecting the difference between dx and ds. In the following figures α is exaggerated. The relation between the changing of the depth t in the direction of flow (i.e., dt/dx) and the slope dy/dx is then given by the equation

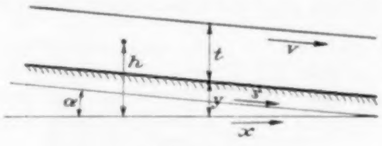

FIG. 27

$$\frac{dt}{dx} \left[1 - \left(\frac{v}{c}\right)^2\right] = - \left[\frac{dy}{dx} + \frac{\lambda}{2} \left(\frac{v}{c}\right)^2\right] \ldots\ldots [41]$$

where $c = \sqrt{gt}$ and $y = f(x)$ is the contour of the river bed.

Assuming a constant slope $-dy/dx = S_0$ and replacing v by Q/bt and c^2 by gt, Equation [41] can be integrated:

$$dt \cdot \frac{1 - \frac{A}{t^3}}{S_0 - \frac{\lambda}{2} \frac{A}{t^3}} = dx$$

where $A = Q/bg$ for the sake of simplicity.

Or

$$\frac{t^3 - A}{S_0 \frac{2}{\lambda} t^3 - A} dt = \frac{\lambda}{2} dx \ldots\ldots\ldots\ldots\ldots [42]$$

Assuming a slope S_0 less than $\lambda/2$, the variation of the depth t with x is shown in Fig. 28. For values less than the critical depth corresponding to a velocity equal to $c = \sqrt{g t_{cr}}$ it may be noted that the depth increases rapidly up to the critical value t_{cr}. The continuation of this line (marked as a dotted line) has no physical meaning. There is one line for each slope S_0 which corresponds to a steady motion (v = const.); this line approaches the line corresponding to the velocity equal c as S_0 approaches $\lambda/2$. For velocities smaller than that of steady flow, the upper line shows the increase of the depth with x. Fig. 29 shows a way in which a water level as determined by Fig. 28 can actually occur.

Assuming a slope S_0 larger than $\lambda/2$ we obtain Fig. 30. It is seen in this figure that the depth of steady flow is less than that corresponding to a velocity equal c. Fig. 31 shows that the flow below a sluice assumes quite a different appearance from that in Fig. 29 if the slope exceeds the critical value $\lambda/2$.

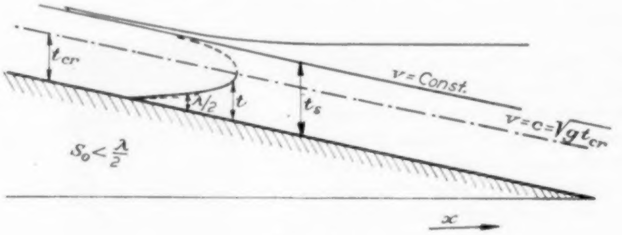

Fig. 28

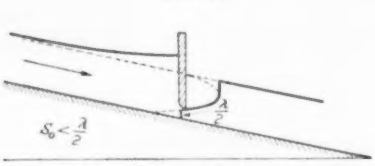

Fig. 29

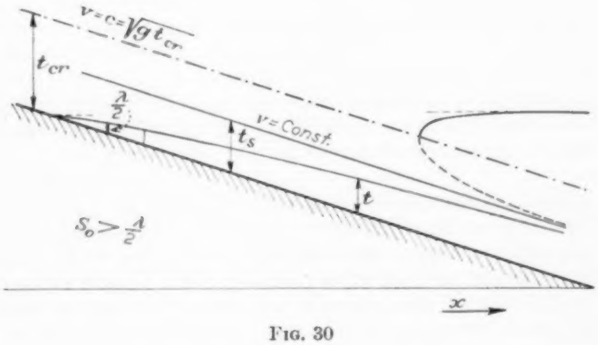

Fig. 30

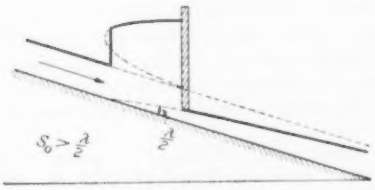

Fig. 31

This method of representing the behavior of the water flow so far as the hydraulic jump is concerned does not give any information about the jump itself. However, it may contribute a little to the understanding of these phenomena.

Finally, it may be of interest to mention the analogy between the hydraulic jump and the compression shock in the flow of gases through nozzles.[14] The critical velocity for water corresponds to the velocity of wave propagation just as the critical velocity of a gas corresponds to the acoustic velocity.

Author's Closure

The profession owes it to Dr. Tietjens for bringing the discussion back to fundamentals.

Naturally the expression of specific energy, as given in Equation [1], is similar in form to the so-called Bernoulli equation; for both the Bernoulli equation and the specific energy Equation [1] represent energy carried by a unit weight of the flowing liquid.

There is, nevertheless, an essential difference. The Bernoulli equation features the principle of conservation of energy applied to a single streamline or, in the case of parallel open flow, to the movement as a whole. The energy in this case is referred to a horizontal datum line *O-O* in Fig. 32, the equation describing the energetic "history" of the moving fluid with regard to such datum line.

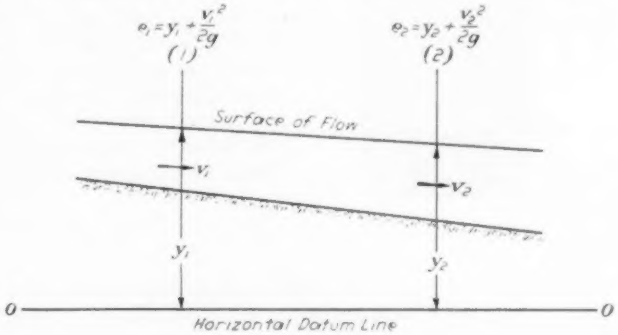

Fig. 32

The purpose of the specific energy diagram (Fig. 1) is to describe the energetic conditions in a cross-section as such. It characterizes the *state* of flow under varying stages. The energy is referred to a datum line which passes through the bottom of the channel cross-section. When the canal is laid with a bottom slope, the position of the datum line in two cross-sections will be at different levels.

The lower part of Fig. 23 is the specific energy diagram, traced as a function of the kinetic energy head. The two possible forms of movement, illustrated by Figs. 24 and 25, may be derived from the specific energy diagram (Fig. 1) by drawing a vertical (ϵ const) to intersect with the two branches of the energy curve. The points of intersection will determine the two depths—one in the zone of tranquil flow and the other in the zone of rapid flow—which will be the two possible ways in which the given discharge may flow with an energy content, determined by the distance of the vertical line from the zero point.

The specific energy diagram (Fig. 1) describes the change of energy for a given discharge Q. Dr. Tietjens' most interesting analysis implies the assumption of ϵ constant. Supplementing his presentation, one may determine the different discharges:

$$q = d \cdot v = d\sqrt{2gh} = d\sqrt{2g(\epsilon - d)} = (\epsilon - h)\sqrt{2gh}$$

which will carry the given ϵ. In general, to every discharge there will correspond two sets of depths and connected velocities, except for the critical depth, at which the discharge will be a maximum. This method has been extensively used by the late Professor Koch of Darmstadt (see "Koch-Carstanjen, "Bewegung des Wassers," Berlin, 1926). Featuring the critical depth as the one at which the discharge for a given energy content is a maximum is customary also in American hydraulic literature.[15]

[14] O. G. Tietjens, "Flow of Gases at a Rate Exceeding the Acoustic Velocity," Trans. A.S.M.E., Applied Mechanics Division, January-April, 1931, vol. 53, no. 3.

[15] See discussion by Bakhmeteff in Proc. A.S.C.E., February, 1931.

Certain historical remarks might be of interest in connection with the topics referred to in Dr. Tietjens' discussion. The reasoning, leading to the determination of the loss in a hydraulic jump, as presented in Equation [39], was developed by Bélanger in the 1840s' and since has been customary with French hydraulicians; see, for example, Flamant, "Hydraulique," 1923, p. 133.

The different surface curves in varied flow (Figs. 28–31) were first presented in systematic form by the Belgian engineer and professor, M. Boudin. ("Annales Trav. Pub. de Belgique," T. XX, 1861–62.)

The bottom slope designated in Equation [42] by Dr. Tietjens as $\lambda/2$ is the so-called critical slope at which the depth of uniform movement becomes identical with the critical depth. The critical slope divides all possible bottom slopes into "mild" slopes ($s_0 <$ critical) and "steep" slopes ($s_0 >$ critical).

The distinction, with the characteristics of flow in each case, was made clear by St. Venant (1851) and further developed by Boussinesq ("Essai sur la théorie des eaux courantes," Paris, 1877; "Théorie de l'écoulement tourbillonant et tumultueux," Paris, 1897).

APM-54-2

Analysis of Stresses in Circular Plates and Rings

With Application to Cylinders With Rigidly Attached Flat Heads and Flanges

By E. O. HOLMBERG[1] and KARL AXELSON,[2] MILWAUKEE, WIS.

E. O. Holmberg

While the fundamental theory for calculating stresses in circular plates is well known, it has not been employed generally by engineers because of its complexity. In the present paper the authors present a simplified method for calculating the stresses in flat, circular plates, with or without a hole in the center, the loads being applied in any manner provided they are uniformly distributed in circles concentric with the edges. They also discuss the stresses in a hollow cylinder having rigidly attached flat heads, and give a method of calculating stresses in cylinders with rigidly attached flanges.

Karl Axelson

ALTHOUGH the fundamental theory for calculating stresses in circular plates is well known, it has not been employed to any great extent by the engineer, being considered too complicated for practical use. Lately, however, increased attention has been given to this subject and several attempts have been made to simplify the problem.

In May, 1927, in Mechanical Engineering, Prof. E. O. Waters and J. Hall Taylor published a method for determining stresses and deflections in pipe flanges in strict accordance with the theory of elasticity. The deflection formulas were checked by a series of tests.

In developing his formulas Professor Waters made the assumption "that the proportions of commercial flanges are such that the bolt load is applied near the outer edge and the pipe load near the inner edge." This assumption limits the exact application of these formulas to cases where the flanges are loaded as stated above.

Messrs. A. H. Wahl and J. Lobo, Jr., in their paper on stresses in circular plates in Trans. A.S.M.E. Applied Mech. Section, Jan.-April, 1930, in deriving their simplified formulas for various loading conditions make similar assumptions, treating cases where the loads are applied either at the extreme edge of the plate or uniformly distributed over the whole surface thereof.

Part I of the present paper will show a method for calculating the stresses in flat, circular plates with or without hole in the center without making the aforementioned assumptions. The loads may be applied in any manner, the only condition being that they are uniformly distributed in circles concentric with the edges. In Part II are treated the stresses in a hollow cylinder with rigidly attached flat heads. Part III presents a method of calculating stresses in cylinders with rigidly attached flanges.

I—CALCULATION OF STRESSES IN FLAT, CIRCULAR PLATES WITH OR WITHOUT CENTRAL HOLES

Referring to Fig. 1, the following symbols are used:

h = thickness of plate
x = distance from center of plate to point under consideration
φ = slope of plate at radius x due to elastic deformation
z = distance from neutral surface to point under consideration

Further

σ_t = tangential or hoop stress
σ_r = radial stress
$\frac{1}{m}$ = Poisson's ratio
E = modulus of elasticity

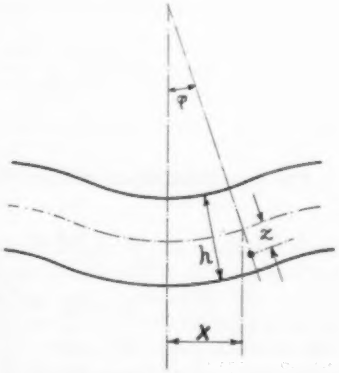

Fig. 1

For various loading conditions of the plate the following differential equations may be set up:

A—For uniformly distributed load (over area a, Fig. 2):

$$\frac{d^2\varphi}{dx^2} + \frac{1}{x}\frac{d\varphi}{dx} - \frac{\varphi}{x^2} + Nx = 0 \quad \ldots\ldots\ldots\ldots [1]$$

where $N = \frac{6(m^2 - 1)}{m^2} \times \frac{p}{Eh^3}$ and p = pressure per unit area.

Contributed by the Applied Mechanics Division and presented at the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

B—For a single force in center or load uniformly distributed in a circle (over area b in Fig. 2):

$$\frac{d^2\varphi}{dx^2} + \frac{1}{x}\frac{d\varphi}{dx} - \frac{\varphi}{x^2} + \frac{S}{x} = 0 \ldots\ldots\ldots\ldots [2]$$

where $S = \frac{6(m^2 - 1)}{\pi m^2} \times \frac{P}{Eh^3}$ and P = total load.

C—For part of plate where no shearing forces occur (area c in Fig. 2):

$$\frac{d^2\varphi}{dx^2} + \frac{1}{x}\frac{d\varphi}{dx} - \frac{\varphi}{x^2} = 0 \ldots\ldots\ldots\ldots [3]$$

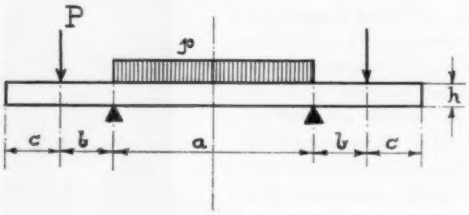

FIG. 2

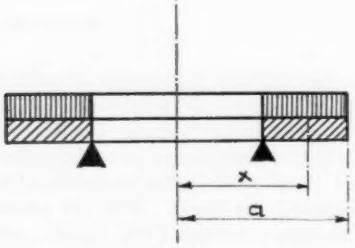

FIG. 3

$$\varphi = C_1x + \frac{C_2}{x} - \frac{N}{8}x^3 + \frac{Na^2}{2}x \log_e x$$

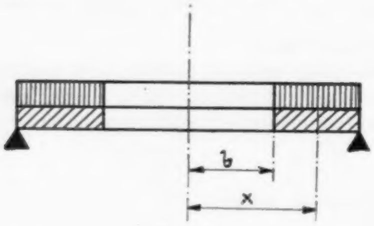

FIG. 4

$$\varphi = C_1x + \frac{C_2}{x} + \frac{N}{8}x^3 - \frac{Nb^2}{2}x \log_e x$$

The general solutions of these differential equations are:

$$\varphi = C_1x + \frac{C_2}{x} - \frac{N}{8}x^3 \ldots\ldots\ldots\ldots [1a]$$

$$\varphi = C_3x + \frac{C_4}{x} - \frac{S}{2}x \log_e x \ldots\ldots\ldots\ldots [2a]$$

$$\varphi = C_5x + \frac{C_6}{x} \ldots\ldots\ldots\ldots [3a]$$

where the integration constants C_1 to C_6, inclusive, may be determined from the conditions at the edges of the plate.

Loading conditions may be assumed for which none of the three equations given holds true. Two such cases are illustrated in Figs. 3 and 4. The respective equations are given in the figures.

If it is desired to find the linear deflections the operation

$$y = \int \varphi dx + C$$

has to be performed and the constant C determined by the conditions at the edges.

While all of the above formulas are well known, they are derived here for completeness and as an introduction to what follows.

The application of these formulas will now be shown for two specific cases.

(a) LOOSE PIPE FLANGE LOADED WITH BOLT LOAD AND GASKET LOAD ONLY

Referring to Fig. 5: From a to a_0, Equation [3a] holds; from a to b, Equation [2a] holds; and from b to d, Equation [3a] holds.

Applying these equations, the six constants are determined by the following conditions:

$\sigma_r = 0$ for $x = a_0$ and $x = d$

φ and $d\varphi/dx$ are continuous for $x = a$ and $x = b$.

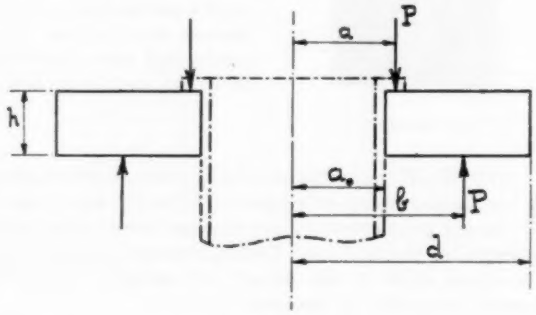

FIG. 5

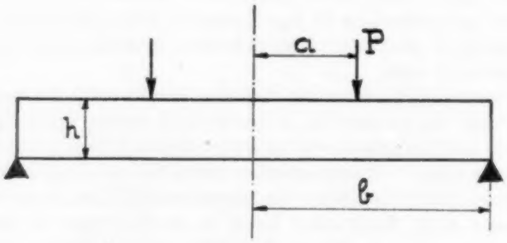

FIG. 6

The maximum stress is a hoop stress, occurs at the corners for $x = a_0$, and is given by

$$\sigma_t = \frac{3}{2\pi} \times \frac{P}{h^2(d^2 - a_0^2)}\left[\frac{m-1}{m}(b^2 - a^2) + \frac{2(m+1)}{m}d^2\log_e \frac{b}{a}\right]$$

or for $m = 4$,[3]

$$\sigma_t = \frac{1.195P}{h^2(d^2 - a_0^2)}\left[0.3(b^2 - a^2) + d^2 \log_e \frac{b}{a}\right] \ldots\ldots [4]$$

Numerical results obtained from this formula check closely with those evaluated by the use of Professor Waters' formula for flat rings[4] if the relation between a_0 and d is such as is commonly used for commercial flanges. Equation [4], however, is correct for any values of a_0 and d. Waters' formula when applied

---

[3] See "Determination of Poisson's Ratio, Etc.," by Prof. T. McLean Jasper, *Proc. Am. Soc. Testing Materials*, vol. 24, part II, 1924.

[4] Waters' formula for flat rings:

$$\sigma_t = \frac{5.72P(b - a)}{2h^2(d - a_0)}\left[\frac{d^2 \log_{10} \frac{d}{a_0}}{d^2 - a_0^2} + 0.117\right]$$

to a case where a_0 is small in relation to d gives too high values for σ_t. Equation [4] is therefore far more general and just as simple to apply.

(*b*) FLAT PLATE SUPPORTED ALONG THE OUTER EDGE AND LOADED BY A CONCENTRIC LOAD *P*

Referring to Fig. 6: From $x = 0$ to $x = a$, Equation [3a] holds; and from $x = a$ to $x = b$, Equation [2a] holds.

The equation for the maximum stress is obtained in similar manner as before. This stress occurs in the center of the plate and is

$$\sigma_0 = \frac{0.5975P}{h^2}\left[0.3\,\frac{b^2 - a^2}{b^2} + \log_e \frac{b}{a}\right] \quad\ldots\ldots\ldots [5]$$

If in Equation [4] a_0 is set equal to zero and $d = b$—in other words, if the plate is pierced in the center by a very small hole—the stress becomes

$$\sigma_t = \frac{1.195P}{h^2}\left[0.3\,\frac{b^2 - a^2}{b^2} + \log_e \frac{b}{a}\right] \quad\ldots\ldots\ [4a]$$

A comparison of Equations [5] and [4a] shows that if a plate is pierced by a small hole in the center, the maximum stress in the plate is theoretically twice as large as if the plate had been solid. This may be of importance in case the plate is made of brittle material.

II—STRESSES IN A CYLINDER WITH RIGIDLY ATTACHED FLAT HEADS UNDER INTERNAL PRESSURE

Fig. 7 shows a cylinder with rigidly attached flat head. The head may be either cast in one piece with the cylindrical body or attached thereto by welding. Fig. 8 is an exaggerated picture of this cylinder when subjected to internal pressure.

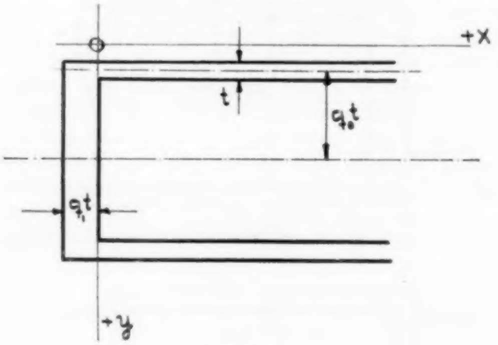

FIG. 7

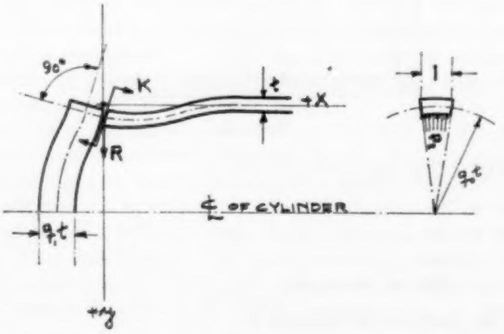

FIG. 8

In deriving the stresses involved, the formulas established in Part I have been used. The cylinder wall has been considered a beam on an elastic foundation. For complete derivation see Appendix No. 2.

Notation:

t = thickness of cylinder wall in inches
q_0t = mean radius of cylinder in inches
q_1t = thickness of head in inches
p = internal pressure, lb. per sq. in.
K = couple acting at junction of head and cylinder per inch of circumference, in in-lb. per inch
R = shearing force at junction of head and cylinder per inch of circumference, lb. per inch.

The stresses influencing design are:

(1) The bending stress in the cylinder wall at the junction with the head:

$$\sigma = \frac{6K}{t^2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots [6]$$

(2) The longitudinal tension stress in the wall:

$$\sigma_l = \frac{q_0}{2}\,p \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots [7]$$

σ_l must be numerically added to σ.

(3) The bending stress at the center of the plate:

$$\sigma_{r0} = \sigma_{t0} = \frac{2}{3q_1}\left(\frac{1.83q_0^2}{q_1}p - \frac{9K}{q_1t^2} - 4.5\,\frac{R}{t}\right) \quad\ldots\ldots\ [8]$$

(4) The radial bending stress at the radius q_0t:

$$\sigma_r = -\frac{6}{q_1^2}\left(\frac{K}{t^2} + \frac{q_1}{2}\,\frac{R}{t}\right) \quad\ldots\ldots\ldots\ldots [9]$$

(5) The tangential bending stress at the same radius:

$$\sigma_t = \sigma_r + 0.5625\,\frac{q_0^2}{q_1^2}\,p \quad\ldots\ldots\ldots\ldots [10]$$

(6) To the stresses evaluated under (4) and (5) must be *numerically* added tension stress due to R:

$$\sigma_r{}' = \sigma_t{}' = \frac{R}{q_1t} \quad\ldots\ldots\ldots\ldots\ldots [11]$$

In the foregoing formulas R and K are found from

$$\frac{R}{tp} = \frac{q_0q_1(6.93q_1^3 + 3.89q_0q_1 + 2.97q_0\sqrt{q_0} + 6.85\sqrt{q_0})}{9.13q_1^4\sqrt{q_0} + 20.78q_1^3 + 23.7q_1^2\sqrt{q_0} + 18q_1q_0 + 5.15\sqrt{q_0}} \quad\ldots\ldots\ldots [12]$$

$$\frac{K}{t^2p} = \frac{R/tp(3q_1 + 2.63q_1^2\sqrt{q_0}) - q_0q_1^2 - 0.5625q_0^2}{2\sqrt{3}\;q_1^2 - 4.5} \quad\ldots\ldots\ [13]$$

In the formula for σ the concentration of stress due to the sharp corner has not been taken into account. This stress concentration is localized over a very small area and cannot affect any of the other stresses evaluated above. In practice it is usual to provide a fillet large enough to reduce this stress concentration to within safe values. A fillet will materially reduce the bending stress σ and slightly reduce the tangential stress σ_t at the virtual edge of the plate, but no efforts have been made to accurately evaluate its influence.

The foregoing is also applicable to the flange treated in Part III.

To facilitate the use of the stress formulas given above the values of R/tp and K/t^2p have been plotted in Figs. 9 and 10 for various values of q_0 and q_1. Their application will now be illustrated by numerical examples.

EXAMPLE 1 (Fig. 11):

$q_0 = 10$
$q_1 = 3$
$t = 1$ in.
$p = 1000$ lb. per sq. in.

From Figs. 9 and 10:

$$\frac{R}{tp} = 3.05 \qquad R = 3050 \text{ lb. per in.}$$

$$\frac{K}{t^2p} = 4.3 \qquad K = 4300 \text{ in-lb. per inch}$$

Stresses in cylinder wall:

From Equation [6], $\sigma = 6 \times 4300 = 25{,}800$ lb. per sq. in.
From Equation [7], $\sigma_l = 5 \times 1000 = 5000$ lb. per sq. in.

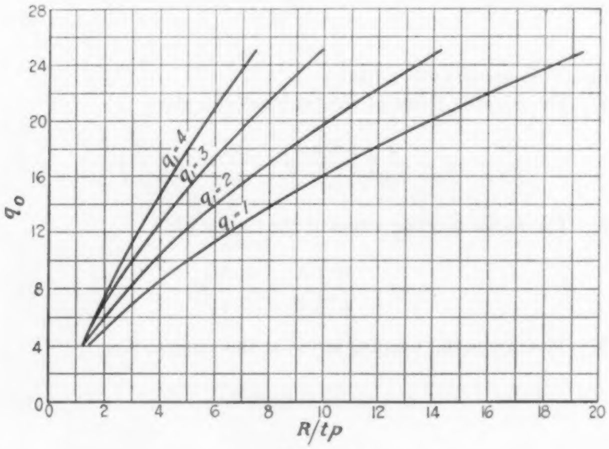

FIG. 9

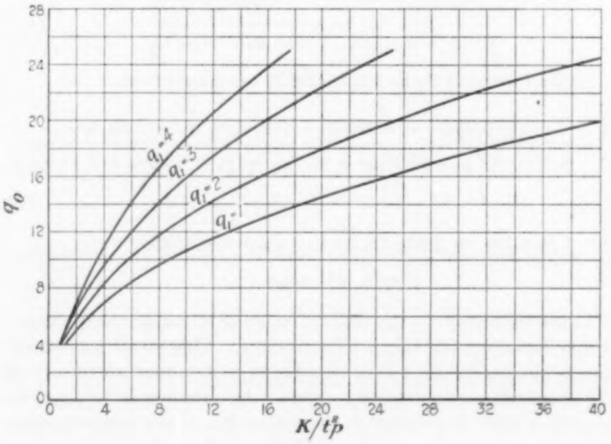

FIG. 10

Total stress in cylinder wall:

$$\sigma + \sigma_l = 30{,}800 \text{ lb. per sq. in.}$$

Stresses in plate:
Bending stress in center. From Eq. [8],

$$\sigma_{r0} = \sigma_{t0} = \frac{2}{3 \times 3}\left(\frac{1.83 \times 10^2 \times 1000}{3} - \frac{9 \times 4300}{3} - \frac{4.5 \times 3050}{1}\right)$$

$$= 7650 \text{ lb. per sq. in.}$$

To this must be added numerically stress due to R. From Eq. [11]:

$$\sigma_r' = \sigma_t' = \frac{3050}{3} = 1016 \text{ lb. per sq. inch, or}$$

Total stress at center of plate:

$$\sigma_{tot} = 8666 \text{ lb. per sq. in.}$$

Bending stresses at virtual edge of plate. From Equations [9] and [10]:

$$\sigma_r = -\frac{6}{3^2}\left(4300 + \frac{3}{2} \times 3050\right) = -5920 \text{ lb. per sq. in.}$$

$$\sigma_t = -5920 + 0.5625 \times \frac{10^2}{3^2} \times 1000 = 330 \text{ lb. per sq. in.}$$

To these must be numerically added as before

$$\sigma' = 1016 \text{ lb. per sq. in.}$$

Total $\sigma_r = 6936$ lb. per sq. in.
Total $\sigma_t = 1346$ lb. per sq. in.

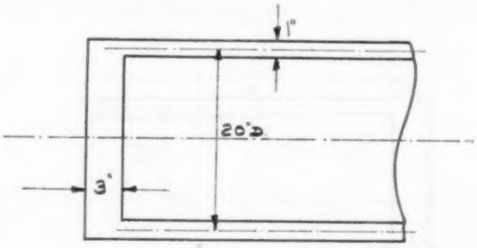

FIG. 11

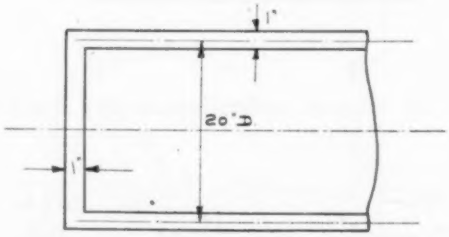

FIG. 12

EXAMPLE 2 (Fig. 12):

$q_0 = 10$
$q_1 = 1$
$t = 1$ in.
$p = 1000$ lb. per sq. in.

From the charts as in Example 1:

$R = 5050$ lb. per inch
$K = 8800$ in-lb. per inch

Stresses in cylinder wall:

$\sigma = 6 \times 8800 = 52{,}800$ lb. per sq. in.
$\sigma_l = 5 \times 1000 = 5000$ lb. per sq. in.

$\sigma + \sigma_l = 57{,}800$ lb. per sq. in.

Stresses in plate:

Bending stresses in center:

$$\sigma_{r0} = \sigma_{t0} = \frac{2}{3}(1.83 \times 10^2 \times 1000 - 9 \times 8800 - 4.5 \times 5050)$$

$$= 50{,}600 \text{ lb. per sq. in.}$$

To this must be added as before

$$\sigma_r' = \sigma_t' = 5050 \text{ lb. per sq. in.}$$

Total stress in center of plate:

$$\sigma_{tot} = 50{,}600 + 5050 = 55{,}650 \text{ lb. per sq. in.}$$

Bending stresses in virtual edge of plate:

$$\sigma_r = -6\left(\frac{8800}{1} + \frac{5050}{2 \times 1}\right) = -68{,}000 \text{ lb. per sq. in.}$$

$$\sigma_t = -68{,}000 + 0.5625 \times 100 \times 1000 = -11{,}700 \text{ lb. per sq. in.}$$

To these stresses must be added numerically as before

$$\sigma' = 5050 \text{ lb. per sq. in.}$$

Total σ_r = 73,000 lb. per sq. in.
Total σ_t = 16,700 lb. per sq. in.

When considering that the tension stress in the cylinder far from the head is only 10,000 lb. per sq. in., the stresses at the junction in both examples are far too high for correct design. This condition may be remedied, as generally is the case in practice, by thickening the wall of the cylinder as the junction is approached. As the bending moment K can be shown to decrease very rapidly with increasing distance from the junction[5] a large fillet will in most cases suffice to decrease the stress to lower values. The examples show that a considerable increase of the thickness of the head also effects a considerable decrease of the bending stress in the cylinder wall. The proportions between thickness of head and cylinder wall, as chosen in Example 1, are evidently fairly close to economical design if a large fillet or a tapering cylinder wall is introduced at the junction. This is particularly important if the cylinder is manufactured of brittle material.

III—STRESSES IN A CYLINDER WITH A RIGIDLY ATTACHED FLANGE

Analysis of the stresses in pipe flanges with high and low hubs have been made during recent years by Professor Waters and others. In the formulas developed, however, the effect of internal pressure has been omitted. With the high pressures sometimes encountered in modern practice it has been felt that their effect has too much influence to be neglected.

The object of the following analysis has not been to develop a simplified formula for calculating pipe flanges, but to furnish a method for figuring extreme cases where large dimensions and high loads make a more accurate formula desirable.

Fig. 13 shows a cylinder with rigidly attached flange which may be either cast integral with or welded to the cylinder. Fig. 14 is an exaggerated picture of the cylinder when subjected to a bolt and gasket load P and an internal pressure p.

Notation:

t = thickness of cylinder wall in inches
q_0t = mean radius of cylinder in inches
q_1t = thickness of flange in inches
q_2t = radius of bolt circle in inches
q_3t = outside radius of flange in inches
p = internal pressure, lb. per sq. in.
P = total bolt load, lb.
K = couple acting at junction of flange and cylinder per inch circumference, in in-lb. per inch
R = shearing force at junction of flange and cylinder per inch circumference, lb. per inch.

The stresses influencing design are:

(1) The bending stress in the cylinder wall at the junction with the flange:

$$\sigma = \frac{6K}{t^2} \quad \text{[14]}$$

(2) The longitudinal tension stress in the cylinder wall σ_l due to internal pressure or external forces. This stress must be *numerically* added to σ.

(3) Maximum radial bending stress in the flange at the virtual inner edge at both faces of the flange. Virtual inner edge = radius q_0t:

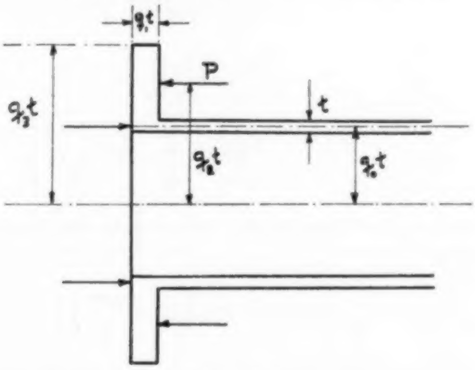

FIG. 13

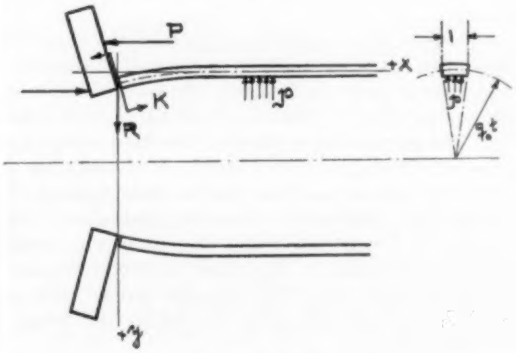

FIG. 14

$$\sigma_{r0} = \frac{6}{q_1^2t^2}\left(K - \frac{q_1t}{2}\dot{R}\right) \quad \text{[15]}$$

(4) To stress σ_{r0} must be *numerically* added stress arising from R and p:

$$\sigma_{rR} = \frac{R}{q_1t} + p \quad \text{[16]}$$

(5) Maximum tangential bending stress, occurring at the same point as σ_{r0}:

$$\sigma_{t0} = \sigma_{r0} + \frac{0.800}{q_1^2t^2(q_3^2 - q_0^2)}\left[q_3^2\left(-15K + 7.5q_1tR\right.\right.$$

---

[5] See Appendix No. 2.

$$\left. + 1.492P \log_e \frac{q_2}{q_0}\right) + 0.4475P\,(q_2^2 - q_0^2)\Bigg] \ldots\ldots [17]$$

(6) To stress σ_{t0} must be *numerically* added tangential stresses arising from radial deformation due to R and p:

$$\sigma_{tR} = \frac{q_1^2}{4}\,T_1 \times \frac{R + q_1 tp}{t} \ldots\ldots\ldots\ldots\ldots [18]$$

In the foregoing formulas R and K are found from

$$R = \frac{\left(q_0 - \dfrac{q_1^3 T_1}{4}\right)(1 + 0.329\sqrt{q_0}\,T_1)\,tp - T_2\left(q_1 + 0.76\sqrt{q_0}\right)\dfrac{P}{t}}{1.315\sqrt{q_0} + T_1\,[q_1^2(1 + 0.0822\sqrt{q_0}\,T_1) + 1.136q_1\sqrt{q_0} + 0.865q_0]} \ldots\ldots\ldots [19]$$

$$K = \frac{(q_1^2 T_1 + 2.63\sqrt{q_0})\,Rt + q_1 T_2 P - \left(q_0 - \dfrac{q_1^3 T_1}{4}\right)t^2 p}{1.5q_1 T_1 - 3.464} . [20]$$

$$T_1 = \frac{3q_0^2 + 5q_3^2}{q_1^3(q_3^2 - q_0^2)} \ldots\ldots\ldots\ldots\ldots\ldots [21]$$

$$T_2 = \frac{3.58}{q_1^3(q_3^2 - q_0^2)}\left(\frac{q_3^2}{3}\log_e \frac{q_2}{q_0} + \frac{q_2^2 - q_0^2}{10}\right) \ldots\ldots [22]$$

The slope of the flange at the virtual inner edge is given by the equation

$$\varphi_0 = \frac{q_0}{Et^2}\left[2PT_2 - 3T_1\left(K - \frac{q_1 tR}{2}\right)\right]$$

An approximate value of the linear deflection of the outer edge of the flange may be obtained by multiplying φ_0 with the width of the flange.

In the foregoing the dimensions of cylinder, thickness of flange, etc., have been given as multiples of the wall thickness t. This has been done in order to facilitate the work of constructing a chart from which the quantities T_1, T_2, and R could be determined directly. The preparation of charts of this kind, covering a great number of conditions, involves a multitude of numerical calculations, and the authors have not had to their disposal sufficient time to perform this work. However, preliminary work has been started, and it is hoped that the charts will considerably facilitate the application of the rather involved formulas.

For a more direct use of the formulas derived they are here given with the actual dimensions of cylinder and flange substituted for the ratios.

Notation:

t = thickness of cylinder wall in inches
a = mean diameter of cylinder in inches
b = diameter of bolt circle in inches
d = outside diameter of flange in inches
h = thickness of flange in inches
p = internal pressure, lb. per sq. in.
P = total bolt load, lb.

$$R = \frac{\left(s^2 - \dfrac{h^3}{2t}T_1\right)(t + 0.2325sT_1)p - 2T_2(h + 0.5377s)P}{1.860st + T_1\left[h^2\left(2 + 0.1160\dfrac{s}{t}T_1\right) + 1.6103sh + 0.866s^2\right]} \ldots\ldots\ldots [19a]$$

$$K = \frac{(h^2 T_1 + 1.860st)R + hT_2 P - 0.500tp\left(s^2 - \dfrac{h^3}{2t}T_1\right)}{1.500hT_1 - 3.464t} [20a]$$

$$s = \sqrt{at} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [23]$$

$$T_1 = \frac{t^3(3a^2 + 5d^2)}{h^3(d^2 - a^2)} \ldots\ldots\ldots\ldots\ldots\ldots [21a]$$

$$T_2 = \frac{3.580t^3}{h^3(d^2 - a^2)}\left[\frac{d^2}{3}\log_e \frac{b}{a} + 0.100(b^2 - a^2)\right] \ldots [22a]$$

$$\sigma_{r0} = \frac{6}{h^2}\left(K - \frac{h}{2}R\right) \ldots\ldots\ldots\ldots\ldots [15a]$$

$$\sigma_{rR} = \frac{R}{h} + p \ldots\ldots\ldots\ldots\ldots\ldots\ldots [16a]$$

$$\sigma_{t0} = \sigma_{r0} + \frac{0.800}{h^2(d^2 - a^2)}\left[d^2\left(-15K + 7.5hR + 1.492P\log_e \frac{b}{a}\right) + 0.4475P(b^2 - a^2)\right] \ldots\ldots\ldots [17a]$$

$$\sigma_{tR} = \frac{h^2}{4t^3}\,T_1(R + hp) \ldots\ldots\ldots\ldots\ldots [18a]$$

Although the foregoing equations have been derived with the assumption of a cylinder of infinite length attached to the flange, they may be applied with a high degree of accuracy to flanges with shorter hubs, provided the length of the hub is

$$l \gtreqless 1.1\sqrt{at} \ldots\ldots\ldots\ldots\ldots\ldots [24]$$

See Professor Timoshenko's discussion of Waters' formula for hubbed flanges.

The use of the foregoing formulas will be illustrated by numerical examples.

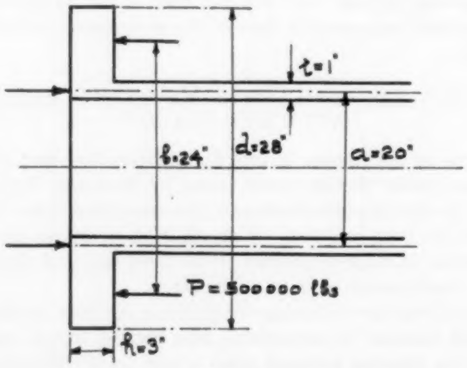

FIG. 15

EXAMPLE 1 (Fig. 15):

In Fig. 15 is shown a cylinder with rigidly attached flange, loaded with bolt and gasket load and subjected to an internal pressure of 1000 lb. per sq. in. The longitudinal load is assumed to be produced by the internal pressure acting over the full area of the cylinder.

Hoop stress and longitudinal stress far from the flange:

σ_h = 9500 lb. per sq. in.
σ_l = 4750 lb. per sq. in.

From Equation [23] $s = \sqrt{20} = 4.472$
From Equation [21a], $T_1 = 0.493$
From Equation [22a], $T_2 = 0.0225$

Inserting values of s, T_1, T_2, and given dimensions and loads into [19a] and [20a], gives

$R = -2700$ lb. per in.
$K = 5910$ in-lb. per in.

Stresses in cylinder wall:

From Equation [14] $\sigma = 35{,}460$ lb. per sq. in.
To this add numerically $\sigma_l = 4750$ lb. per sq. in.

Total stress in cylinder wall:

$\sigma + \sigma_l = 40{,}210$ lb. per sq. in.

Stresses in flange:

Radial:

From Equation [15a], $\sigma_{r0} = 6640$ lb. per sq. in.
From Equation [16a], $\sigma_{rR} = 100$ lb. per sq. in.

Total radial stress:

$\sigma_{r\,tot} = \sigma_{r0} + \sigma_{rR} = 6740$ lb. per sq. in.

Tangential:

From Equation [17a], $\sigma_{t0} = 13{,}320$ lb. per sq. in.
From Equation [18a], $\sigma_{tR} = 330$ lb. per sq. in.

Total tangential stress:

$\sigma_{t\,tot} = \sigma_{t0} + \sigma_{tR} = 13{,}650$ lb. per sq. in.

Minimum length of hub:

From Equation [24], $l = 5$ in.

In the same manner stresses have been calculated when the internal pressure p has been removed. In Example 2, Table 1, all dimensions except thickness of flange have been maintained. The pressure p and bolt load P remain the same. Example 3 is calculated with very high internal pressure. All figures pertaining to these three examples will be found in Table 1.

TABLE 1 CALCULATIONS

		Example 1		Example 2		Example 3

R,	lb. per in.	− 2,700	− 3,243	− 3,720	− 4,170	− 9,130	−12,120
K,	in-lb. per in.	5,910	6,108	8,880	8,800	23,750	26,000
σ_l,	lb. per sq. in.	4,750	0	4,750	0	8,750	0
σ_h,	lb. per sq. in.	9,500	0	9,500	0	23,800	0
σ	lb. per sq. in.	35,460	36,650	53,280	52,800	35,630	39,000
$\sigma + \sigma_l$,	lb. per sq. in.	40,210	36,650	58,030	52,800	44,380	39,000
σ_{r0},	lb. per sq. in.	6,640	7,315	18,900	19,460	8,520	10,400
σ_{rR},	lb. per sq. in.	100	1,080	860	2,085	3,480	2,020
$\sigma_{r\,tot.}$	lb. per sq. in.	6,740	8,395	19,760	21,545	12,000	12,420
σ_{t0},	lb. per sq. in.	13,320	11,250	17,770	16,060	18,900	15,800
σ_{tR},	lb. per sq. in.	330	3,400	2,870	6,950	6,670	3,900
$\sigma_{t\,tot.}$	lb. per sq. in.	13,650	14,650	20,640	23,010	25,570	19,700

The stress $\sigma + \sigma_l$ drops considerably with removal of pressure p but this is due to the removal of the longitudinal forces acting on the cylinder and not to a reduced bending moment. The maximum change in σ amounts to about 10 per cent in Example 3 where a high internal pressure was assumed.

In Example 2 where the flange is reduced in thickness to 2 in. the stress σ is materially higher due to the greater flexibility of the thinner flange. The radial and tangential stresses in the flange become higher for the same reason.

In all the examples given the greatest stress by far has been encountered in the cylinder wall at the junction with the flange. This stress may obviously be reduced by introducing a large fillet or a tapering cylinder wall at the junction. The bending moment K can be shown to decrease rapidly with increasing distance from the junction. The tapering section will consequently be effective even if very short. No effort has been made to accurately evaluate this effect due to the mathematical difficulties encountered. Sufficient safety may be obtained by applying above formulas as they stand and using the section modulus obtained from the thickened cylinder wall when calculating the stress σ.

Appendix No. 1

The differential Equations [1], [2], and [3] are derived as follows:

Referring to Fig. 1:

ϵ_t = unit elongation in tangential direction
ϵ_r = unit elongation in radial direction

At the point under consideration

$$\epsilon_t = \frac{z\varphi}{x} \qquad \epsilon_r = z\frac{d\varphi}{dx}$$

From the theory of elasticity,

$$\epsilon_t = \frac{1}{E}\left(\sigma_t - \frac{\sigma_r}{m}\right) \qquad \epsilon_r = \frac{1}{E}\left(\sigma_r - \frac{\sigma_t}{m}\right)$$

From these four equations

$$\sigma_t = \frac{mEz}{m^2-1}\left(m\frac{\varphi}{x} + \frac{d\varphi}{dx}\right)$$

$$\sigma_r = \frac{mEz}{m^2-1}\left(m\frac{d\varphi}{dx} + \frac{\varphi}{x}\right)$$

By means of these expressions a differential equation for the relation between slope φ and distance x may be set up.[6] For different loading conditions this equation will be found to assume the shapes given in Part I.

Appendix No. 2

DERIVATION OF FORMULAS FOR CYLINDER WITH RIGIDLY ATTACHED FLAT HEAD

In Figs. 8 and 16 a system of coordinates is erected with the x-axis coinciding with the center line of the cylinder wall far from the head when the cylinder is expanded by internal pressure. The y-axis passes through the junction between cylinder and head.

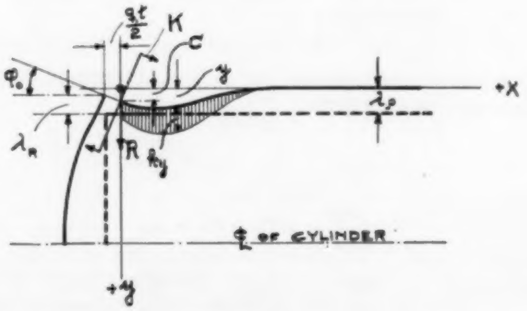

FIG. 16

---

[6] Timoshenko and Lessells, "Applied Elasticity." Föppl "Technische Mechanik," vol. III.

In Fig. 16 the heavy broken line represents the center line of the cylinder wall and head before deformation. The heavy solid line represents the same center line after deformation.

A strip of unit width is cut out as shown to the right in Fig. 8. This strip may be treated as a beam on an elastic foundation. When the x-axis is chosen as shown, the y-values are produced by couple K and shearing force R only.

Notation:

t = thickness of cylinder wall in inches
$q_0 t$ = mean radius of cylinder in inches
$q_1 t$ = thickness of head in inches
p = internal pressure, lb. per sq. in.
K = couple acting at junction of head and cylinder per inch circumference, in in-lb. per inch
R = shearing force at junction of head and cylinder per inch circumference, lb. per inch
y = deflection of cylinder wall due to K and R in inches
λ_p = radial deformation of cylinder far from head due to p in inches
λ_R = radial deformation of head due to R in inches
φ_0 = slope of cylinder wall for $x = 0$ equals slope of head at radius $q_0 t$ in radians
E = modulus of elasticity
$\frac{1}{m}$ = Poisson's ratio ($m = 4$)
$I = t^3/12$ = moment of inertia of strip of unit width
k = resistance of elastic foundation for unity deflection $= E/q_0^2 t$

$$\beta = \sqrt[4]{\frac{k}{4IE}} = \frac{1.315}{t\sqrt{q_0}}$$

For a long cylinder the following equations hold:

$$y = e^{-\beta x}(C \cos \beta x + D \sin \beta x) \ldots\ldots\ldots\ldots [25]$$

$$dy/dx = \beta e^{-\beta x}[-C(\cos \beta x + \sin \beta x) + D(\cos \beta x - \sin \beta x)] \ldots\ldots [26]$$

$$d^2y/dx^2 = 2\beta^2 e^{-\beta x}(C \sin \beta x - D \cos \beta x) \ldots\ldots [27]$$

$$d^3y/dx^3 = 2\beta^3 e^{-\beta x}[C(\cos \beta x - \sin \beta x) + D(\cos \beta x + \sin \beta x)] \ldots\ldots [28]$$

(See Timoshenko and Lessells, "Applied Elasticity.")
In these equations

y = deflection
$\frac{dy}{dx}$ = slope
$\frac{d^2y}{dx^2} = \frac{\text{Bending moment}}{IE}$
$\frac{d^3y}{dx^3} = \frac{\text{Shearing force}}{IE}$

At the end of the cylinder, for $x = 0$, Equations [25]–[28] assume the following forms:

$$y = C = \lambda_p - \lambda_R + \frac{q_1 t}{2}\varphi_0 \ldots\ldots\ldots\ldots [25a]$$

$$\frac{dy}{dx} = \beta(D - C) = \varphi_0 \ldots\ldots\ldots\ldots [26a]$$

$$\frac{d^2y}{dx^2} = -2\beta^2 D = -\frac{K}{IE} \ldots\ldots\ldots\ldots [27a]$$

$$\frac{d^3y}{dx^3} = 2\beta^3(C + D) = \frac{R}{IE} \ldots\ldots\ldots\ldots [28a]$$

Fig. 17 shows the head of the vessel after pressure is applied. Couple K and force R are here shown as reaction forces from the cylinder wall acting in opposite direction from those shown in Fig. 16.

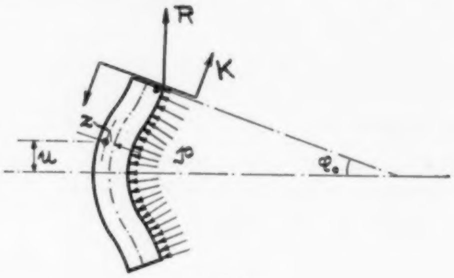

FIG. 17

Referring to Fig. 17,

u = distance from center of plate
z = distance from neutral surface of plate

For a round plate loaded by a uniformly distributed load the slope at a point at distance u from center is

$$\varphi = C_1 u + \frac{C_2}{u} - \frac{N}{8}u^3$$

where

$$N = \frac{m^2 - 1}{m^2} \cdot \frac{6p}{Eq_1^3 t^3} \quad \text{(See Equation [1a])}$$

For this case $C_2 = 0$ because otherwise $\varphi = \infty$ for $u = 0$. The equation becomes

$$\varphi = C_1 u - \frac{N}{8}u^3 \ldots\ldots\ldots\ldots [29]$$

and its derivative

$$\frac{d\varphi}{du} = C_1 - \frac{3N}{8}u^2 \ldots\ldots\ldots\ldots [30]$$

As shown in Appendix 1, the radial stress at a point at radius u at a distance z from the neutral surface of a circular flat plate is

$$\sigma_r = \frac{mEz}{m^2 - 1}\left(m\frac{d\varphi}{du} + \frac{\varphi}{u}\right)$$

For the virtual edge of the plate where $u = q_0 t$ we may write

$$\frac{mE}{m^2 - 1}\left(m\frac{d\varphi}{du} + \frac{\varphi}{u}\right)_{u = q_0 t} = k_1 \ldots\ldots\ldots\ldots [31]$$

or

$$\sigma_r = k_1 z$$

The moment of these σ_r-forces taken over the whole thickness of the plate per unit length of circumference is obviously balanced by the couple K and the moment of the shearing force R.

$$\int_{-\frac{q_1 t}{2}}^{+\frac{q_1 t}{2}} \sigma_r z\,dz = \int_{-\frac{q_1 t}{2}}^{+\frac{q_1 t}{2}} k_1 z^2\,dz = k_1\frac{q_1^3 t^3}{12} = -K - \frac{q_1 t}{2}R \ldots [32]$$

From Equations [29], [30], [31], and [32] the following relation is obtained:

$$C_1 = \frac{6(m - 1)}{mEq_1^3 t^3}\left(pq_0^2 t^2\frac{(3m + 1)}{8m} - 2K - q_1 tR\right)$$

and for $m = 4$,

$$C_1 = \frac{117}{64}\frac{pq_0^2}{Eq_1^3t} - \frac{9K}{Eq_1^3t^3} - \frac{4.5\,R}{Eq_1^2t^2}$$

This value inserted into Equation [29] gives, for $u = q_0t$,

$$\varphi_0 = \frac{9}{8}\frac{q_0^3}{Eq_1^3}p - \frac{9q_0}{Eq_1^3t^2}K - \frac{4.5\,q_0}{Eq_1^2t}R \ldots\ldots\ [33]$$

The radial increase λ_R must now be determined (Fig. 18).

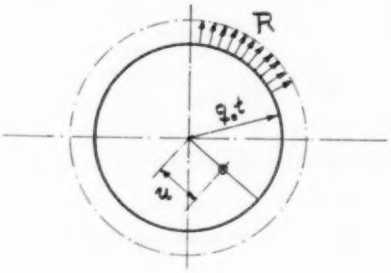

FIG. 18

Radial displacement of a point at radius u is

$$v = Cu + \frac{C_0}{u}$$

C_0 obviously equals zero, which gives

$$v = Cu;\quad \frac{dv}{du} = C$$

The stress due to R at the virtual edge of the plate is

$$\sigma_r' = \frac{R}{q_1t} = \frac{mE}{m^2-1}\left(m\frac{dv}{du} + \frac{v}{u}\right) = \frac{mEC}{m-1}$$

or

$$C = \frac{m-1}{m}\,\frac{R}{Eq_1t}$$

This expression combined with the equation $v_{q_0t} = \lambda_R = Cq_0t$ gives

$$\lambda_R = \frac{m-1}{m} \times \frac{Rq_0}{Eq_1}$$

or, for $m = 4$,

$$\lambda R = \frac{3}{4} \times \frac{Rq_0}{Eq_1} \ldots\ldots\ [34]$$

The increase in radius of the cylinder when under pressure is obviously

$$\lambda_p = \frac{q_0^2tp}{E} \ldots\ldots\ [35]$$

The values for φ_0, λ_R, and λ_p as given by Equations [33]–[35] inserted into Equations [25a]–[28a] give the following four equations:

$$C = \frac{q_0^2tp}{E} - \frac{3}{4}\frac{Rq_0}{Eq_1} + \frac{9}{16}\frac{q_0^3}{Eq_1^2}tp - \frac{4.5q_0}{Eq_1^2} \times \frac{K}{t} - \frac{2.25q_0R}{Eq_1} \ldots\ldots\ [25b]$$

$$D - C = 0.857\ \frac{q_0^3\sqrt{q_0}}{Eq_1^3}tp - \frac{6.85q_0\sqrt{q_0}}{Eq_1^2t}K - \frac{3.425q_0\sqrt{q_0}}{Eq_1^2}R \ldots\ldots\ [26b]$$

$$D = \frac{2\sqrt{3}\,q_0}{E}\,\frac{K}{t} \ldots\ldots\ [27b]$$

$$C + D = \frac{2.63q_0\sqrt{q_0}}{E}R \ldots\ldots\ [28b]$$

from which the values of the unknown quantities C, D, R, and K may be obtained.

$$\frac{R}{tp} = \frac{q_0q_1(6.93q_1^3 + 3.89q_0q_1 + 2.97q_0\sqrt{q_0} + 6.85\sqrt{q_0})}{9.13q_1^4\sqrt{q_0} + 20.78q_1^3 + 23.7q_1^2\sqrt{q_0} + 18q_0q_1 + 5.15\sqrt{q_0}} \ldots\ldots\ [12]$$

$$\frac{K}{t^2p} = \frac{\frac{R}{tp}\left(3q_1 + 2.63q_1^2\sqrt{q_0}\right) - q_0q_1^2 - 0.5625q_0^2}{2\sqrt{3}\,q_1^2 - 4.5} \ldots\ [13]$$

$$D = \frac{2\sqrt{3}\,q_0}{E} \cdot \frac{K}{t} \ldots\ldots\ [36]$$

$$C = \frac{2.63q_0\sqrt{q_0}}{E}R - D \ldots\ldots\ [37]$$

When K is known the bending stress may be found immediately by dividing by the section modulus of the strip. See Equation [6].

The bending moment K_x at a distance x from the junction decreases very rapidly with increasing values for x, following the equation

$$K_x = e^{-\beta x}\left[\left(-\frac{R}{\beta} + K\right)\sin\beta x + K\cos\beta x\right]$$

The stresses in the head may now be evaluated by inserting the values for φ and $d\varphi/du$ as given by Equations [28] and [29] into the equations

$$\sigma_r = \frac{mEz}{m^2-1}\left(m\frac{d\varphi}{du} + \frac{\varphi}{u}\right)$$

$$\sigma_t = \frac{mEz}{m^2-1}\left(m\frac{\varphi}{u} + \frac{d\varphi}{du}\right)$$

using the value

$$C_1 = 1.83\,\frac{pq_0^2}{Eq_1^2t} - \frac{9K}{Eq_1^3t^3} - \frac{4.5R}{Eq_1^2t^2}$$

For the center of the plate, where $u = 0$, these stresses become

$$\sigma_{r0} = \sigma_{t0} = \frac{2}{3q_1}\left(\frac{1.83q_0^2}{q_1}p - \frac{9K}{q_1t^2} - \frac{4.5R}{t}\right) \ldots\ldots\ [8]$$

and for the virtual edge of the plate, where $u = q_0t$,

$$\sigma_r = -\frac{6}{q_1^2}\left(\frac{K}{t^2} + \frac{q_1}{2}\frac{R}{t}\right) \ldots\ldots\ [9]$$

$$\sigma_t = \sigma_r + 0.5625\,\frac{q_0^2}{q_1^2}\,p \ldots\ldots\ [10]$$

These are the *bending* stresses produced by K, R, and p. To these must be added numerically stresses produced by R considered as tension equally distributed along the circumference:

$$\sigma_r^1 = \sigma_t^1 = \frac{R}{q_1t} \ldots\ldots\ [11]$$

Appendix No. 3

DERIVATION OF FORMULAS FOR CYLINDER WITH RIGIDLY ATTACHED FLANGE

Similarly, as in the problem treated in Part II, the point of origin is chosen as indicated in Figs. 14 and 19, so that the x-axis coincides with the center line of the cylinder wall far from the flange when the cylinder is expanded by pressure p. In Fig. 19 the center lines of cylinder wall and flange are shown before and after deformation by heavy broken and heavy solid lines, respectively. A strip of unit width is cut out of the cylinder as shown to the right in Fig. 14. This strip may be treated as a beam on an elastic foundation. When the x-axis is chosen as shown, the y-values are produced by K and R only.

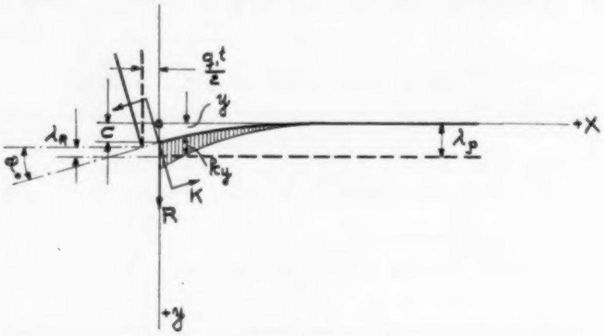

FIG. 19

Notation:

t = thickness of cylinder wall in inches
$q_0 t$ = mean radius of cylinder in inches
$q_1 t$ = thickness of flange in inches
$q_2 t$ = radius of bolt circle in inches
$q_3 t$ = outside radius of flange in inches
p = internal pressure in lb. per sq. in.
P = total bolt load, lb.
K = couple acting at junction of flange and cylinder per inch circumference in in-lb. per inch
R = shearing force at junction of flange and cylinder per inch circumference, lb. per inch
y = deflection of cylinder wall due to K and R in inches
λ_p = radial deformation of cylinder far from flange due to p in inches
λ_R = radial deformation of flange due to R in inches
φ_0 = slope of cylinder wall for $x = 0$ equals slope of flange at radius $q_0 t$ in radians

For further nomenclature see Appendix No. 2.

For the longitudinal strip shown in Fig. 14 Equations [24]–[27] hold. (See Appendix No. 2, II.) For the end of the cylinder, for $x = 0$, these equations assume the following forms:

$$y = C = \lambda_p - \lambda_R - \frac{q_1 t}{2}\varphi_0 \qquad [38]$$

$$\frac{dy}{dx} = \beta(D - C) = -\varphi_0 \qquad [39]$$

$$\frac{d^2y}{dx^2} = -2\beta^2 D = \frac{K}{IE} \qquad [40]$$

$$\frac{d^3y}{dx^3} = 2\beta^3(C + D) = \frac{R}{IE} \qquad [41]$$

For a flange as shown in Fig. 20 the slope is expressed by Equations [2a] and [3a] in part I. Equation [2a] holds for values of u from $q_0 t$ to $q_2 t$, and [3a] from $q_2 t$ to $q_3 t$.

1—From $q_0 t$ to $q_2 t$:

$$\varphi = C_1 u + \frac{C_2}{u} - \frac{S}{2} u \log_e u \qquad \text{where} \qquad S = \frac{1.79\,P}{E q_1^3 t^3}$$

$$\frac{d\varphi}{du} = C_1 - \frac{C_2}{u^2} - \frac{S}{2}(\log_e u + 1)$$

2—From $q_2 t$ to $q_3 t$:

$$\varphi = C_3 u + \frac{C_4}{u}$$

$$\frac{d\varphi}{du} = C_3 - \frac{C_4}{u^2}$$

For the outer edge of the flange where $u = q_3 t$, $\sigma_r = 0$. Therefore

$$m\frac{d\varphi}{du} + \frac{\varphi}{u} = 0 \quad \text{(See Appendix No. 1)}$$

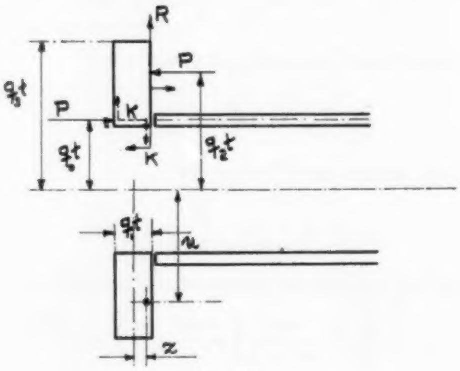

FIG. 20

By inserting the values of $d\varphi/du$ and φ/u for $u = q_3 t$ into this equation it becomes

$$mC_3 - \frac{mC_4}{q_3^2 t^2} + C_3 + \frac{C_4}{q_3^2 t^2} = 0$$

For $u = q_2 t$ two equations are obtained due to continuity.

$$C_1 + \frac{C_2}{q_2^2 t^2} - \frac{S}{2}\log_e(q_2 t) = C_3 + \frac{C_4}{q_2^2 t^2}$$

$$C_1 - \frac{C_2}{q_2^2 t^2} - \frac{S}{2}\left(1 + \log_e(q_2 t)\right) = C_3 - \frac{C_4}{q_2^2 t^2}$$

Eliminating C_3 and C_4 the following relation between C_1 and C_2 is obtained:

$$C_1 = \frac{m-1}{m+1}\frac{C_2}{q_3^2 t^2} + \frac{S}{2}\log_e(q_2 t) + \frac{S}{4}\left(\frac{m-1}{m+1}\frac{q_2^2}{q_3^2} + 1\right)$$

For the virtual inner edge of the flange, where $u = q_0 t$, the moment of the σ_r-forces must be equal to the moment caused by the cylinder wall. This moment is

$$K - \frac{q_1 t}{2} R = \int_{-\frac{q_1 t}{2}}^{+\frac{q_1 t}{2}} \frac{mEz}{m^2 - 1}\left(m\frac{d\varphi}{du} + \frac{\varphi}{u}\right) z\,dz$$

$$= \frac{mE}{m^2 - 1}\left(m\frac{d\varphi}{du} + \frac{\varphi}{u}\right)\frac{q_1^3 t^3}{12}$$

Inserting the values of φ/u and $d\varphi/du$ for $u = q_0t$ gives

$$C_2 = \frac{q_0^2q_3^2t^2}{q_3^2 - q_0^2}\left[-\frac{12(m+1)}{mEq_1^3t^3}\left(K - \frac{q_1t}{2}R\right) + \frac{m+1}{m-1}\frac{S}{2}\log_e\frac{q_2}{q_0} - \frac{S}{4}\frac{q_3^2 - q_2^2}{q_3^2}\right]$$

If the values of C_1 and C_2 are inserted in the equation

$$\varphi_0 = C_1q_0t + \frac{C_2}{q_0t} - \frac{S}{2}q_0t\log_e q_0t$$

and m is set $= 4$, the following expression for the slope results:

$$\varphi_0 = -\frac{3q_0(3q_0^2 + 5q_3^2)}{Eq_1^3t^2(q_3^2 - q_0^2)}\left(K - \frac{q_1t}{2}R\right) + \frac{7.16q_0P}{Eq_1^3t^2(q_3^2 - q_0^2)}\left(\frac{q_3^2}{3}\log_e\frac{q_2}{q_0} + \frac{q_2^2 - q_0^2}{10}\right)$$

The values λ_p and λ_R must next be determined.

$$\lambda_p = \frac{q_0^2tp}{E}$$

The flange may be considered as a thick-walled cylinder loaded by internal pressure of magnitude

$$\frac{R}{q_1t} + p \text{ lb. per sq. in.}$$

The radial deformation for $u = q_0t$ is therefore

$$\lambda_R = \frac{R + q_1tp}{4E}\,\frac{q_0(3q_0^2 + 5q_3^2)}{q_1(q_3^2 - q_0^2)}$$

The expressions for φ_0, λ_p, and λ_R are now inserted into Equations [38] and [39], which, taken together with Equations [40] and [41], give a system of four equations containing the four unknown quantities C, D, K, and R. The solution of this system is

$$R = \frac{\left(q_0 - \frac{q_1^3T_1}{4}\right)(1 + 0.329\sqrt{q_0}\,T_1)tp - T_2(q_1 + 0.76\sqrt{q_0})\frac{P}{t}}{1.315\sqrt{q_0} + T_1[q_1^2(1 + 0.0822\sqrt{q_0}\,T_1) + 1.136q_1\sqrt{q_0} + 0.865q_0]} \quad \ldots\ldots\ldots[19]$$

$$K = \frac{(q_1^2T_1 + 2.63\sqrt{q_0})Rt + q_1T_2P - \left(q_0 - \frac{q_1^3T_1}{4}\right)t^2p}{1.5q_1T_1 - 3.464} \quad \ldots[20]$$

$$T_1 = \frac{3q_0^2 + 5q_3^2}{q_1^3(q_3^2 - q_0^2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots[21]$$

$$T_2 = \frac{3.58}{q_1^3(q_3^2 - q_0^2)}\left(\frac{q_3^2}{3}\log_e\frac{q_2}{q_0} + \frac{q_2^2 - q_0^2}{10}\right) \quad \ldots\ldots[22]$$

$$D = -\frac{2\sqrt{3}q_0}{Et}K \quad \ldots\ldots\ldots\ldots\ldots[42]$$

$$C = \frac{2.63q_0\sqrt{q_0}}{E}R + \frac{2\sqrt{3}q_0}{Et}K \quad \ldots\ldots\ldots\ldots[43]$$

When K is known the bending stress in the cylinder wall may be found immediately by division by the section modulus of the strip. (See Equation [14], Part III.)

The bending moment K_x at a distance x from the junction decreases rapidly with increasing values of x, following the equation

$$K_x = e^{-\beta x}\left[\left(\frac{R}{\beta} + K\right)\sin\beta x + K\cos\beta x\right]$$

Compare this with similar expression in Appendix No. 2.

The maximum radial bending stress in the flange at the virtual inner edge at both faces of the flange becomes (see Fig. 21)

$$\sigma_{r0} = \frac{6}{q_1^2t^2}\left(K - \frac{q_1t}{2}\text{R}\right) \quad \ldots\ldots\ldots\ldots\ldots[15]$$

To this stress must be *numerically* added stress arising from the force R distributed over the whole thickness of the flange and also stress due to pressure p.

This stress is $\qquad \sigma_{rR} = \dfrac{R}{q_1t} + p \quad \ldots\ldots\ldots\ldots\ldots[16]$

The maximum tangential bending stress occurs at the same point as σ_{r1} shown in Fig. 21 and is

$$\sigma_{t0} = \sigma_{r0} + \frac{0.800}{q_1^2t^2(q_3^2 - q_0^2)}\left[q_3^2\left(-15K + 7.5q_1tR + 1.492P\log_e\frac{q_2}{q_0}\right) + 0.4475P\left(q_2^2 - q_0^2\right)\right] \quad \ldots[17]$$

To this stress must be *numerically* added tangential stresses arising from radial deformation, λ_R, over the whole thickness of the flange, due to R and p.

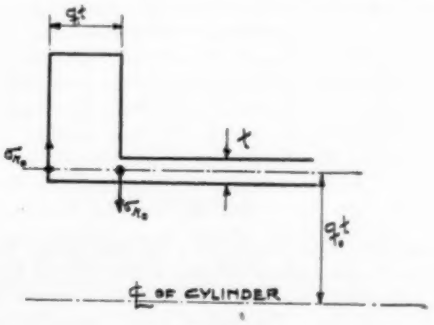

FIG. 21

$$\sigma_{tR} = \frac{q_1^2}{4}T_1\cdot\frac{R + q_1tp}{t} \quad \ldots\ldots\ldots\ldots\ldots[18]$$

Discussion

E. O. WATERS.[7] Four years ago, when the writer, with J. Hall Taylor, presented a paper on "The Strength of Pipe Flanges," there was some question as to whether industry was ready to use a design procedure that involved the elastic theory of flat plates. At that time it was common practice to assume that a flange was a beam and to design it accordingly. Naturally, the authors of that paper wished to avoid all complications and refinements of analysis that would prejudice designers against the use of the flat-plate theory, and therefore made the simplifying assumption, as quoted by Messrs. Holmberg and Axelson, "that the proportions of commercial flanges are such that the bolt load is applied near the outer edge and the pipe load near the inner edge." Furthermore, they made the assumption, in the case of hubbed flanges, that the bending moment at the root of the hub could be computed at the meridian plane of the flange instead of at its inner surface and that the expansion of the hub due to fluid pressure (if such existed) could safely be neglected. A very large number of deflection measurements on flanges, of both the flat and hubbed types, indicated that these assumptions were reasonable as long as the proportions or the loadings were not extreme.

---

[7] Associate Professor of Mechanical Engineering, Yale University, New Haven, Conn. Assoc-Mem. A.S.M.E.

Since 1927 there has been marked progress, both in the design of standard flanges and of extremely high pressure vessels and fittings, and it is appropriate that engineers should have the more refined methods of analysis brought to their attention, as the authors of the present paper have done in such capable fashion.

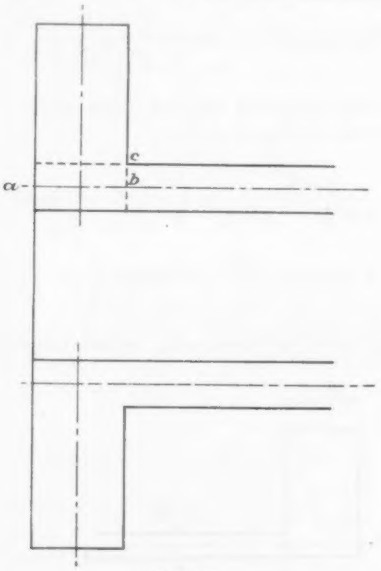

FIG. 22

In deriving their Equation [4] for a flat loose flange, the authors have employed a principle which has a wide field of application, but which apparently has escaped notice on the part of investigators of this subject. The writer called attention to this in his discussion of the paper by Wahl and Lobo on "Stresses and Deflections in Flat Circular Plates with Central Holes," wherein the authors, after giving their simplified formulas for various loading conditions, point out that these loading conditions may be combined, and a combined result obtained, by the method of superposition. Actually, however, the Wahl and Lobo formulas are capable of a still wider range of usefulness, by employing the principle of juxtaposition—i.e., a flat plate with a variety of loadings at different points may be broken down into a series of concentric rings each of which has a simple loading, and the simplified equations may be used and solved by the condition that the slope and radial moment are continuous at the boundary of each ring. This is what the authors have done in deriving Equation [4], and it will be noted that, with three juxtaposed rings, six constants had to be determined. In fact, the number of constants will always be twice the number of rings, and the large number of simultaneous equations that are involved when this method is applied to any but the simplest cases has probably militated against its use. However, the writer has devised a method, similar to the three-moment method for continuous beams, which makes it possible to solve any flat-plate problem with loadings uniformly distributed over circles or annular areas, without recourse to intricate networks of simultaneous equations.

It might be of interest to compare the results of the authors' examples 1, 2, and 3, on the cylinder-flange combination, with calculations based on the Taylor-Waters formulas. The latter give 16,916, 19,810, and 25,230 lb. per sq. in., respectively, for the maximum tangential flange stress, which compare surprisingly well with the more refined solutions, bearing in mind that the Taylor-Waters method takes no account of fluid pressure and the ratio $b-a/d-a$ assumed in the examples is somewhat extreme. Coming to the bending stresses in the cylinder, the agreement is not so close. The Taylor-Waters formulas give 45,430, 67,800, and 69,570 lb. per sq. in. as the theoretical maxima, which when transferred to the boundary between the flange and cylinder (point c, Fig. 22) become 20,150, 41,100, and 14,820. The authors' results, it will be noted, lie about halfway between these extremes. The discrepancy is essentially due to the fact that the authors have assumed that line ab, Fig. 22, remains straight, while the Taylor-Waters formula assumes that it takes the curvature of a crimped tube. The writer believes that the actual state of stress lies somewhere between these two extremes, and would like to see experimental evidence on this point.

In conclusion, the writer would like to ask why the authors have treated the cylinder as made up of strips without any lateral constraint. In the formula for β, just preceding Equation [25], the factor $m^2 - 1/m^2$ seems to have been omitted, which is contrary to the treatment in Timoshenko and Lessells' "Applied Elasticity," the authors' principal reference.

A. M. WAHL.[8] It is gratifying to note that the flat-plate theory is apparently being increasingly applied in practical design. Although the underlying theory, as used by the authors, is well known, nevertheless they deserve credit for demonstrating particular methods of attack for the guidance of practical men. In this connection, the writer would like to mention that he also has used the same general theory in the calculation of rotating thin cylinders with flat ends, which is a case very similar to that of a cylinder with a flat end under internal pressure, as treated by the authors.

In solving problems of this kind involving a cylinder with a flat end, the writer has found that the principle of superposition may often be applied so as to result in considerable simplification of the analytical work. As is well known, the action of a thin-walled cylinder is essentially that of a bar on an elastic foundation, and the results using the theory of a bar on elastic foundation may often be directly applied. By determining the slopes and deflections at the ends of the cylindrical portion, in terms of the unknown moments and reactions, and equating these to the slopes and deflections similarly determined for the plate portion, sufficient equations may be obtained to allow of the determination of the unknown moments, reactions, and deflections. In applying the principle of superposition, the simplified formulas given in a previous paper on circular plates by the writer and G. Lobo, Jr. (Trans. A.S.M.E., 1930, APM-52-3) may also be used. In many cases, when calculating flat plates, a considerable simplification is made possible by using these formulas.

On the third page the authors discuss the question of concentration of stress at the fillet where the plate portion joins the cylindrical portion. This effect might, in the writer's opinion, be determined with sufficient accuracy by the use of photoelastic tests. In case the thickness of the plate portion is much larger than that of the cylindrical portion and the fillet radius is small, a rough approximation may be had by using the stress concentration factors for fillets given by Timoshenko and Dietz (Trans. A.S.M.E., 1925, p. 199), since these factors were found to apply for cases of bending with relatively small fillet radii.

W. M. Coates.[9] The contribution made in this paper is a new application of well-established theory concerning the state of stress and strain in thin circular plates and thin cylindrical shells. The formulas given by this theory are not complicated in themselves, although they often have been so regarded. Since they provide a direct attack on a large group of problems, they deserve to be brought into general engineering usage, to provide the possibility of check and possible improvement by experience. The comparative simplicity of rational as against empirical methods is often only a matter of presentation, and the authors of this paper have demonstrated the possibility of a simple rational method of solving their problems. By using for the most part the generally accepted notation, they have made their work more easily followed. However, there are certain points at which over-conciseness in the descriptive matter leads to uncertainty as to their intention. In the following, the discussion is confined to Part II, "Stresses in a Cylinder With Rigidly Attached Flat Heads Under Internal Pressure," and the accompanying Appendix No. 2. The writer's purpose is to bring to the authors' attention the points mentioned, as well as certain others upon which improvement seems possible.

In discussing the thin cylinder, from Equation [6] on, and in Appendix No. 2, on the eighth page, the first column, and on the ninth page, the middle of the second column, there is no consideration of the hoop stress among those which influence the design, although it may be shown to exceed the longitudinal stress in some cases. This may be demonstrated by considering the behavior of both of these stresses for the general case: a thin cylinder under uniform inner pressure p with a head on it which causes the edge loads K and R, as shown in Fig. 16.

At some distance from the junction of cylinder and head, the membrane formulas[10] apply with sufficient accuracy:

$$\text{membrane}\left\{\begin{array}{ll}\text{longitudinal stress} = \dfrac{pq_0}{2} & \text{(See Eq. [7])}\\ \text{hoop stress} = pq_0 & \end{array}\right\} \quad [44]$$

Near the junction, the change in the nature of the shell, from cylinder to head, sets up discontinuity stresses which must be superimposed upon the membrane stresses. The forces which cause these are shown in Fig. 23. They give rise to the stresses[10]

$$\left.\begin{array}{lll}\text{direct} & \text{hoop} & = \sigma_2 = \dfrac{T_2}{t} = -2q_0\beta\,[R\breve{S}_1 - \beta K\breve{S}_4]\\ \text{bending}\left\{\begin{array}{l}\\ \\ \end{array}\right. & \begin{array}{l}\text{longitudinal}\\ \\ \text{hoop}\end{array} & \begin{array}{l}= \sigma_{1\theta} = \dfrac{6K_1}{t^2} = \dfrac{6}{\beta t^2}\,[R\breve{S}_3 - \beta K\breve{S}_2]\\ \\ = \sigma_{2\theta} = \dfrac{6K_2}{t^2} = \mu 6_1\theta\end{array}\end{array}\right\} \quad \ldots\ldots\ldots\ldots [45]$$

in which the notation is as given in the paper, except that, in addition, T_2, K_1, and K_2 are as shown in the accompanying Fig. 23, and

$$\left.\begin{array}{ll}\breve{S}_1 = e^{-\beta x}\cos\beta x & \breve{S}_3 = e^{-\beta x}\sin\beta x\\ \breve{S}_2 = \breve{S}_1 + \breve{S}_3 & \breve{S}_4 = \breve{S}_1 - \breve{S}_3\end{array}\right\} \ldots\ldots [46]$$

$\mu = 1/m$ = ratio of lateral to longitudinal strain in simple tension

$$\beta = \sqrt[4]{\frac{3(1-\mu^2)}{g_0^2t^4}} \cong \frac{1.285}{t\sqrt{g_0}} \qquad \text{for } \mu = 0.3$$

These $\breve{S}$ functions are the only variables. They are made up, it is seen, of damped trigonometric functions; they have been tabulated,[11] and are as easily used as the ordinary trigonometric functions.

The resultant stress, either longitudinal or hoop, is obtained as the algebraic sum of the component stresses in the direction in question. The bending stresses $\sigma_{1\theta}$ and $\sigma_{2\theta}$, given above are at the outer surface, and have their signs reversed at the inner surface.

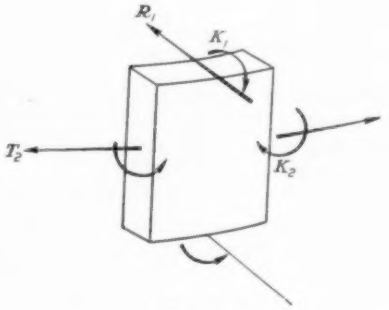

Fig. 23

The discussion of these discontinuity stresses in the paper gives $\sigma_{1\theta}$—see σ in Equation [6] for the edge value and the equation following Equation [37] for the law by which the longitudinal moment K_x (here K_1) varies. The equations which will lead to the others are given on the eighth page without further development except for the edge values, given in Equations [26a] through [28a]. Inasmuch as some of these stresses reach their maxima away from the edge, the presentation of the paper is incomplete. In these Equations [26a] through [28a] the mathematical constants C and D are left to be determined (see Equations [36] and [37]) whereas they are already determined in Equations [45] herein. The physical constants (K, the edge moment, and R the edge shearing force) are determined from the condition that cylinder and head join at their edges with the same radial displacement and the same angular displacement.

In setting up this condition, as well as in setting up the equations already referred to, there are certain inaccuracies which, although perhaps not of great consequence, are still inconsistent, since they amount to a neglect of μ without mention, whereas at other places at which the role is about the same, μ is considered—e.g., in the expression for λR. The corrections are: The expression for β, using μ instead of $1/m$ for algebraic simplicity, should read:

$$\beta = \sqrt[4]{\frac{3\,(1-\mu^2)}{g_0^2t^4}} \cong \frac{1.295}{t\sqrt{g_0}} \qquad \text{for } \mu = {}^1/_4$$

In the explanation following Equation [28], the denominators of the expressions containing the bending moment and the shearing force should be the "flexural rigidity" of the plate, $\dfrac{Et^3}{12\,(1-\mu^2)}$ instead of $\dfrac{Et^3}{12}$.

The radial (normal) displacement of the cylindrical membrane should be $\lambda_p = \dfrac{pq_0^2t}{2E}\,(2-\mu)$, instead of as given by Equation [35].

In Equations [36] and [37], the expressions for the constants of integration C and D should be corrected by the use of the above value of β, instead of the value given in the paper.

There are other inaccuracies which seem more serious, although it is possible that they may be removed by a fuller explanation of the method of attack. The solution for the angular displacement φ in the equation following Fig. 17 is for the case given by Equation [1], with u in place of x. The derivation of this equation hypothesizes no forces applied parallel to the middle surface of the circular plate. However, the forces R of Fig. 17 are exactly of this nature; their presence tends to reduce φ; and in the equation which replaces Equation [1] they introduce an additional term, to give

[10] "The State of Stress in Full Heads of Pressure Vessels," W. M. Coates, Trans. A.S.M.E.

[11] "Strength of Materials," S. Timoshenko, vol. 2, p. 405. There, φ gives $\breve{S}_2$, ψ gives $\breve{S}_4$, θ gives $\breve{S}_1$; then S_3 may be computed.

$$\frac{d^2\varphi}{du^2} + \frac{1}{u}\frac{d\varphi}{du} - \frac{\varphi}{u^2} - \frac{2NR}{pq_1t} + Nu = 0$$

where R is assumed to be uniformly distributed across the thickness q_1t of the plate. Then the solution for φ will differ from the value taken in Equation [29], and it is the new value which should be used throughout the application.

It is possible that the authors of this paper propose to regard the effect of R as negligible and to consider an approximate solution to the foregoing equation. In that case, the question warrants some discussion in the presentation. This discussion should also cover the use of R on one side of Equation [32] when it is disregarded on the other, and also the fact that the application of the boundary conditions on φ between cylinder and head will determine a value of R which is not zero.

It might also be mentioned that the C which enters after Fig. 18 is not the C used elsewhere and that its appearance is confined to the derivation of the expression for λ_R. If the effect of R on φ be assumed to be negligible, the logic of introducing λ_R at all is not clear.

In view of these facts, the accuracy of the values determined for the physical constants R and K in Equations [12] and [13] is questioned. If approximations are to be made, they may also be taken more directly, and will yield simpler formulas. Consider as a limiting case a very thick flat head applied to the cylinder, such that it restrains the end as completely as if it were built in. Then the radial and angular displacements are both zero at the edge, and the values of R and K become

$$R = \frac{p(2-\mu)}{2\beta} \cong 0.66\ pt\sqrt{g_0}$$

$$K = \frac{p(2-\mu)}{4\beta^2} \cong 0.26\ pt^2g_0$$

If these are inserted into Equation [45] of this discussion, they become

$$\left.\begin{aligned} 0_2 &= -0.85\ pq_0\check{S}_2 \\ 0_{1\theta} &= -1.55\ pq_0\check{S}_4 \\ 0_{2\theta} &= -0.46\ pq_0\check{S}_4 \end{aligned}\right\} \qquad [45a]$$

Then by taking the algebraic sum of components in Equations [44] and [45], the resultant stresses are:

$$\left.\begin{aligned} \Sigma\sigma_1 &= \text{resultant longitudinal stress} = pq_0\ [0.5 \pm 1.55\ S_4] \\ \Sigma\sigma_2 &= \text{resultant hoop stress} = pq_0\ [1-0.85\ S_2 \pm 0.46\ S_4] \end{aligned}\right\}$$

........[47]

These give the stresses at the outer and inner surfaces at any section of the cylinder, the coordinate x of the section entering the $\check{S}$ functions as given by Equation [46].

These stresses reach their greatest values as follows:

$(\Sigma\sigma_1)_{\max} = 2.05\ pq_0$ occurs at edge on outer surface

$({}_2\Sigma\sigma)_{\max} = 1.07\ pq_0$ occurs at βx 2.65 on inner surface, $x = 2.06\ t\sqrt{g_0}$.

In case the head applied to the cylinder is thicker than the cylinder, but not thick enough to warrant the assumption of full restraint against angular deflection at the end, the approximation that there is no radial displacement will be kept, but the moment K will be cut to n times its previous value, where n is a fraction. Then, running through the same processes, the resultant stresses are:

$$\left.\begin{aligned} \Sigma\sigma_1 &= pq_0\ [0.5 \pm 1.55\ (\check{S}_4 - n\check{S}_1)] \\ \Sigma\sigma_2 &= pq_0\ [1 - 0.85\ (\check{S}_1 + n\check{S}_3) \pm 0.46\ (\check{S}_4 - n\check{S}_1)] \end{aligned}\right\} . [48]$$

This is a more general form of Equations [47], which may be obtained from it for $n = 0$. These stresses may be investigated for various values of n and the results tabulated. Here it is sufficient to consider the case $n = 0.5$; then

$\Sigma(\sigma_1)_{\max.} = 0.86\ pq_0$ occurs at $\beta x = 1.25$, $x = 0.97\ t\sqrt{q_0}$

$\Sigma(\sigma_2)_{\max.} = 1.07\ pq_0$ occurs at $\beta x = 2.32$, $x = 1.81\ t\sqrt{q_0}$

Both of these maxima are at the outer surface.

This demonstrates the point mentioned at the beginning of the discussion, that in some cases it is possible that the hoop stress will exceed the longitudinal stress in the cylinder, and hence it should be considered. Another point which should be kept in mind is that for ductile materials the numerical maxima of the differences between the principal stresses is the criterion for yield. Since the third principal stress is approximately zero, this means that to the consideration of the maxima of $\Sigma\sigma_1$ and $\Sigma\sigma_2$ should be added also that of $|\Sigma\sigma_1 - \Sigma\sigma_2|$ at both surfaces. The distances at which the membrane formulas may be regarded as sufficiently accurate may also be obtained from the equations. It is a matter of interest, and also of possible further investigation, that the maximum resultant hoop stress in both cases considered is about the same, and in each case only about 7 per cent in excess of the membrane stress. Evidently, the fraction n is a function of the thickness of the head, and for each thickness there corresponds an n which may be inserted into Equation [48] to give the complete determination of the stresses at any point on either surface of the cylinder. The limitations on these equations must be kept in mind:

(1) The cylinder is "thin," that is, the ratio $\dfrac{\text{radius}}{\text{thickness}} = q_0$ is above, say, 10, for safety; there is probably reasonably good accuracy for somewhat lower values. If q_0 is too small, the effect of the shearing forces and the displacement of the neutral surface from the middle will introduce error.

(2) The derivation assumed no radial displacement at the end. The accuracy of this assumption is a matter of experience. It probably holds good for thicknesses of the flat circular head down to and somewhat below the thickness of the cylinder.

The state of stress in the flat circular head has not been mentioned in this discussion; however, it is seen that a similar approximation may be made, using Equation [1] and its solution as given by Equation [29], but determining C from the condition that the plate is supported at its edge and carries the uniformly distributed bending moments K. This is handled in Timoshenko, "Strength of Materials," vol. 2, pars. 19 and 22. From the fact that the angular displacement φ is numerically the same at the edges of the circular plate and the cylinder, the value of K may be determined, or what amounts to the same thing, that of n.

The determination of the foregoing limitations, or of the values of n for different head thicknesses, or even of R and K directly, is a matter which might be well referred to experiment. The problem is of such a nature that it may be carried out very nicely and also comparatively inexpensively, by measuring at the outer surface of the cylinder both the resultant strains or the angular displacement due to bending. Such measurements have been made by Huggenberger among others, on slightly different structures, and the instruments and the method of experiment are very completely described in his publications.[12] It is to be hoped that if such experiments are made, the results may be published completely.

T. McLean Jasper.[13] This paper adds to the mathematical precision available for obtaining the theoretical stress values in the problems dealing with plates and rings and is worthy of commendation for the amount of thought which has been expended aiming to approach an exact solution of some of the problems outlined in the title.

The writer is particularly interested in the flange problem and especially in the question of a balanced design for flanges used in high-pressure vessels of considerable size. This problem involves flanges of considerable thickness and also the methods of attaching the flanges to the cylinders. The formulas presented in this paper presume the use of a very rigid material in which the deformations are relatively small and apply most appropriately to flanges made of steel for the conditions in which Hooke's law applies. It does not consider, however, the effect of the sharpness of the corner at the junction between the flange and the cylinder. This is a matter which is now under experimental consideration and which it is hoped can be so adjusted as to approach or even exceed in safety by proper filleting the theoretical stresses presented in this paper. If proper filleting is not carried out, the stresses calculated by the method presented in the paper will be very much too low. The effect of the experimental work will be to influence the coefficient to be applied to the formulas developed by the authors.

The flange problem from many angles is a complicated one, and the adequacy of flanges is dependent on the manner of gasket design and the sealing qualities of gaskets under working conditions, the general intelligence of the people tightening bolts and fitting covers to openings, the proper balance between cylinder and flange stiffness, and the proper bolt sizes and their location.

When one considers the operation of vessels such as are used in the oil and chemical industry, in which the flanged openings are uncovered frequently, and also the class of operator employed on such work whose idea of stopping a leak is simply to pull the bolts tighter with wrenches whose lever arm is increased promiscuously, then the problem presents many very great difficulties indeed.

The authors have presented a very commendable piece of mathematical work which should be fully appreciated by elasticians everywhere.

Arthur McCutchan.[14] The authors are to be complimented for the clear presentation of their analysis of stresses in circular plates and rings. The curves of Figs. 9 and 10 should prove particularly helpful in designing welded pressure vessels.

From a reader's standpoint the addition of a subscript b, or one perhaps more suitable, to the symbol σ for bending stress would be of assistance, as subscripts are used to designate the other stresses, and the lack of one for this particular stress continually raises a question in the reader's mind as to whether the authors are referring to bending stress or some other stress for which the proper subscript might have been omitted in printing.

In the analysis of stresses in a cylinder with a rigidly attached flange, on the fifth page, the authors state that their object is "to furnish a method for figuring extreme cases where large dimensions and high loads make a more accurate formula desirable." In the furtherance of this object numerical examples are worked out which should presumably indicate the correct method of procedure in attacking such problems. An examination of these examples, however, shows several assumptions and conclusions that are not in harmony with the principles usually employed in flange design.

Material presented in the paper deals with broad general principles applicable to the design of welded and flanged structures for pressure vessels and piping. It is possible that, due to the wide scope of the paper, certain principles of practical pipe-flange design have not been given the consideration they deserve. A few of the controlling factors in pipe-flange design are called to attention in the following discussion of bolt loading.

Example 1, sketched in Fig. 15, closely approximates a 20-in. fitting flange for which facing dimensions are available in the A.S.A. Steel Flanged Standard. It is stated that a gasket joint is under consideration, so it appears reasonable that some necessary gasket compression in terms of the internal pressure should be established, as well as the area over which the internal pressure may be considered as acting, rather than arbitrarily placing the total bolt load as that equal to the internal pressure acting over the "full" area of the cylinder.

The actual bolt load on any such joint depends largely on what system of control, if any, is used in making up the joint. A rather comprehensive study of raised-face gasket joints in steam lines operating at 400 lb. pressure and 700 deg. fahr. shows that the practice of sledging up the bolts "until the joint is solid" and then retightening in the same manner after a short period of service makes a thoroughly satisfactory joint at this temperature. Alloy-steel bolting material having a minimum yield point of 70,000 lb. per sq. in. is used in these joints, and numerous tests have shown that stresses in the neighborhood of this yield point are obtained in the bolts by this method of making up pipe joints. The corresponding stresses in the flanges as calculated by the Waters-Taylor formulas would be considerably above the yield points of the material, yet no objectionable deformation of the flanges results. This condition is possible because of the localized nature of the region of maximum stress. Local flow of the material which is stressed beyond the yield point apparently results in a redistribution of stress without evidence of instability of the flange as a whole.

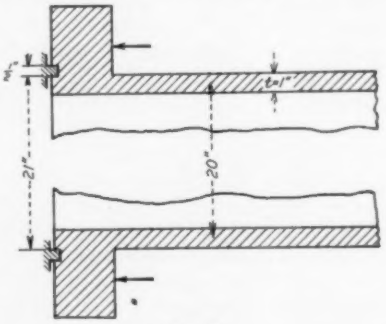

Fig. 24

Experience with flanges subjected to loads which would develop excessively high stresses as calculated by such formulas, together with Professor Waters' statement that the stresses as found by his formula did not have the same practical significance as tension in a bolt, leads one to question the desirability of making fine distinctions as to method of calculating bending stress in flanges.

---

[12] "Über die Festigkeit der gewölbten Böden und der Zylinderschale," Höhn-Huggenberger, part 2, p. 184.

[13] Director of Research, A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

[14] Engineer, Engineering Division, Detroit Edison Company, Detroit, Mich.

In particular, if a small tongue-and-groove joint is assumed for the flange illustrated in Fig. 15, with dimensions corresponding to a 20-in. A.S.A. flanged facing (see Fig. 24), the bolt load may be recalculated as follows. The area over which internal pressure acts, as considered in the A.S.A. Steel Flanged Standards, extends to the outer periphery of the gasket surface.

The force equal to the internal pressure of 1000 lb. given by 1000 × $\pi/4\ (22)^2 = 381{,}000$ lb.

The gasket area of the small tongue-and-groove joint is found as $\pi 21^1/_2 \times {}^1/_2 = 33.8$ sq. in.

The required gasket compression to secure a fluid-tight joint varies with each type and size of gasket and is largely a matter of experience for any given service. In high-pressure steam lines a gasket compression of 6 to 8 times the working steam pressure is generally found to be a satisfactory initial gasket compression for a raised-face joint. In the case of a narrow gasket such as the small tongue-and-groove joint, assumed as applicable to the joint under consideration, a gasket compression of 12 to 16 times the W.S.P. usually is considered a suitable gasket pressure to use in design. Assuming a gasket compression of 12 times the W.S.P., with the pressure acting as being necessary, the bolt load to give this compression may be found as 12 × 1000 × 33.8 = 406,000 lb.

The initial bolt load for which the flange should be designed is the sum of the foregoing forces, or 787,000 lb., rather than the 500,000 lb. assumed by the authors.

In the example of a calculation using very high internal pressure, example 3 of Table 1, the discrepancy between assumed bolt loading and that which experience has shown to be necessary is more apparent. The total bolt load for which the flange should be designed is approximately 1.75 times that used by the authors.

While the differences in magntiude of the bolt loadings used in the examples of the calculation of flange stresses in nowise affect the application of the authors' formulas, they do affect the flanges finally determined as satisfactory.

A little discussion as to the magnitude of the stresses which may be considered as reasonably satisfactory for the particular sections investigated and materials considered would be a useful addition to the authors' paper. As mentioned in connection with the application of the Waters-Taylor formula, the tangential or hoop stress at the inner edge of the flange ring is not related to failure of the material in the same manner as tension in the bolting. An analysis of the true significance of such stresses as affecting the practical design of flanges would be of value.

Authors' Closure

The authors are grateful indeed for the amount of constructive criticism to which their paper has given rise.

The discrepancies in numerical results when the Waters-Taylor formula and the authors' formula are applied are due to different assumptions of the shape of the deflected flange, as pointed out by Professor Waters. The authors agree with Professor Waters that the actual curvature of line *a–b*, Fig. 22, is probably somewhere between a straight line (the authors' assumption) and the shape of a crimped tube (Waters' assumption). Considering the actual proportions of a flange, however, it seems somewhat more probable that the curvature will closely approach a straight line.

Referring to the discussion by Prof. W. M. Coates, the authors acknowledge his suggestions regarding a more accurate value for β and the employment of the modulus of flexural rigidity. The use of these new values causes slight changes in the numerical coefficients of the expressions for R and K. These expressions become:

1 For cylinder with flat head:

$$\frac{R}{tp} = \frac{q_0q_1\left(5.86q_1^3 + 3.77q_0q_1 + 2.912\,q_0\sqrt{q_0} + 6.08\,\sqrt{q_0}\right)}{8.65q^4\sqrt{q_0} + 20.10q_1^3 + 23.26q_1^2\sqrt{q_0} + 17.94\,q_1q_0 + 5.20\,\sqrt{q_0}} \quad \ldots [12b]$$

$$\frac{K}{t^2p} = \frac{\frac{\overline{R}}{tp}\left(3q_1 + 2.58\,q_1^2\sqrt{q_0}\right) - 0.875\,q_0q_1^2 - 0.5625\,q_0^2}{3.35\,q_1^2 - 4.5} \quad \ldots [13b]$$

$$D = \frac{3.35\,q_0}{E} \times \frac{K}{t} \quad \ldots\ldots\ldots\ldots\ldots [36b]$$

$$C = \frac{2.58\,q_0\sqrt{q_0}}{E}R - D \quad \ldots\ldots\ldots\ldots [37b]$$

II For cylinder with flange:

$$R = \frac{\left(q_0 - 0.286\,q_1^3T_1\right)\left(0.875 + 0.303\sqrt{q_0}\,T_1\right)tp - T_2\left(q_1 + 0.772\sqrt{q_0}\right)\frac{P}{t}}{1.295\sqrt{q_0} + T_1\left[q_1^2\left(1 + 0.0862\sqrt{q_0}T_1\right) + 1.16\sqrt{q_0}q_1 + 0.895\,q_0\right]} \quad \ldots [19b]$$

$$K = \frac{\left(q_1^2T_1 + 2.59\sqrt{q_0}\right)Rt + q_1T_2P - 0.875\left(q_0 - 0.286q_1^3T_1\right)t^2p}{1.5\,q_1T_1 - 3.35} \quad \ldots\ldots [20b]$$

$$D = -\left(3.35\,q_0/E\right) \times (K/t) \quad \ldots\ldots\ldots\ldots [42b]$$

$$C = \left(2.59q_0\sqrt{q_0}/E\right) \times (R - D) \quad \ldots\ldots\ldots [43b]$$

These equations supersede Equations [12], [13], [36], [37], [19], [20], [42], and [43].

The influence of these changes on numerical results is very small, in the neighborhood of 1 to 2 per cent, or of the same order as inaccuracies due to an assumed value of Poisson's ratio.

In the discussion of the influence of the radial force R on the angular deformation of the flat head, Professor Coates sets up a differential equation identical with the authors' Equation [1] except for the term $2NR/pq_1t$

This term, however, cannot be accurate, as it is of a different dimension than the other terms of the equation. The influence of the shearing force R on angular deflections varies with the linear deflection of the plate. In all practical applications the linear deflections are of such a magnitude that the influence of R on the *angular deflection* may be safely neglected. The influence of R on the *radial extension* of the plate, however, is of a different magnitude and cannot be neglected.

The authors agree with Professor Coates that the hoop stresses at a certain distance from the junction reach a maximum higher than the hoop stress far from the junction. The difference amounts to only a few per cent.

Prof. T. McLean Jasper brings out the fact that the effect of a fillet has not been adequately treated. The reasons why the authors did not attempt to consider a fillet in their mathematical analysis is simply the tremendous complexity of the problem. It is hoped that the tests now being conducted by Professor Jasper will contribute to a clearer conception of the matter.

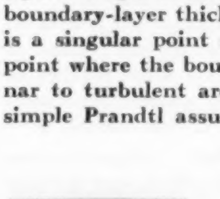
The interesting fact mentioned by Mr. A. McCutchan regarding a localized stress above the elastic limit of the material causing a regional permanent deformation without impairing the flange as a whole, can hold true only for ductile materials. In a brittle material a stress beyond this limit will immediately cause cracking.

The Boundary Layer and Skin Friction for a Figure of Revolution

By CLARK B. MILLIKAN,[1] PASADENA, CALIF.

The boundary-layer equations for a figure of revolution are first derived in the Prandtl form. These are then integrated to give the so-called "integral relation" for the case in question. Power-series expressions for the boundary-layer profiles in laminar and turbulent flow are assumed and substituted into the integral relation. In this way expressions are obtained for the boundary-layer thickness and for the contribution to the skin friction of the laminar and turbulent portions of the boundary layer. In particular a simple expression is given for the boundary-layer thickness at the stagnation point, which is a singular point of the equation. Conditions at the point where the boundary-layer flow changes from laminar to turbulent are discussed in some detail, and the simple Prandtl assumption for the transition-point behavior is adopted as the basis of the further calculations. Numerical values for the N.P.L. International Airship Model are introduced, and theoretical curves are given for the resistance coefficient as a function of the Reynolds number. These are compared with previous theoretical results and with experimental values.

The agreement of the theory with experiment is considered satisfactory in view of the assumptions which had to be introduced into the analysis in order to supplement the present state of knowledge concerning boundary-layer phenomena. The general integral relation developed in the paper can be used to obtain more accurate results in the future, when more is known regarding boundary-layer profiles in curved and diverging (or converging) flows.



1—Introduction

In 1927 Prandtl published a theory giving the skin friction acting on pointed flat plate in a two-dimensional flow parallel to the surface and perpendicular to the leading edge (1).[2] This theory, which gave excellent accordance with experiment, was based on the assumptions that over the forward part of the plate the flow was laminar and followed Blasius' solution of the Prandtl boundary-layer equations, over the rear portion it was turbulent and followed the "$^1/_7$-power law" for velocity distribution, and that the transition point from laminar to turbulent flow followed a definite and simple law. Experiments have since indicated that this theory gives a satisfactory value for the skin friction at the curved surface of a streamlike body in a two-dimensional flow when the radius of curvature is large compared to the boundary layer thickness. Recently Jones (2) and Dryden and Kuethe (3) have further extended the theory so as to give an account of the skin friction acting on a dirigible model in an axial flow. In both of these discussions the dirigible was replaced by an "equivalent flat plate," so that the essential differences between a two-dimensional flow and one about a finite figure of revolution had either to be ignored or, in the latter case, taken into account by means of rather arbitrary assumptions. Hence it seemed desirable to investigate the possibility of a more precise consideration of the problem. The fundamental aim of the present work has therefore been the investigation of the boundary-layer phenomena for a body with axial symmetry about an axis in the direction of flow.

The laminar boundary layer for such a case was treated as long ago as 1908 by Dr. E. Boltze (4). Boltze's dissertation is, however, rather inaccessible, so that the present author has been unable to examine it. From the published abstracts it appears that Boltze gave the laminar boundary-layer equations for the case of axial symmetry and also gave numerical integrations in certain cases. In view of the difficulty of obtaining Boltze's paper, and at the risk of repeating some of his analysis, the author will derive the laminar boundary-layer differential equations for axial symmetry before proceeding to the deduction of the integral relation for this case and its subsequent application to both the laminar and turbulent régimes. The latter two topics are almost certainly not treated in Boltze's paper, since even for plane flow they were first discussed by Karman and Prandtl much later.

2—Derivation of the Laminar Boundary-Layer Equations for Axial Symmetry

We start with the vector form of the Navier-Stokes and continuity equations for the steady motion of a viscous incompressible fluid,

$$\left.\begin{aligned} \boldsymbol{q}\cdot\nabla\boldsymbol{q} + \frac{1}{\rho}\nabla p &= \nu\nabla^2\boldsymbol{q} \\ \nabla\cdot\boldsymbol{q} &= 0 \end{aligned}\right\} \qquad \ldots\ldots\ldots\ldots\ [1]$$

where $\boldsymbol{q}$ is the vector velocity, p the pressure, ρ the density, ν the kinematic coefficient of viscosity, ∇ the vector operator "gradient," and the standard Gibbs vector notation is used. We must find the approximate form which these equations take in the neighborhood of the surface of a figure of revolution when the viscosity is very small, i.e., $\nu \longrightarrow 0$. For this purpose it is convenient to introduce an orthogonal, curvilinear coordinate system defined as follows: Let x_1 = constant, x_2 = constant, x_3 =

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

constant denote the three families of orthogonal surfaces defining the coordinate system. Then we choose x_1 such that one member of the family x_1 = constant coincides with the boundary of our surface of revolution (cf. Fig. 1). x_3 is chosen so that x_3 = constant gives planes through the axis of symmetry, i.e., x_3 is the azimuthal angle θ of Fig. 1. Then the surfaces x_2 = constant are perpendicular to the two other families. If ds is an element of length, then for such an orthogonal system we have in general

$$ds^2 = h_1^2dx_1^2 + h_2^2dx_2^2 + h_3^2dx_3^2$$

where the coefficients h_1, h_2, h_3, are functions of x_1, x_2, x_3. Putting $dx_1 = dx_2 = 0$ we see that $h_3 = r$, where r is the distance of any point (x_1, x_2, x_3) from the axis. In our case we are interested only in a thin region of thickness δ on either side of the boundary. If C_r denotes the "longitudinal" radius of curvature of the boundary then if $\delta \ll C_r$ we may write $h_1 = 1$, $h_2 = 1$. Hence

$$h_1 = 1; \quad h_2 = 1; \quad h_3 = r, \text{ where } \delta \ll C_r$$

We now choose the origin of x_1 at the boundary and that of x_2 at the most upstream point of the boundary (i.e., at the forward stagnation point for a closed body) and write for simplicity

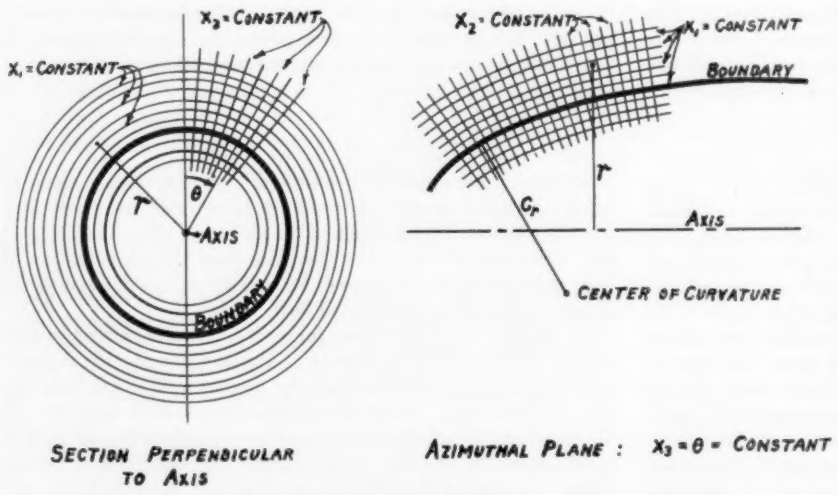

FIG. 1 COORDINATE SYSTEM FOR A FIGURE OF REVOLUTION

$x_1 = y$ = normal distance from the boundary

$x_2 = x$ = distance along the boundary from the leading edge or forward stagnation point.

Hence our curvilinear system is specified by:

$$\left.\begin{array}{lllll} x_1 = y & h_1 = 1 & & \boldsymbol{q} = u\boldsymbol{i}_x + v\boldsymbol{i}_y + q_\theta\boldsymbol{i}_\theta & \\ x_2 = x & h_2 = 1 & & & \\ x_3 = \theta & h_3 = r(x,y) & y \ll C_r & \dfrac{\partial}{\partial\theta} = 0 & q_\theta = 0 \end{array}\right\} \ldots[2]$$

where u, v, q_θ are the x, y, θ components of velocity and $\boldsymbol{i}_x$, $\boldsymbol{i}_y$, $\boldsymbol{i}_\theta$ are unit vectors in the indicated directions. The final two restrictions are imposed by our fundamental assumption of axial symmetry.

We must now express Equations [1] in terms of these curvilinear coordinates. The general expressions for ∇p and $\nabla \cdot \boldsymbol{q}$ are (writing q_1, q_2, q_3 as general velocity components in the directions x_1, x_2, x_3).

$$\nabla p = \frac{1}{h_1}\frac{\partial p}{\partial x_1}\boldsymbol{i}_1 + \frac{1}{h_2}\frac{\partial p}{\partial x_2}\boldsymbol{i}_2 + \frac{1}{h_3}\frac{\partial p}{\partial x_3}\boldsymbol{i}_3$$

$$\nabla \cdot \boldsymbol{q} = \frac{1}{h_1h_2h_3}\left[\frac{\partial}{\partial x_1}(h_2h_3q_1) + \frac{\partial}{\partial x_2}(h_3h_1q_2) + \frac{\partial}{\partial x_3}(h_1h_2q_3)\right]$$

Analogous general expressions for $\boldsymbol{q}.\nabla\boldsymbol{q}$, and $\nabla^2\boldsymbol{q}$ have been given by the author (5), but will not be reproduced here in view of their complexity. If the restrictions [2] are introduced into these expressions and the two above, the following expressions follow immediately from [1]:

$$\left.\begin{array}{l} u\dfrac{\partial u}{\partial x} + v\dfrac{\partial u}{\partial y} + \dfrac{1}{\rho}\dfrac{\partial p}{\partial x} = \nu\left[\dfrac{\partial^2 u}{\partial y^2} - \dfrac{\partial^2 v}{\partial x\partial y} + \left(\dfrac{\partial u}{\partial y} - \dfrac{\partial v}{\partial x}\right)\dfrac{1}{r}\dfrac{\partial r}{\partial y}\right] \\ u\dfrac{\partial v}{\partial x} + v\dfrac{\partial v}{\partial y} + \dfrac{1}{\rho}\dfrac{\partial p}{\partial y} = \nu\left[\dfrac{\partial^2 v}{\partial x^2} - \dfrac{\partial^2 u}{\partial x\partial y} + \left(\dfrac{\partial v}{\partial x} - \dfrac{\partial u}{\partial y}\right)\dfrac{1}{r}\dfrac{\partial r}{\partial x}\right] \\ \qquad\dfrac{\partial(ru)}{\partial x} + \dfrac{\partial(rv)}{\partial y} = 0 \qquad (\text{where } y \ll C_r) \end{array}\right\} \ldots\ldots\ldots[3]$$

In order to get the boundary-layer equations we must let $\nu \rightarrow 0$ in [3]. To get an approximate form of [3] in this case we must use the method of asymptotic integration which requires us to replace y (already assumed small compared with C_r) by a new variable $\eta = y/\sqrt{\nu}$. Then the final (continuity) equation of [3] shows us that as $\nu \rightarrow 0$, v also approaches 0 like $\sqrt{\nu}$. Hence we introduce the new variables

$$\eta = y/\sqrt{\nu} \qquad u = f(x, \eta)$$
$$v = \sqrt{\nu}\,h\,(x, \eta)$$

Substituting these into [3] and neglecting powers of $\sqrt{\nu}$ higher than the first, the two first equations of [3] give

$$f\frac{\partial f}{\partial x} + h\frac{\partial f}{\partial \eta} + \frac{1}{\rho}\frac{\partial p}{\partial x} = \frac{\partial^2 f}{\partial \eta^2} + \frac{\partial f}{\partial \eta}\frac{1}{r}\frac{\partial r}{\partial \eta}$$

$$\frac{\partial p}{\partial \eta} = 0$$

Returning to the original variables we get therefor as the boundary layer equations for axial symmetry,

$$\left.\begin{array}{ll} u\dfrac{\partial u}{\partial x} + v\dfrac{\partial u}{\partial y} = -\dfrac{1}{\rho}\dfrac{dp}{dx} + \nu\left(\dfrac{\partial^2 u}{\partial y^2} + \dfrac{1}{r}\dfrac{\partial r}{\partial y}\dfrac{\partial u}{\partial y}\right) & \\ \qquad p = p(x) & \\ \dfrac{\partial(ru)}{\partial x} + \dfrac{\partial(rv)}{\partial y} = 0 & y \ll C_r \end{array}\right\} \ldots\ldots[4]$$

For a two-dimensional flow $r \rightarrow \infty$, and these equations reduce to the classical ones given by Prandtl for this case. Other interesting special cases are: (*a*) axial flow outside or inside of a circular tube where $r = r_0 \pm y$, r_0 = constant, $\partial r/\partial y = \pm 1$; and (*b*) flow impinging perpendicularly on a flat circular disk where $r = x$, $\partial r/\partial y = 0$.

It appears to be practically impossible to give a general solution of these equations except in very special cases. For given functions $p(x)$ and $r(x, y)$ numerical solution of the equations is of course possible, but the calculations would in general be very tedious. Boltze has apparently given a certain number of such numerical integrations, but for the present work we shall use the alternative method of approximation first given by Karman for two-dimensional flow.

3—The Integral Relation for the Boundary Layer About a Figure of Revolution

Karman's method for the approximate discussion of conditions in a boundary layer is based on the use of the so-called "Karman Integral Relation," which is essentially a first integral of the Prandtl differential equations (6, 7). This method was originally given for two-dimensional flow. In the present section, then, we shall derive the analogous integral relation for axially symmetrical flow.

We define the thickness of the boundary layer by $y = \delta$ and assume that for $y \geq \delta$ the flow is unaffected by viscosity, i.e., is a potential flow. We also assume that the boundary layer is so thin compared to the dimensions of the body that the potential flow at $y = \delta$ is the same as would be given at $y = 0$ by the potential flow of a perfect fluid about the body. If U denotes the velocity at a point x of the boundary which would occur for such a potential flow, then we assume that at $y = \delta$ $u(x, y) = U(x)$, where $U(x)$ is the actual velocity just outside the boundary layer.

Bernoulli's theorem gives for the potential flow

$$\frac{1}{\rho}\frac{dp}{dx} = -U\frac{dU}{dx} = -UU' \qquad \text{(say)}$$

so that the first equation of [4] may be rewritten as

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = UU' + \nu\left(\frac{\partial^2 u}{\partial y^2} + \frac{1}{r}\frac{\partial r}{\partial y}\frac{\partial u}{\partial y}\right)$$

Let us now multiply this equation by rdy and integrate from 0 to δ, obtaining the following expression:

$$\int_0^\delta ru\frac{\partial u}{\partial x}dy + \int_0^\delta rv\frac{\partial u}{\partial y}dy = UU'\int_0^\delta rdy + \nu\int_0^\delta\left(r\frac{\partial^2 u}{\partial y^2} + \frac{\partial r}{\partial y}\frac{\partial u}{\partial y}\right)dy \qquad [5]$$

Let us consider the terms individually. Discussing the second term first, we obtain by a partial integration

$$\int_0^\delta rv\frac{\partial u}{\partial y}dy = rvu\Big|_0^\delta - \int_0^\delta u\frac{\partial(rv)}{\partial y}dy$$

But at both $y = 0$ and $y = \delta$ the velocity v vanishes, hence the integrated term disappears. Applying the continuity equation (the final equation of [4]) we obtain

$$\int_0^\delta rv\frac{\partial u}{\partial y}dy = +\int_0^\delta u\frac{\partial(ru)}{\partial x}dy$$

and hence the left-hand side of [5] becomes

$$\int_0^\delta ru\frac{\partial u}{\partial x}dy + \int_0^\delta rv\frac{\partial u}{\partial y}dy = \int_0^\delta\left[ru\frac{\partial u}{\partial x} + u\frac{\partial(ru)}{\partial x}\right]dy$$

$$= \int_0^\delta\frac{\partial(ru^2)}{\partial x}dy = \frac{d}{dx}\int_0^\delta ru^2dy - r_\delta U^2\frac{d\delta}{dx}$$

by Leibnitz' rule for the differentiation of an integral with variable limits of integration. Here r_δ is the value of r at $y = \delta$.

Consider an element of the boundary layer (Fig. 2) and let Q be the flux across any section x = constant of the boundary layer. Then

$$Q = 2\pi\int_0^\delta rudy \qquad \frac{dQ}{dx} = 2\pi\frac{d}{dx}\int_0^\delta rudy$$

But now since we have postulated steady motion, the conservation of mass in the element states that the total flux out of it must be zero. Hence, neglecting second-order differentials,

$$2\pi r_\delta U\frac{d\delta}{dx}dx = \frac{dQ}{dx}dx = 2\pi\,dx\frac{d}{dx}\int_0^\delta rudy$$

$$\therefore\ r_\delta U^2\frac{d\delta}{dx} = U\frac{d}{dx}\int_0^\delta rudy$$

so that we have finally for the left-hand side of [5]

$$\int_0^\delta ru\frac{\partial u}{\partial x}dy + \int_0^\delta rv\frac{\partial u}{\partial y}dy = \frac{d}{dx}\int_0^\delta ru^2dy - U\frac{d}{dx}\int_0^\delta rudy$$

For the final integral of [5] we have

$$\nu\int_0^\delta\left(r\frac{\partial^2 u}{\partial y^2} + \frac{\partial r}{\partial y}\frac{\partial u}{\partial y}\right)dy = \nu\int_0^\delta\frac{\partial}{\partial y}\left(r\frac{\partial u}{\partial y}\right)dy = \nu r\frac{\partial u}{\partial y}\Big|_0^\delta$$

$$= -\nu r_0\left(\frac{\partial u}{\partial y}\right)_0$$

where we use a subscript zero to denote conditions at the boundary itself, and the integrated term vanishes at the upper limit because of the fact that we approximate to the known asymptotic approach of $u \rightarrow U$ for $y \rightarrow \delta$ by requiring that $\partial u/\partial y = 0$ at $y = \delta$.

Hence Equation [5] finally becomes

$$\frac{d}{dx}\int_0^\delta ru^2dy - U\frac{d}{dx}\int_0^\delta rudy = UU'\int_0^\delta rdy - \nu r_0\left(\frac{\partial u}{\partial y}\right)_0 \qquad [6]$$

This is the simplest form of the boundary-layer integral relation for the case of axial symmetry. There are two remarks which should immediately be made with reference to this equation. The first is that the relation may also be deduced by elementary methods, using only the "momentum law" and the continuity condition, and without assuming a laminar flow satisfying the Navier-Stokes equations [2]. This latter was the method originally employed by Karman for the two-dimensional case (6; see also 3) so that this alternative derivation will not be given here. If a laminar flow is not assumed the resulting equation differs from [6] in one particular. If τ_0 represents the shearing stress or skin friction per unit area at the wall, then $\nu(\partial u/\partial y)_0$ is replaced by τ_0/ρ. In using [6] in the future we shall use the more general form given by this substitution, remembering that for laminar flow

$$\frac{\tau_0}{\rho} = \nu\left(\frac{\partial u}{\partial y}\right)_0$$

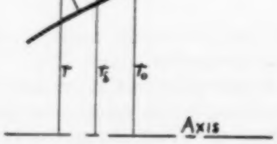

FIG. 2 BOUNDARY-LAYER ELEMENT IN A PLANE THROUGH THE AXIS

The second remark is that [6] can be transformed into another form which is somewhat more complex in appearance but which is more useful for calculations and which also brings out more clearly the essential similarities and differences between the axially symmetrical and two-dimensional integral relations. We proceed to deduce this alternative expression.

Consider a small section of the boundary, Fig. 3(a). Then since $y \ll C_r$ the element P_0P may be taken as a straight line and

$$r = r_0 + y\cos\alpha$$

where α gives the inclination of the boundary to the axis. But from Fig. 3(b)

$$\cos\alpha = \sqrt{1 - r_0'^2} = \beta(x)\ (\text{say}) \qquad \text{[7]}$$

where r_0' denotes dr_0/dx. Hence

$$r(x, y) = r_0(x) + y\beta(x) \qquad \text{[8]}$$

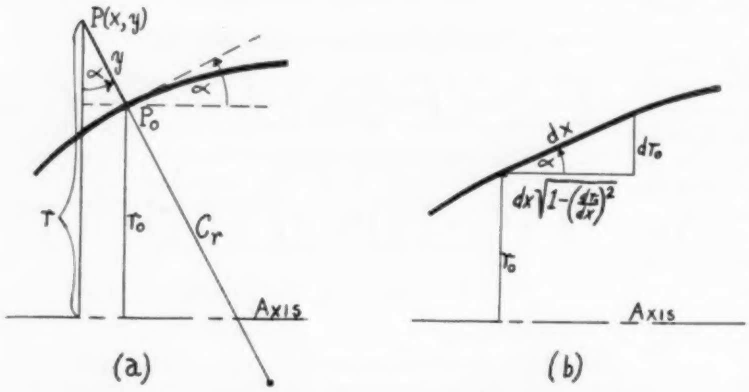

FIG. 3 BOUNDARY ELEMENT IN A PLANE THROUGH THE AXIS

where for any given boundary r_0 and β are known functions of x. Substituting [8] into [6] we are led very simply to

$$\left.\begin{aligned} &\frac{d}{dx}\int_0^\delta u^2dy - U\frac{d}{dx}\int_0^\delta udy + \frac{r_0'}{r_0}\left[\int_0^\delta u^2dy - U\int_0^\delta udy\right] \\ &+\frac{\beta}{r_0}\left[\frac{d}{dx}\int_0^\delta u^2ydy - U\frac{d}{dx}\int_0^\delta uydy\right] + \frac{\beta'}{r_0}\left[\int_0^\delta u^2ydy\right. \\ &\qquad \left. - U\int_0^\delta uydy\right] = UU'\delta\left(1 + \frac{\beta}{2}\frac{\delta}{r_0}\right) - \frac{\tau_0}{\rho} \end{aligned}\right\} \qquad \text{[9]}$$

where $\beta' = d\beta/dx$, and we have replaced $\nu(\partial u/\partial y)_0$ by the more general τ_0/ρ. The point $r_0 = 0$ is a singular point of this equation which must be investigated in more detail for each special case. For a two-dimensional flow we must let $r_0 \rightarrow \infty$, in which case [9] reduces to the simple Karman integral relation. For purposes of practical calculations we may make a further important simplification by assuming $\delta \ll r_0$. Then we get finally:

$$\left.\begin{aligned} &\frac{d}{dx}\int_0^\delta u^2dy - U\frac{d}{dx}\int_0^\delta udy + \frac{r_0'}{r_0}\left[\int_0^\delta u^2dy - U\int_0^\delta udy\right] \\ &\qquad = UU'\delta - \frac{\tau_0}{\rho} \\ &\text{where} \qquad \delta \ll C_r;\ \delta \ll r_0 \end{aligned}\right\} \qquad \text{[10]}$$

The legitimacy of this simplification near the singular point $r_0 = 0$ must later be investigated for any particular boundary $r_0(x)$.

This equation differs from the two-dimensional Karman integral relation only by the term in r_0'/r_0, which vanishes in the limiting case of two-dimensional flow, $r_0 \rightarrow \infty$, and also in the very important case of axial flow inside or outside of a uniform circular tube, r_0 = constant. The method of using [10] is the same as that employed so successfully in the two-dimensional case, i.e., a velocity profile $u(y)$ and a corresponding law of shearing stress $\tau_0(u)$ are assumed and the integrals evaluated. The equation then becomes an ordinary differential equation for $\delta(x)$. From the solution of this differential equation all of the characteristics of the boundary layer may be calculated.

4—APPLICATION OF THE INTEGRAL RELATION TO THE AXIAL FLOW ABOUT A STREAMLINE FIGURE OF REVOLUTION

The initial and fundamental assumption made in applying the previous analysis to the axial flow about streamline bodies of revolution is that the phenomenon of separation does not occur. That this assumption is justified has been verified for several dirigible models both by detailed investigations on the boundary layer and by calculating the form drag from experimentally observed pressure distributions [cf., for example, (3) and (8)]. The form drag for good streamline shapes has in several investigations been found to be zero within the limits of the experimental accuracy, which means that the theoretical potential flow is very closely approximated by the real flow outside of the boundary layer. Hence we may safely assume in general that over the experimentally used range of Reynolds' numbers separation does not occur for moderately or very well-streamlined figures of revolution. This assumption has two important consequences. First, it implies that the Prandtl boundary-layer method of approximating to the real flow is valid (for any Reynolds numbers of usual magnitude or larger), and second, it allows us to equate the skin friction integrated over the surface with the total drag of the body.

The second assumption which we shall make is that the flow in the forward portion of the boundary layer is laminar while that over the rear portion may be turbulent, and that the transition from laminar to turbulent flow occurs instantaneously. In other words, the entire boundary layer upstream from a certain critical value of $x(x_c)$ is laminar, while that downstream from x_c is completely turbulent. We shall consider the conditions at this critical or transition point in detail in section 5.

In accordance with the method of procedure mentioned at the end of the previous section, we must now make definite assumptions for the velocity profile and shearing stress in the laminar and turbulent regions. For the laminar régime the type of profile originally used by Pohlhausen (7) appears to be most convenient. This is

$$\frac{u}{U} = a + b\frac{y}{\delta} + c\left(\frac{y}{\delta}\right)^2 + d\left(\frac{y}{\delta}\right)^3 + \ldots\ldots$$

where the constants $a, b, c, d, \ldots\ldots$ are determined by boundary conditions at $y = 0, \delta$. The analysis is of exactly equal difficulty for a linear and a parabolic profile, and the latter should be the more accurate of the two. For the two-dimensional flow along a flat plate Pohlhausen found that a linear profile gave a skin friction about 13 per cent higher than the Blasius accurate profile, while a parabolic profile gave a value about 6 per cent low. If terms of degree higher than 2 in y/δ are retained, two serious difficulties are introduced. First, the differential equation for δ becomes very awkward in general, requiring a very tedious numerical or graphical integration. Second, the quantity U' occurs throughout all of the calculations. U' can only be obtained (in general) by a graphical or numerical differentiation of the experimentally determined U (from pressure distribution and Bernoulli's equation). Both of these difficulties are fortunately avoided if we cut off the power series for u/U after the second-degree term. Hence in this paper we assume a parabolic laminar velocity profile of

$$\frac{u}{U} = a + b\frac{y}{\delta} + c\left(\frac{y}{\delta}\right)^2$$

To determine the coefficients we have the two obvious boundary conditions furnished by the "zero slip" requirement and by the definition of the boundary-layer thickness

$$y = 0 \rightarrow u = 0; \quad y = \delta \rightarrow u = U$$

We know that actually u approaches U asymptotically as y increases. To get an approximation to this behavior we add as a third boundary condition

$$y = \delta \rightarrow \frac{\partial u}{\partial y} = 0$$

These three conditions determine the constants a, b, c and give

$$\frac{u}{U} = 2\,\frac{y}{\delta} - \left(\frac{y}{\delta}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

The shearing stress at the boundary is then

$$\frac{\tau_0}{\rho} = \nu\left(\frac{\partial u}{\partial y}\right)_0 = 2\nu\,\frac{U}{\delta} \ldots\ldots\ldots\ldots\ldots [11a]$$

For a turbulent boundary layer in a flow where $U' = 0$ (flat plate, uniform tube) it is well known that, at least for the range of Reynolds' numbers encountered in normal wind-tunnel tests, the velocity profile may be satisfactorily represented by the approximation formula $u/U = (y/\delta)^{1/7}$. There is at present no theory and there are also very few experimental data giving the velocity profile for cases in which the basic streamlines have either divergence or curvature. However, such experimental results as have been published indicate that a formula of the form $u/U = (y/\delta)^{1/n}$ may fairly generally be used. For pure divergence Nikuradse found $n \backsim 7$ until the divergence became so rapid that separation occurred (9). In similar experiments Doench found $n \backsim 8$ (10). By measuring the velocity distribution in the boundary layers about airship models Simmons found values of n varying between about 3.6 and 4.7, depending on the position along the dirigible (11), while Ower and Hutton found an approximately constant value of about 6 (12). In view of these very incomplete and rather conflicting data it seems that in order to get an approximate idea of the flow processes about a streamline figure of revolution, as satisfactory an assumption as any is to use the constant rectilinear flow value of $n = 7$. Hence in the following calculations we have assumed for the turbulent boundary layer

$$\frac{u}{U} = \left(\frac{y}{\delta}\right)^{1/7} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [12]$$

By dimensional analysis Karman and Prandtl have shown that in a boundary layer the surface shearing stress is completely determined by the law for velocity distribution (7, 1), and Karman has given the following expression corresponding to the velocity profile [12]:

$$\frac{\tau_0}{\rho} = 0.0225\ U^2\left(\frac{\nu}{U\delta}\right)^{1/4} \ldots\ldots\ldots\ldots [12a]$$

This expression has been verified experimentally and will be used in the succeeding analysis.

For purposes of calculation it is convenient to introduce the notation:

$$w = \frac{u}{U}, \quad z = \frac{y}{\delta}$$

in terms of which [10] takes the form

$$\frac{d}{dx}\left[U^2\delta\int_0^1 w^2dz\right] - U\frac{d}{dx}\left[U\delta\int_0^1 wdz\right]$$
$$+\frac{r_0'}{r_0}U^2\delta\left[\int_0^1 w^2dz - \int_0^1 wdz\right] = UU'\delta - \frac{\tau_0}{\rho}\,..[13]$$

Let us first consider the laminar portion of the boundary layer. From Equation [11]

$$\int_0^1 w^2dz = \frac{8}{15} \qquad \int_0^1 wdz = \frac{10}{15}$$

Introducing these and [11a] into [13] we obtain after a little reduction:

$$\frac{d\delta^2}{dx} + \left(9\,\frac{U'}{U} + 2\,\frac{r_0'}{r_0}\right)\delta^2 = 30\,\frac{\nu}{U} \ldots\ldots\ldots [14]$$

This equation is easy to integrate between $x = 0$ and x, and gives

$$U^9r_0^2\,\delta^2\Big|_0^x = 30\nu\int_0^x U^8r_0^2dx$$

But at $x = 0$, $U = r_0 = 0$, hence

$$\delta^2 = \frac{30\nu}{U^9r_0^2}\int_0^x U^8r_0^2dx$$

It is very convenient to express all quantities as dimensionless ratios, so that we define

L = axial overall length of the streamline body
a = distance along axis measured downstream from the forward stagnation point. From Fig. 3: $da = dx\cdot\sqrt{(1 - r_0'^2)} = \beta dx$
U_0 = axial velocity of flow far upstream from the body
R = U_0L/ν = Reynolds' number of the flow (independent of x, a)
R_δ = $U\delta/\nu$ = boundary-layer Reynolds' number $[R_\delta = R_\delta(a)]$
$()_l \sim ()_{\text{laminar}}$

With this new notation we get very simply

$$\left.\begin{aligned}&\frac{\delta_l}{L} = \frac{\sqrt{30}}{R^{1/2}}M\left(\frac{a}{L}\right); \quad R_{\delta l} = \sqrt{30}\,R^{1/2}\,\frac{U}{U_0}M\left(\frac{a}{L}\right)\\ &M\left(\frac{a}{L}\right) = \frac{1}{\left(\dfrac{U}{U_0}\right)^{9/2}\dfrac{r_0}{L}}\int_0^{a/L}\frac{\left(\dfrac{U}{U_0}\right)^8\left(\dfrac{r_0}{L}\right)^2}{\beta}\,d\left(\frac{a}{L}\right)\end{aligned}\right\} \ldots\ldots\ldots [15]$$

The auxiliary function M has been introduced for the sake of conciseness. [15] gives the laminar boundary-layer thickness as a function of the Reynolds number of the flow and of the position along the model surface. (Assuming a given streamline body, i.e., U/U_0, r_0/L given functions of a/L.)

The total contribution of the laminar boundary layer to the drag is the integral of the axial component of the skin-friction force per unit area from $a = 0$ to $a = a_c$ where the transition to the turbulent boundary layer occurs.

$$(\text{Drag})_l = 2\pi\int_0^{a_c} r_0\tau_0da = 4\pi\nu\rho\int_0^{a_c}\frac{r_0U}{\delta_l}\,da$$

from [11a]. We define the laminar contribution to the drag coefficient by

$$C_{vl} = \frac{(\text{Drag})_l}{\frac{\rho}{2} U_0^2 (\text{Vol})^{2/3}}$$

where (Vol) = the total volume of the body. Expressing everything in the form of dimensionless ratios and introducing [15],

$$C_{vl} = \frac{4.59}{R^{1/2}} \frac{L^2}{(\text{Vol})^{2/3}} \int_0^{\frac{a_c}{L}} \frac{\frac{U}{U_0}\frac{r_0}{L}}{M} d\left(\frac{a}{L}\right) \ldots\ldots [16]$$

Before proceeding to the turbulent layer it will be well to discuss the behavior of the equations at the singular points $r_0 = 0$. We shall first show that at least for a blunt-nosed body, the approximate form [10] of [9] is still valid in the neighborhood of the stagnation point at the nose, even though the condition $\delta \ll r_0$ is not necessarily satisfied in this region. Let O be the forward stagnation point, P a neighboring point on the surface, C_{r0} the radius of curvature at P, and φ the angle between C_{r0} and the axis (Fig. 4). For a blunt-nosed body, since P is close to O, we may take OP as a circular arc, so that C_{r0} is constant and the center of curvature Q is the same for any point P and lies on the axis. x is the length of the arc OP and the angle φ is small. Hence near the singular point O:

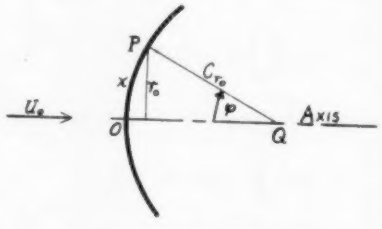

FIG. 4 ELEMENT AT THE NOSE, I.E., AT THE STAGNATION POINT

$$x = C_{r0}\varphi; \quad r_0 = C_{r0} \sin\varphi = C_{r0} \quad \varphi \left(1 - \frac{\varphi^2}{6} + \ldots\ldots\right)$$

$$\therefore r_0' = \frac{dr_0}{dx} = \frac{1}{Cr_0}\frac{dr_0}{d\varphi} = 1 - \frac{\varphi^2}{2} + \ldots\ldots$$

$$\beta = \sqrt{1 - r_0'^2} = (1 - 1 + \varphi^2 + \ldots\ldots)^{1/2} \doteq \pm\varphi$$

$$\therefore \frac{\beta}{r_0} = \pm\frac{1}{C_{r0}}; \quad \beta' = \frac{d\beta}{dx} = \pm\frac{1}{C_{r0}}$$

Hence, considering only absolute values:

$$\frac{\beta}{r_0}\left[\frac{d}{dx}\int_0^\delta u^2 y dy - U\frac{d}{dx}\int_0^\delta uydy\right] = \frac{d}{dx}\int_0^\delta u^2\frac{y}{C_{r0}}dy$$

$$- U\frac{d}{dx}\int_0^\delta u\frac{y}{C_{r0}}dy \ll \frac{d}{dx}\int_0^\delta u^2 dy - U\frac{d}{dx}\int_0^\delta udy;$$

$$\frac{\beta'}{r_0}\left[\int_0^\delta u^2 ydy - U\int_0^\delta uydy\right] = \frac{1}{r_0}\left[\int_0^\delta u^2\frac{y}{C_{r0}}dy\right.$$

$$\left.- U\int_0^\delta u\frac{y}{C_{r0}}dy\right] \ll \frac{r_0'}{r_0}\left[\int_0^\delta u^2 dy - U\int_0^\delta udy\right];$$

$$\frac{\beta}{2}\frac{\delta}{r_0} = \frac{1}{2}\frac{\delta}{C_{r0}} \ll 1$$

since it has already been assumed in [9] that $\delta \ll C_{r0}$. Hence, even at the nose where $r_0 \rightarrow 0$, [10] and the subsequent differential Equation [14] are valid approximations to [9] and may legitimately be used to describe the boundary layer. We use the laminar Equation [14] since for any normal conditions the flow would be expected to be laminar in this region.

If we rewrite [14] in the form

$$\frac{d\delta^2}{dx} = \frac{30\nu - \left(9U' + 2r_0'\frac{U}{r_0}\right)\delta^2}{U}$$

we see that $r_0 = 0$ is a singular point of this equation since there $U = 0$. In order to avoid infinite values of $d\delta^2/dx$ which are physically inadmissible, the numerator of the right side must also vanish with r_0. Hence using subscripts s to denote conditions at the stagnation point $r = 0$, we have

$$\delta_s = \sqrt{\frac{30\nu}{9U_s' + 2r_{0s}'\frac{U_s}{r_{0s}}}} \ldots\ldots\ldots\ldots [17]$$

in order to evaluate [17] we must make some assumption as to the nature of the flow near the stagnation point. We therefore assume that in this region the potential flow is the same as would occur near the stagnation point of a sphere of radius C_{r0} in the uniform flow U_0. This gives the well-known result

$$U = \frac{3}{2}U_0 \sin\varphi \doteq \frac{3}{2}U_0\varphi$$

$$\therefore U_s' = \left(\frac{dU}{dx}\right)_s = \frac{1}{C_{r0}}\left(\frac{dU}{d\varphi}\right)_s = \frac{3}{2}\frac{U_0}{C_{r0}} \quad \text{and} \quad r_{0s}'\frac{U_s}{r_{0s}} = \frac{3}{2}\frac{U_0}{C_{r0}}$$

Hence

$$\delta_s = \sqrt{\frac{60\nu}{33\frac{U_0}{C_{r0}}}} = \sqrt{\frac{60}{33}}\, L \frac{\sqrt{C_{r0}/L}}{\sqrt{\frac{U_0 L}{\nu}}}$$

Therefore at the stagnation point at a rounded nose the laminar boundary layer has a finite thickness given by

$$\frac{\delta_s}{L} \doteq \frac{1.348}{\sqrt{R}}\sqrt{\frac{C_{r0}}{L}} \ldots\ldots\ldots\ldots\ldots\ldots [18]$$

In the neighborhood of the other singular point at the tail of the body, the boundary layer will be relatively thick and the assumptions leading from [9] to [10] are not justified. Hence near the tail our calculations no longer give the true conditions. This means that our determination of δ near the tail may be in considerable error. However, the error introduced into the most interesting characteristic, the total drag coefficient, will probably be very small. This is because the boundary layer in this region is so thick that the skin friction is very small. Hence a considerable error in it will affect the total drag coefficient very little.

Turning now to the turbulent region, we have, from [12],

$$\int_0^1 w^2 dz = 7/9 \qquad \int_0^1 wdz = 7/8$$

and substituting these expressions and [12a] into [13] we obtain for the differential equation for the turbulent-boundary-layer thickness

$$\frac{d\delta^{\frac{5}{4}}}{dx} + \left(\frac{115}{28}\frac{U'}{U} + \frac{35}{28}\frac{r_0'}{r_0}\right)\delta^{\frac{5}{4}} = 0.289\frac{\nu^{\frac{1}{4}}}{U^{1/4}} \ldots [18a]$$

This equation is readily integrated and gives, where we shall in the future use a subscript c to denote conditions at the critical or transition point,

$$U^{\frac{115}{28}} r_0^{\frac{35}{28}} \delta^{\frac{5}{4}} \Big|_{x_c}^{x} = 0.289\, \nu^{\frac{1}{4}} \int_{x_c}^{x} U^{\frac{108}{28}} r_0^{\frac{35}{28}}\, dx$$

or

$$\delta^{\frac{5}{4}} = \frac{0.289\, \nu^{\frac{1}{4}}}{U^{\frac{115}{28}} r_0^{\frac{35}{28}}} \int_{a_c}^{a} \frac{U^{\frac{108}{28}} r_0^{\frac{35}{28}}}{\beta}\, da + \left(\frac{U_c}{U}\right)^{\frac{115}{28}} \left(\frac{r_{0c}}{r_0}\right)^{\frac{35}{28}} \delta_c^{\frac{5}{4}}$$

Introducing the previously used dimensionless parameters we get finally, corresponding to [15],

$$\left.\begin{aligned} \frac{\delta_t}{L} &= \frac{0.370}{R^{\frac{1}{5}}} N\left(\frac{a}{L}, \frac{a_c}{L}\right); \quad R_{\delta t} = 0.370 R^{\frac{4}{5}} \frac{U}{U_0} N\left(\frac{a}{L}, \frac{a_c}{L}\right) \\ N\left(\frac{a}{L}, \frac{a_c}{L}\right) &= \frac{1}{\left(\frac{U}{U_0}\right)^{\frac{23}{7}} \frac{r_0}{L}} \left[\int_{a_c/L}^{\frac{a}{L}} \frac{\left(\frac{U}{U_0}\right)^{\frac{27}{7}} \left(\frac{r_0}{L}\right)^{\frac{5}{4}}}{\beta} \right. \\ &\qquad \left. d\left(\frac{a}{L}\right) + 3.46 R^{\frac{1}{4}} \left(\frac{\delta_{ct}}{L}\right)^{\frac{5}{4}} \left(\frac{U_c}{U_0}\right)^{\frac{115}{28}} \left(\frac{r_{0c}}{L}\right)^{\frac{5}{4}}\right]^{\frac{4}{5}} \end{aligned}\right\} \quad ..[19]$$

where $()_t \backsim ()_{\text{turbulent}}$.

For the contribution of the turbulent-boundary-layer to the skin friction we have

$$(\text{Drag})_t = 2\pi\rho \int_{a_c}^{L} r_0 \frac{\tau_0}{\rho}\, da = 0.045\, \pi\rho\nu^{\frac{1}{4}} \int_{a_c}^{L} \frac{r_0 U^{7/4}}{\delta^{1/4}}\, da$$

or defining

$$C_{vt} = \frac{(\text{Drag})_t}{\frac{\rho}{2} U_0^2 (\text{Vol})^{2/3}}$$

a short calculation gives

$$C_{vt} = \frac{0.3625}{R^{1/5}} \frac{L^2}{(\text{Vol})^{2/3}} \int_{a_c/L}^{1} \frac{\left(\frac{U}{U_0}\right)^{7/4} \frac{r_0}{L}}{N^{1/4}} d\left(\frac{a}{L}\right) \quad \ldots [20]$$

Equations [15], [16], [18], [19], and [20] enable us to calculate the boundary-layer thickness over the entire surface except near the extreme tail, and the complete drag coefficient:

$$C_v = C_{vl} + C_{vt} \ldots\ldots\ldots\ldots\ldots\ldots [21]$$

as soon as the transition conditions have been assumed and made precise.

5—Transition Conditions and Hypotheses

Although experiment and theory agree in indicating that a breakdown may occur from the laminar to the turbulent régime in a boundary layer, the actual conditions in this transition region are still largely in the dark. Experiments with flat-plate boundaries (13, 14) show that the transition is far from instantaneous, and indeed that the distance between the last well-defined laminar profile and the first fully developed turbulent profile may be fairly large. The experiments on the boundary layer about figures of revolution appear to indicate a somewhat smaller transition region, but no very definite conclusions in this regard can be drawn as yet. The assumption which Prandtl made in his theory mentioned at the beginning of this paper was that the transition was instantaneous, and that behind the transition point the turbulent boundary layer had the same thickness and behaved exactly as it would have if the entire boundary had been turbulent from the leading edge. This very simple assumption gives a considerable jump or discontinuity in δ at the transition point, which is not experimentally observed. Before discussing the reason for the good agreement between the Prandtl predictions relative to skin friction, which are based on this assumption and on experiment, let us try to formulate an alternative method of handling the transition region.

For this purpose we consider first a two-dimensional flow over a flat plate so that $r_0 = \infty$, U = constant, and the integral relation [10] reduces to the classical Karman form:

$$\frac{d}{dx}\int^{\delta} u^2 dy - U \frac{d}{dx}\int_0^{\delta} u\, dy = -\frac{\tau_0}{\rho}$$

Let us suppose that at $x = x_1$ we have still a laminar velocity profile while at x_2 the boundary layer has the turbulence characteristics fully developed. Considering the region of the boundary layer bounded by x_1 and x_2, i.e., the transition region, we require the momentum law to be satisfied in it. This means that we require the transition region to satisfy the elementary dynamical laws. Hence integrating the Karman integral relation between the limits x_1 and x_2 we get

$$\int_{x_1}^{x_2} \left[\frac{d}{dx}\left(U^2\delta \int_0^1 w^2 dz\right) - U \frac{d}{dx}\left(U\delta \int_0^1 w\, dz\right)\right] dx$$

$$= -\int_{x_1}^{x_2} \frac{\tau_0}{\rho}\, dx$$

$$\therefore\ U^2\delta \int_0^1 (w^2 - w)\, dz \Big|_{x_1}^{x_2} = -\int_{x_1}^{x_2} \frac{\tau_0}{\rho}\, dx$$

Now writing $\bar{\tau}_0$ = mean value of τ_0 over the transition region

$$\delta \int_0^1 (w^2 - w)\, dz \Big|_{x_1}^{x_2} = -\frac{\bar{\tau}_0}{\rho U^2} (x_2 - x_1)$$

If now we suppose that at x_1 we have our laminar parabolic profile and at x_2 the $1/7$th-power turbulent profile, then a little calculation gives

$$\delta_{t2} = 1.37\delta_{l1} + 10.3 \frac{\bar{\tau}_0}{\rho U^2} (x_2 - x_1) \ldots\ldots\ldots [22]$$

If we had assumed that the profile at x_1 was the true Blasius profile, then this equation would be unchanged except that the coefficient of δ_{l1} would be altered from 1.37 to 1.27.

Unfortunately not enough experimental or theoretical data on the transition region exist to enable us to use [22]. If we assume $x_2 = x_1$, i.e., that the transition is practically instantaneous, then

$$\delta_{tc} = 1.37\delta_{lc} \ldots\ldots\ldots\ldots\ldots\ldots [23]$$

which gives a discontinuity in δ at the transition point. It is easy to show that [23] also holds for an instantaneous transition in the boundary layer around a streamline figure of revolution, if the same velocity profiles as above are assumed. The discontinuity in δ_c given by [23] is in general much less than that given by Prandtl's transition hypothesis, so that it would appear that [23] should more closely represent the true behavior of δ than does the latter hypothesis.

With regard to the skin friction, however, it is not at all certain that [23] is a better assumption than that of Prandtl, for the following reason: For a given boundary-layer thickness the skin friction for a turbulent profile is much larger than for a laminar profile. In the true gradual transition the flow character changes continuously from laminar to turbulent and hence

r_0 also changes smoothly from the laminar value at x_1 to the (in general larger) turbulent value at x_2. If, however, we assume an instantaneous transition then there is a large discontinuity in r_0 unless there is a correspondingly considerable discontinuity in δ_c. From the excellent agreement between Prandtl's theory and experiments on flat plates it would appear that the very large jump from δ_{lc} to δ_{tc} implied by this theory is approximately the correct one in order to give a fairly smoothly increasing value of r_0. If this conclusion is also valid for figures of revolution, then it would seem that if skin friction is the most important quantity under investigation, the Prandtl transition hypothesis is more satisfactory than the dynamically more logical hypothesis given by [23].

Another very great advantage of the Prandtl hypothesis lies in the enormously greater simplicity of the calculations in working out any particular case. For since the turbulent boundary layer behaves as if it had started at the stagnation point, therefore in [19], $U_c = r_{0c} = 0$ and $N(a/L, a_c/L)$ becomes $N(a/L)$, a function of only one variable instead of two. For both of the above reasons we have used the Prandtl transition hypothesis in the numerical calculations of the next section.

Having decided upon the nature of the transition region which will be assumed, there remains the question as to how the position of the transition point is to be chosen. In agreement with the experimental results on the flow in tubes (15) and in boundary layers along flat plates we assume that the laminar flow becomes unstable and turbulent flow sets in at a critical value of the boundary-layer Reynolds' number R_δ. Hence the transition point occurs for $R_\delta = R_{\delta c}$. The numerical value for $R_{\delta c}$ is known to depend on the initial turbulence in the incident air stream for flat plates (13). We therefore carry over this result and assume that $R_{\delta c}$ is a function of the turbulence of the free air stream, increasing as the turbulence decreases. The lowest value of $R_{\delta c}$ which Schiller was able to obtain in tubes (corresponding to the most violent incident turbulence) was 1160. Here R_δ was defined in terms of the radius of the tube. Zijnen found a minimum $R_{\delta c}$ for the boundary layer along a flat plate of about 1650. Tollmien has recently calculated theoretically the stability conditions in a flat-plate boundary layer and obtained a minimum $R_{\delta c}$ of 1320 (16). The upper limit for $R_{\delta c}$ is still uncertain; it may be that if all external disturbances could be eliminated $R_{\delta c}$ maximum might approach infinity. However, the highest values normally obtained with experimentally possible flows are of the order of 12,000. Hence for normal experiments we may expect $R_{\delta c}$ to lie between 1500 and 12,000, and to vary inversely with the degree of initial turbulence in the incident flow.

One further remark should be made with reference to the transition hypotheses. It appears that at very small Reynolds' numbers (R) the transition point lies very near to the tail of a normal airship body. Hence under these conditions practically the entire drag is laminar skin friction, and is hence practically independent of the transition characteristics assumed. Conversely at very large Reynolds' numbers the critical or transition point is very near the nose and the drag is almost entirely turbulent skin friction. In this case the boundary layer is extremely thin at the transition point so that a large variation in the transition hypothesis will have a very small effect on the boundary-layer conditions far behind, and hence on the drag. Therefore at both very large and very small Reynolds' numbers the transition hypothesis is of negligible importance. It affects the total drag considerably only at the intermediate Reynolds' numbers where the transition point occurs in the central region of the airship.

6—Numerical Calculations for the N.P.L. International Long Airship Model

For the purpose of numerical calculation to test the present theory the so-called "N.P.L. long airship model" was chosen since it has been the subject of experimental investigations in many of the aerodynamic laboratories of the world (17). Table 1 gives the data used. r_0/L was taken from Table 4, p. 14, of (3), β was obtained from a graphical differentiation of the curve of r_0/L vs. a/L, U/U_0 was calculated from the experimental pressure distribution given in Table 10 of (8).

TABLE 1

$L^2/(\text{Vol})^{2/3} = 24.81.$
$L = 87.2$ cm.

The auxiliary functions M, N (Equations [15], [19]), were obtained by graphical integration with a "Coradi" integraph. Since the calculations were made on the basis of the Prandtl transition hypothesis, N is a function of a/L only just as is M. From [15], $R_{\delta l}/R^{1/2}$ was calculated as a function of a/L. For the succeeding calculations it was found convenient to consider this relation as $R_{\delta c}/R^{1/2}$ as a function of a_c/L. Here and in the future $R_{\delta c}$ denotes the value of $R_{\delta l}$ at the transition point. From [16] and [20] $R^{1/2}C_{vl}(a_c/L)$ and $R^{1/5}C_{vt}(a_c/L)$ were determined (again by graphical integration) as functions of a_c/L. These three functions are shown in Fig. 5. A definite value of $R_{\delta c}$ was now assumed and a_c/L was determined as a function of R from Fig. 5. Using Fig. 5 again, C_{vl} and C_{vt} were then determined as functions of R, and finally the total drag coefficient $C_v = C_{vl} + C_{vt}$ was obtained as a function of R. The process was then repeated for a series of assumed values of $R_{\delta c}$.

The results are plotted to a logarithmic scale in Fig. 6. The abscissas here are not $R = V_0L/\nu$ but $R_v = U_0(\text{Vol})^{1/3}/\nu)$ since most of the experimental results are given in terms of this latter

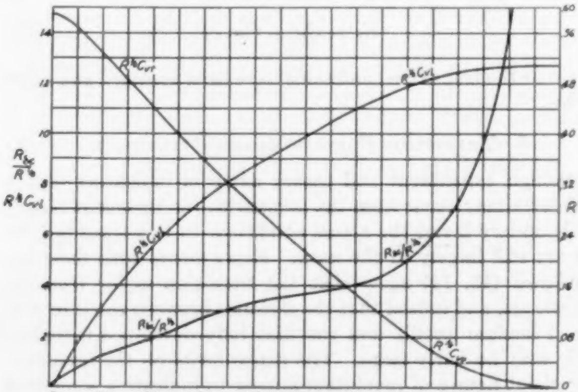

Fig. 5 Curves Giving Laminar and Turbulent Contributions to Drag Coefficient, and Boundary-Layer Thickness at Transition Point, in Terms of Position of Transition Point and the Reynolds Number of the Flow. (For N.P.L. Long Dirigible Model.)

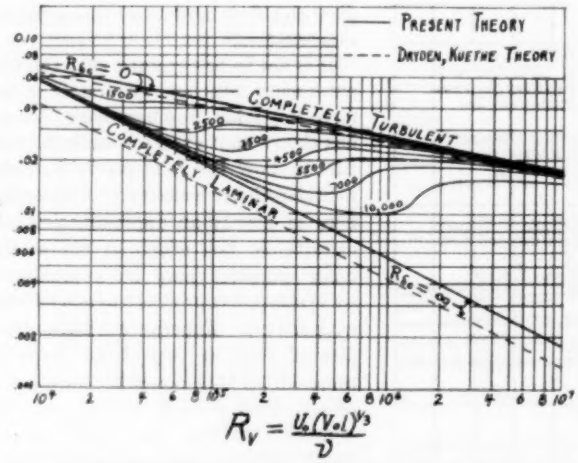

FIG. 6 LOGARITHMIC PLOT OF THEORETICAL TOTAL DRAG COEFFICIENT OF N.P.L. LONG MODEL AS A FUNCTION OF THE REYNOLDS NUMBER OF FLOW (R_v), FOR VARIOUS VALUES OF THE CRITICAL BOUNDARY-LAYER REYNOLDS NUMBER

quantity. For the N.P.L. long model $R_v \doteq {}^1/_5R$. The curves marked laminar and turbulent are limiting cases in which the entire boundary layer is laminar and turbulent, respectively. They are obtained by putting $R_{\delta c} = \infty$ and $R_{\delta c} = 0$. The analytical expressions for these limiting cases are

$$C_{v\text{-laminar}} = \frac{12.70}{R^{1/2}} = \frac{5.68}{R_v^{1/2}}; \qquad C_{v\text{-turbulent}} = \frac{0.590}{R^{1/5}} = \frac{0.428}{R_v^{1/5}}$$

A few curves from Fig. 15 of Dryden and Kuethe's paper (3) have also been plotted for comparison in Fig. 6. We shall discuss these curves a little in the next section.

The laminar and turbulent boundary-layer thickness have been calculated for two values of R_v and are plotted in Fig. 7. The combined δ on the basis of the Prandtl transition hypothesis is indicated for $R_{\delta c} = 4500$ for both values of R_c.

Finally the value of δ_l at the forward stagnation point has been calculated from Equation [18]. From the shape of the nose it was determined that $C_{r0}/L = 0.015$. Hence [18] gives:

$$\frac{\delta_s}{L} = \frac{0.165}{R^{1/2}} = \frac{0.074}{R_v^{1/2}} \ldots\ldots\ldots\ldots\ldots [24]$$

7—COMPARISON WITH EXPERIMENT AND DISCUSSION

A portion of Fig. 6 has been replotted to a linear scale in Fig. 8. The range of Reynolds' numbers included is that which is normally attained in wind-tunnel tests. Six experimentally determined curves have also been plotted. Four of these were obtained at the Bureau of Standards (3), one in the N.A.C.A. variable density tunnel (17), and one in the 10-ft. wind tunnel of the Guggenheim Aeronautics Laboratory at the California Institute of Technology (18). The two limiting curves for pure laminar and pure turbulent flow given by Dryden and Kuethe are also included in the figure.

It is seen that all of the experimental curves lie between the two limiting curves deduced from the present theory. This fact remains true for all of the experimental results on the N.P.L. long model which the author has been able to find. The general shape of the experimental curves is also very similar to the theoretical ones. In particular all the experimental curves approach the "turbulent" limiting curve at large Reynolds' numbers in just the manner prescribed by the theory. For low Reynolds' numbers the experimental results which have been carried far enough to make an estimate possible seem also to be approaching the theoretical limiting values more or less asymptotically. If the critical Reynolds' number for a sphere be taken as a measure of the turbulence in a wind-tunnel stream as suggested by Dryden and Kuethe (3) then the values of $R_{\delta c}$ which must be chosen to give the best theoretical agreement with the various experimental curves of Fig. 8 are qualitatively at least in excellent harmony with the measured turbulence in the various tunnels. Thus the variable density tunnel is known from sphere tests to have had an extremely high degree of turbulence (at least in the condition in which it was when the plotted results were obtained). Hence the very low value of $R_{\delta c}$ of about 1200 which is indicated by Fig. 8 is not surprising. The fact that this value is actually below the lowest experimental values obtained in flat plate or tube tests, and is also slightly lower than Tollmien's lower limit for flat-plate flow, may be due to a real difference between the minimum values of $R_{\delta c}$ possible in essentially rectilinear and in curved flow, or it may occur because of the approximate nature of the velocity profiles assumed in the present theory. Similarly the C.I.T. tunnel has the lowest turbulence, as indicated by sphere tests, of any tunnel which has as yet published data on the subject, and the $R_{\delta c}$ of about 4800 indicated by Fig. 8 is the highest required for any set of results except those obtained in the 3 ft. tunnel at the Bureau of Standards (not reproduced in Fig. 8). The experimental data in the latter case are, however, of quite doubtful accuracy, largely because of the uncertainty as to the wind-tunnel interference effects for this set of experiments.

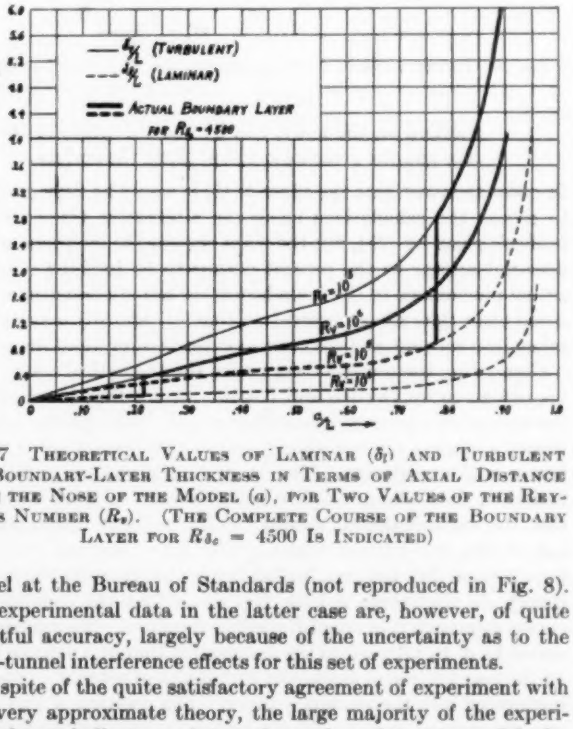

FIG. 7 THEORETICAL VALUES OF LAMINAR (δ_l) AND TURBULENT (δ_t) BOUNDARY-LAYER THICKNESS IN TERMS OF AXIAL DISTANCE FROM THE NOSE OF THE MODEL (a), FOR TWO VALUES OF THE REYNOLDS NUMBER (R_v). (THE COMPLETE COURSE OF THE BOUNDARY LAYER FOR $R_{\delta c}$ = 4500 IS INDICATED)

In spite of the quite satisfactory agreement of experiment with this very approximate theory, the large majority of the experimental tests indicate one interesting and consistent type of deviation from the theory. This deviation may be expressed by stating that the values of $R_{\delta c}$ at low R_v's seem to be higher than those at large R_v's for the same experimental curve. The explanation for this discrepancy may lie in any of the following points:

a The approximate nature of the velocity profiles assumed in the theory

b The over-simplified nature of the Prandtl transition hypothesis employed in making the calculations

c A possible variation in wind-tunnel turbulence with speed with an associated variation in $R_{\delta c}$

d The possibility that $R_{\delta c}$ is not only determined by the turbulence conditions in the incident air, but also by the

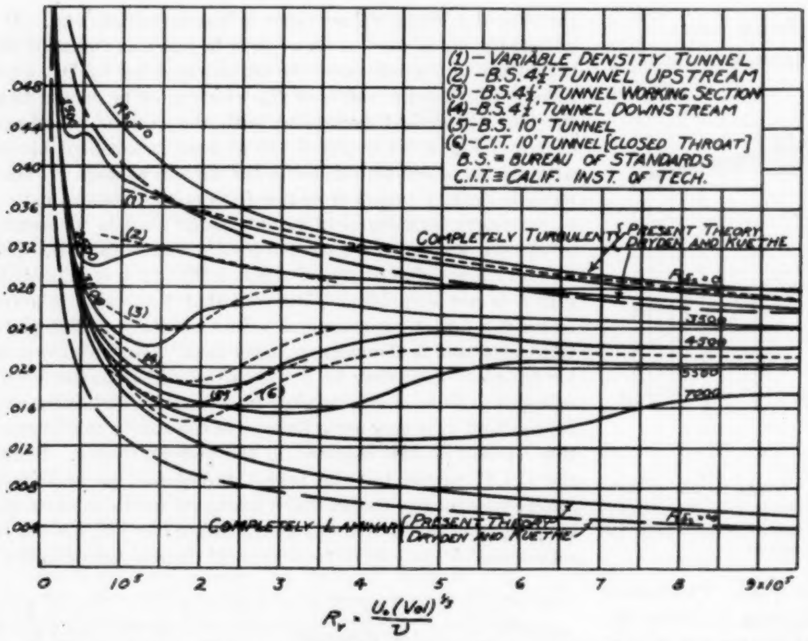

FIG. 8 EXPERIMENTAL CURVES FOR C_v VS. R_v, AND THEORETICAL CURVES FOR VARIOUS VALUES OF R_{δ_c}

position on the body, i.e., by the curvature of the surface and the pressure gradient along the surface.

In order to investigate the effect of (*b*) it would be very desirable to repeat the calculations using the alternative transition hypothesis given by [23], but the work becomes so laborious that it does not appear to the present author to be justified until the actual phenomena in the boundary layer are much better understood than they are at present so that (*a*) and (*d*) may also be taken into account and the corresponding assumptions improved.

Comparing the present theory with the theoretical results previously given by Dryden and Kuethe, we see that the shapes of the transition curves are somewhat similar although the present theory's minima are less abrupt and in this respect agree rather better with experiment. The D. & K. limiting curve for pure turbulent flow falls noticeably beneath ours, so much so indeed that the variable-density-tunnel results lie above it and entirely out of the skin-friction region. The lower limiting curve for pure laminar flow lies even further below that given by the present theory, so that there is little indication that the experimental curves approach it at small Reynolds' numbers. To remedy this defect D. & K. introduced the assumption that at a definite point on the rear portion of the model turbulence of a definite type was introduced into the boundary layer. The position of this point was determined so as to get the best agreement between theory and experiment. The effect of the assumption is that if the transition point occurs near the rear of the model, i.e., at low values of R_v, then $R_{\delta c}$ is smaller than if the transition occurs near the front of the model, as at high R_v's. Hence the theoretical curves are raised for small R_v's and left unchanged at large R_v's. On the basis of the present theory, therefore, this assumption is just the opposite of what is required since it would exaggerate the discrepancies between theory and experiment. It would be very interesting to examine the effect of position along the surface on $R_{\delta c}$, as could be done by testing models of different lengths and seeing whether the discrepancies between theory and experiment occurred at the same values of R in the two cases, or at the same positions of the transition point ac/L on the model. Experiments on the stability of a laminar boundary layer in curved or diverging flow might also throw light on this question.

It is not to be expected that the present theory will hold accurately at very large Reynolds' numbers since Karman has shown that even for essentially rectilinear flow the $^1/_7$th-power turbulent boundary-layer velocity profile assumed here is merely an approximation to a logarithmic law which at higher Reynolds' numbers may be approximated by $1/n$th-power profiles where n increases with R (19). Experiments have also indicated that at very large Reynolds' numbers the $^1/_7$th power becomes a $^1/_8$th power, then a $^1/_9$th power, etc. (20). Hence the limiting "turbulent" curve of Fig. 6 will not remain a straight line but will have an upward curvature at very large Reynolds' numbers, finally approaching a horizontal asymptote. The variable density results actually indicate this phenomenon, the experimental curve curving upward and crossing the "theoretical" straight line at about $R_v = 1.5 \times 10^6$.

The theoretical curves for δ/L given in Fig. 7 have been compared with experiments on other airship models (11, 12) and the general shape and order of magnitude of the curves verified. Near the tail the theory is not valid and gives $\delta \rightarrow \infty$, and at the transition point the discontinuity which we have assumed is, of course, not found in the experimental results. If an accurate knowledge of the boundary layer thickness is desired within the critical range of Reynolds' numbers then it seems that some more rational transition hypotheses than the Prandtl formulation which we have used must be adopted.

8—CONCLUSION

In this paper we have first derived the Prandtl boundary-layer equation for a boundary with axial symmetry and have then obtained a first integral of it giving the "integral relation" for the boundary layer about a figure of revolution. An approximate form of this, valid when the boundary-layer thickness is small compared to the distance from the axis, is obtained as a comparatively simple relation. As an example of the use of this equation, expressions for the laminar and turbulent boundary-layer thickness and skin friction of an airship shape are given, based on simple assumptions relative to the laminar and turbulent boundary-layer velocity profiles. The transition region between laminar and turbulent flow in the boundary layer is discussed and a transition hypothesis alternative to that of Prandtl is given. Finally numerical calculations based on the previous analysis are carried out for a particular airship model and the results compared with experiment and with those of the earlier theory of Dryden and Kuethe. The agreement with experiment is quite satisfactory and leads to the hope that the method will be capable of yielding really accurate results when better approximations to the true velocity distributions and to the transition region become available through basic research on the turbulence problem.

SUMMARY OF FINAL NOTATION EMPLOYED

x = distance along the surface measured from stagnation point
y = distance normal to the surface
a = axial distance from nose of the airship

L = length of airship
r_0 = radius of the airship surface
C_r = longitudinal radius of curvature of airship surface
δ = boundary-layer thickness
U = velocity just outside the boundary layer
U_0 = axial velocity of the flow far from the airship and relative to it
C_v = drag coefficient defined in terms of $(\mathrm{Vol})^{2/3}$
ν = coefficient of kinematic viscosity
$R = U_0L/\nu$
$R_v = U_0\,(\mathrm{Vol})^{1/3}/\nu$
$R_\delta = U\delta/\nu$
$()_l \backsim ()_{\text{laminar}}$
$()_t \backsim ()_{\text{turbulent}}$
$()_c \backsim ()_{\text{critical}}$ (transition point)
$()_s \backsim ()_{\text{stagnation}}$ (forward stagnation point)

Discussion

O. G. Tietjens.[3] It gives the writer great pleasure, as a former student of Dr. L. Prandtl, to lead the discussion of this excellent paper. The two great and still unsolved problems in aerodynamics and hydrodynamics are the problem of air resistance or, generally speaking, of fluid resistance and the problem of turbulence. Or possibly there is only the one problem of turbulence. The solution of this problem, although now remote, would furnish us, probably, with the means of solving the problem of fluid resistance.

This paper is not only a remarkable step forward in the direction of solving the problem of airship resistance, which is of course of eminent practical importance, but it also shows that those conceptions and theories developed by Dr. Prandtl and his associates—the writer wishes to refer particularly to Dr. von Karman—begin to gain friends also in this country.

Attention may be drawn to a paper on a similar subject published about a year ago by T. Levi-Civita, entitled "General Conclusions from Prandtl's Theory of the Boundary Layer."[4] In this paper the differential equations are derived, not only for a body of axial symmetry, but for a body of any shape. The rate of approximation in Levi-Civita's paper is the same as that used by Dr. Millikan; terms in $\sqrt{\nu}$ having powers higher than the first are neglected. However, due to the much more general derivation of the equation, no solution could be given for any particular case.

The writer has a question referring to Equation [12] according to which the velocity in the boundary layer increases with the $^1/_7$ power of the distance from the boundary. Since tests made by J. Nikuradse show for large Reynolds' number proportionality with the $^1/_8$ or even $^1/_9$ power, the writer would like to ask the author how the different assumptions with respect to this exponent influence the final coefficient of drag $C_{v\text{-turbulent}}$. In connection with this, it should be considered whether the tests with $U^1 = \dfrac{dU}{dx} = 0$ (plate, tube) which give the exponent $^1/_7$, etc., will give the same exponent if $U^1 \neq 0$ as along a rounded body.

The writer would like to make some remarks with respect to the transition from laminar to turbulent flow in the boundary layer. First of all, it is not certain that the measurements of the velocity distribution in the boundary layer show sufficiently clearly whether the transition is instantaneous or whether the distance between the last well-defined laminar profile and the first fully developed turbulent profile is large or small. The gage reading will fluctuate too much at this region to allow an exact measurement of the velocity distribution.

Due to the fact that the critical Reynolds' number $U\delta_c/\nu$ depends largely on the turbulence of the free air stream, which may vary slightly from time to time, the breakdown of the laminar flow in the boundary layer will occur irregularly at larger or smaller δ_c corresponding to a more or less turbulent condition of the free air stream. The writer is of the opinion that the transition does not occur instantaneously, but nevertheless in a comparably short time.

About ten years ago the stability of a laminar boundary layer[5] was investigated. A certain disturbance $e^{i(kx-nt)} \cdot f(y)$ was superposed on the laminar layer. Writing $n = r + is$, we have

$$e^{i(kx-rt)} \,.\, e^{st} \,.\, f(y).$$

If the calculation of the stability of such a disturbance gives a positive s, then there is an increase of the disturbance with the time according to e^{st}, and thus finally turbulence; if the calculation gives a negative s, then the disturbance decreases and the laminar flow is stable. At that time the writer was not able to derive from this calculation a critical Reynolds' number. Later it was shown by W. Tollmien[6] that this was due to the linear velocity distribution assumed in the boundary layer. However, the writer did prove that, if the laminar flow is unstable, the rate of increase of the disturbance (i.e., the exponent s) is proportional to $\sqrt{\frac{\nu U}{\delta^3}}$.

[5] Tietjens, O. G., "Beitraege zur Entstehung der Turbulenz," *Zeit. f. ang. Math. u. Mech.*, 5 (1925), s. 200.

If we introduce into the above expression the thickness of the laminar boundary layer, $\delta = \frac{5.5a}{\sqrt{\frac{U \cdot a}{\nu}}}$, we get s proportional to $\frac{U}{a}\sqrt[4]{\frac{U \cdot a}{\nu}}$. Thus it is seen that for large Reynolds' numbers, large velocities, and small values of a, the exponent s becomes large. Although the transition from laminar to turbulent flow will probably be somewhat different in a boundary layer from that in a pipe, it may be of interest to see in Fig. 9 in what short a time the laminar flow changes into the turbulent flow. The Reynolds' number $U\cdot$ diameter/ν is about **16,000**. The number of pictures per second is 400.

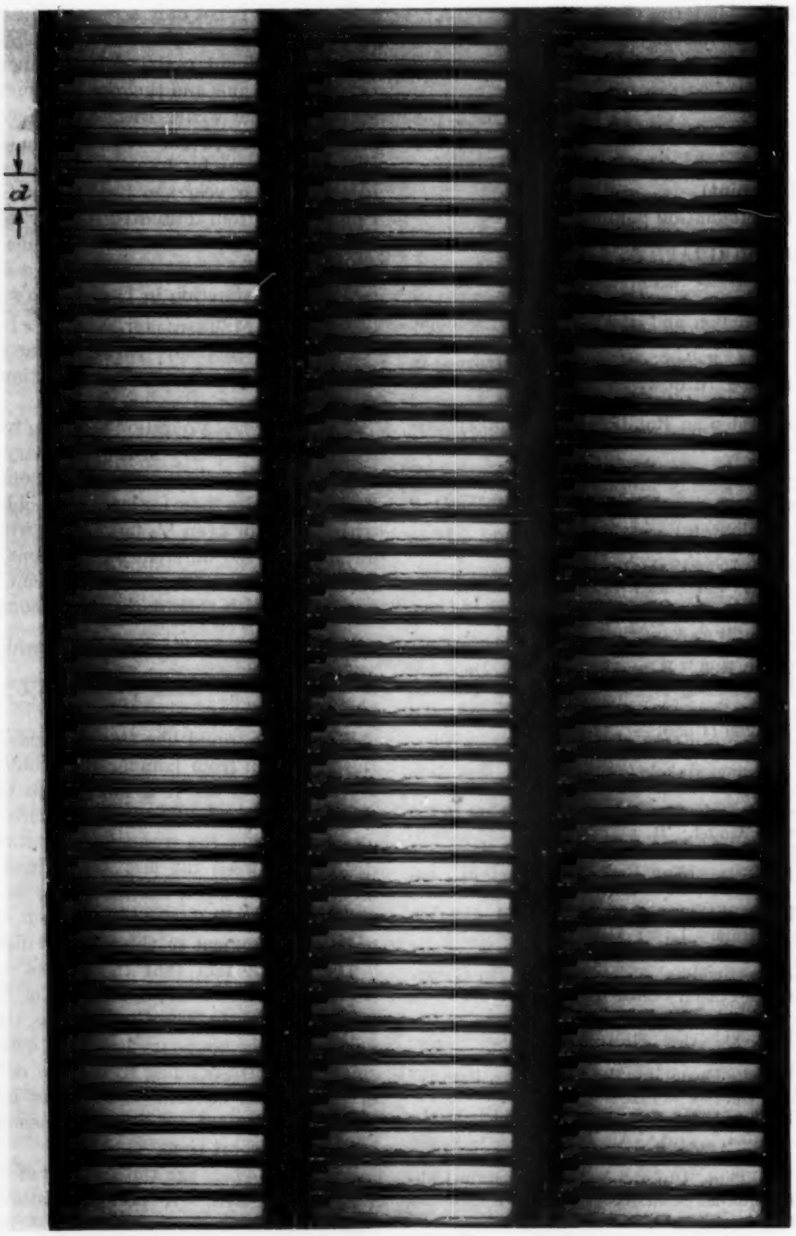

Fig. 9 Transition of Laminar to Turbulent Flow in a Pipe

(High-speed motion pictures taken at 400 per second. Direction of flow is from left to right. $Ud/\nu = 16{,}000$.)

---

[6] Tollmien, W., "Ueber die Entstehung der Turbulenz, Part 1," *Nachr. von der Ges. der Wiss. zu Göttingen* (1929).

With regard to the critical Reynolds' number, it does not seem quite correct to refer to the value 1160 obtained by L. Schiller. In this case there is no question of a transition from a laminar to a turbulent flow, since the flow enters the pipe in an extremely disturbed condition and there is no δ_{laminar} or δ_c to which we can refer.

Regarding the minimum $R_{\delta_c} = 1320$ calculated by W. Tollmien, this value should be compared with the highest critical Reynolds' number that can be obtained by experiments, since the calculation of Tollmien is based on infinitely small disturbances. The critical Reynolds' number has been called by Dr. Tollmien the minimum critical Reynolds' number only with respect to the wave length of the disturbance assumed and not with respect to the amplitude of the disturbance; i.e., the calculation gives a smallest critical Reynolds' number for a certain wave length of the disturbance, and for any other wave length a larger critical Reynolds' number. However, as a disturbance of any wave length may occur, the smallest value of the Reynolds' number obtained for any frequency has to be considered as the critical Reynolds' number.

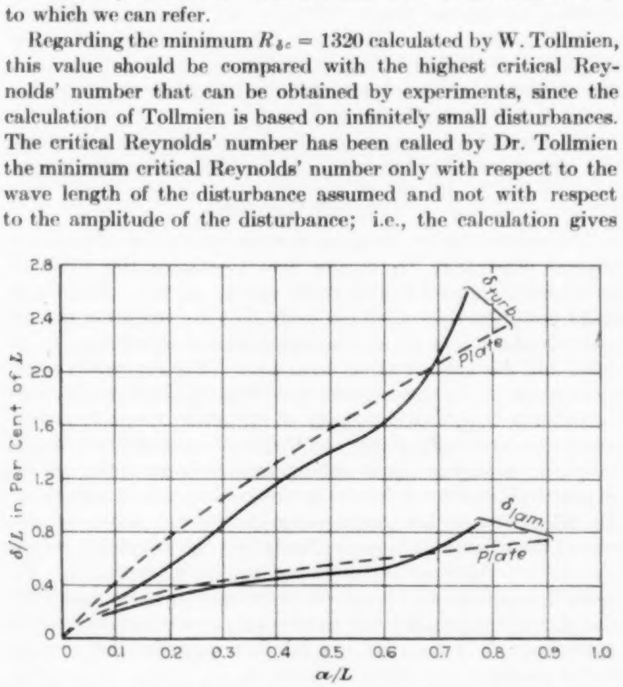

FIG. 10 COMPARISON OF THICKNESS OF BOUNDARY LAYER OF AN AIRSHIP MODEL AND A PLATE

(The laminar and turbulent boundary layers are shown by a solid line; the plate is shown by a broken line. $U.L/\nu = 500{,}000$.)

In order to compare the thickness of the laminar and turbulent boundary layers of an airship hull with those of a plate, Fig. 10 is given. It is interesting to note that both lines are higher for the plate than for the airship hull, which may explain to a certain extent the fact that the curves of the drag coefficient as a function of the Reynolds' number calculated by Dryden and Keuthe are always lower than those calculated by Dr. Millikan. The writer would like to ask Dr. Millikan up to what value of a/L he believes the theory is valid.

W. KLEMPERER.[7] The paper is of signal importance to all aerodynamicists interested in the determination of the drag of round streamlined bodies such as airships and fuselages for airplanes, because it is a successful scientific step toward lifting the puzzling veil from the maze of seemingly conflicting experimental evidence. It has long been a matter of grave concern to the wind-tunnel experimenters that the better a wind-resisting body is streamlined and refined the more vague the theory of drag becomes and the more problematic the direct applicability of small-scale test results grows. Basic theories such as have done so much to clear up the induced-drag problems of wings are still utterly meager in this field of low-parasite-drag problems, because too little is known of how the shape of the solid contour influences the mechanism of air friction. The author has shown how reasonable assumptions about this mechanism, borrowed from other simpler shapes, give a conclusive explanation of the fallacy of airship-model tests made at too low a Reynolds' number and why the great efforts that have been spent in various countries cooperating in elaborate "comparison" tests are very interesting, but failed to solve the mysterious question of which tunnel gives the results truest to full size. The resistance of models whose boundary layer is laminar over a large portion of the hull cannot possibly bear a simple relation to the full-size ship whose boundary layer is undoubtedly turbulent over the major part of the ship. On the other hand, experiments conducted at very high Reynolds' number, and especially on very large models at very high velocity in a wind possessing a fine turbulence texture, may quite well possess drag coefficients which can be correlated to those of full size by proper allowance for the shrinking of the boundary layer with increasing Reynolds' number. As a matter of fact, quite a number of model tests have been made by our company, as well as by others, on models of airships extending into Reynolds' number as high as 3 and even 6 times those of the far end of the author's Fig. 8. The value of these tests appears greatly enhanced in the light of this contribution.

Evidently the most important task for future experimentation is not so much the mere accumulation of further drag measurements on models of arbitrary sizes and surface condition, but it must be accompanied by explorations of the mechanism of surface friction on such bodies, a survey of the phenomena inside the boundary layer. We have made experiments both on large models and aboardship throwing some light on the actual character of the boundary layer. We have evidence that the 7th-root profile is a good approximation in the amidship region, whereas the fractional exponent grows decidedly larger toward the bow and smaller toward the tail. Happily this seems to have only a relatively small influence upon the net results and conclusions drawn by the author. However, it emphasizes the desirability of developing a theory for the variation of the velocity profile normal to the hull as a function of the angle of the meridional tangent and perhaps the local radii of curvature. It may be expected that some correlation can be established with the conditions in conical or wedge-shaped effusors and nozzles. With theory and experiment then forging ahead hand in hand, there is hope that drag-test results of streamline bodies will eventually be amenable to scientific interpretation beyond the vague scope of such obsolete concepts as the "surface friction coefficients" of the hydraulicists.

HUGH L. DRYDEN.[8] The author is to be congratulated for his success in removing one of the assumptions heretofore found necessary for the approximate computation of boundary-layer flow around bodies of revolution. With the many assumptions still remaining, and with the existence of a free constant whose value may be selected to give the best agreement, the theory cannot yet be said to be in a satisfactory position. The major features are undoubtedly correct, and there is great promise, as the author states, that ultimately "the method will be capable of yielding really accurate results."

The remarks on the tenth page, first paragraph, indicate a misunderstanding of a part of the paper by Kuethe and the writer.[9] The assumption that turbulence sets in shortly behind the major cross-section was found necessary, not primarily to explain the shape of the curves at small Reynolds' numbers, but to explain the fact that the effect of turbulence on one model was observed experimentally to be small, although the theory predicts an effect as large as for the other models. In addition, experiments with wire loops on the models confirmed the existence of turbulence behind the maximum cross-section. For further discussion, see page 19 of the paper by Kuethe and the writer.[9]

Albert F. Zahm.[10] This interesting paper purports to investigate "the boundary-layer phenomena for a body with axial symmetry about an axis in the line of flow." The flow meant is, it is judged, that of an undriven, slightly viscid, incompressible, infinite fluid, initially having uniform speed and pressure at all points far from the immersed body assumed to be fixed. The fluid sticks motionless to the body's surface, has a material shear speed $\partial u/\partial y$ very near it, but a negligible one at a short distance δ, where the actual velocity hardly differs from that of a perfect fluid in steady potential flow. This shear region is the thin boundary layer studied in the last century by Froude, Calvert, Hele-Shaw, Marey, etc., and in the present century by numerous researchers.

Of the "boundary-layer phenomena" to be investigated, the prime one is the velocity $\boldsymbol{q}$ within the layer, whence are derived the rate of shear and the friction. To find $\boldsymbol{q}$ one should solve the Navier-Stokes equation

$$\frac{\partial \boldsymbol{q}}{\partial t} + \boldsymbol{q} \cdot \nabla \boldsymbol{q} + \frac{1}{\rho} \nabla p = \nu \nabla^2 \boldsymbol{q}$$

whose first term is the time rate of change of the flow velocity at any point. Omitting this term leaves the form [1], which is Prandtl's 1904 boundary-layer equation. It is easier to solve, though not rigorously correct. The error commonly is assumed negligible.

One might also retain the first term and drop the next two, obtaining

$$\frac{\partial \boldsymbol{q}}{\partial t} = \nu \nabla^2 \boldsymbol{q}$$

as the writer did in 1903, and Dr. Carlo del Lungo in 1905, to express the flow past a skin-friction plane. Solving this equation gives, at normal distance y, the laminar speed

$$u_2 = \frac{2U_0}{\sqrt{\pi}} \int_0^s e^{-s^2}\, ds$$

where $s = \frac{1}{2} \sqrt{\frac{U_0}{\nu}} \frac{y}{\sqrt{x}}$ and $x = U_0 t$. Compare this with Blasius' solution of Prandtl's equation,

$$u_1 = \frac{U_0}{2} (as - bs^4 + cs^7 \ldots\ldots\ldots)$$

where $a = 1.327$, $b = 0.073372041$, $c = 0.0051000561$, etc. The graphs of u_1 and u_2, here shown, comprise between them a good part of the measured values given in [13] and [14] for $U_0 > 50$ ft-sec., thus indicating that neither formula is a perfect expression of the velocity distribution.

A better graph seems to be the intermediate one whose ordinate is

$$u = u_1 + n\,(u_2 - u_1)$$

where $o < n < 1$. The shown careful measurements of Zijnen, uncorrected for tunnel-wall effect, make n about 0.5 for $U_0 =$ 40 met.-sec., while those of Hansen make $o < n < 0.5$ for $U_0 =$ 16 met.-sec. Perhaps, therefore, $\partial \boldsymbol{q}/\partial t$ is not wholly negligible for such plane flow or for the axial flow treated by the author.

The author's premise that "the theoretical potential flow is very closely approximated by the real flow," all over a well-streamlined model, entails equality of the theoretical and actual pressures all over the model, and hence zero pressure drag in a uniform stream. Accurate measurement shows equality of these pressures at the stem, but not at the stern, of models having excellent streamline forms. Witness, for example, Fuhrman's studies of five airship-hull models; also reports 291 and 335 of the National Advisory Committee for Aeronautics. The pressure drag there given is in no case zero, though it may be as low as one-fourth the friction drag.

These comments are merely casual suggestions for any minute and critical scrutiny of the author's carefully constructed theory.

Author's Closure

With regard to Dr. Tietjens' question as to the effect of exponents other than $^1/_6$ of the final $C_{v\text{-turbulent}}$ the author is unfortunately unable to give a very definite answer. The matter could really be settled satisfactorily only by repeating the numerical calculations for other exponents and comparing the results, and this has not as yet been done. The reasonable agreement between the theory and experiment would, however, seem to indicate that, for the range of Reynolds' numbers investigated experimentally, either the $^1/_7$-power assumption is practically satisfactory or the deviations from this assumption are not of practical importance for the determination of drag coefficients. Dr. Klemperer, in his comments on the present paper, has discussed the effect of a "rounded body" on the exponent, as have the British experiments mentioned in the bibliography. The general conclusion which one can draw appears to be that, while the $^1/_7$th-power profile is certainly not rigorously correct over the entire body, it is nevertheless a fair first approximation over the major portion.

The values of a/L beyond which the theory is definitely not valid could only be determined by careful boundary-layer measurements on the same dirigible shape for which the calculations were made. Furthermore, the allowable limits on a/L will almost certainly depend on the shape of the body and on the Reynolds' number R_v. A comparison of such experimental data as are available (referring, however, to dirigible models somewhat different in shape from that used in the present paper) with the theoretical curves of Fig. 7 lead the author to believe that at least for R_v's of the order of 10^6 or larger the behavior of the equations near the singular point near the tail should not cause practically important deviations for values of a/L less than about 0.90. Discrepancies in this region ($a/L > 0.9$) should have a negligible effect on drag.

The "misunderstanding" to which Dr. Dryden refers was in reality rather a "misstatement" for which the author tenders his apologies to Messrs. Dryden and Kuethe. The sentence in question should more properly have read: "The assumption introduced by D. & K.—namely, that at a definite point on the rear portion of the model turbulence of a definite type was introduced into the boundary layer—tends to remedy this defect."

With regard to Dr. Zahm's comments, the author is unable to understand why the omission of the term ($\partial \boldsymbol{q}/\partial t$ in the Navier-Stokes equations should lead even to a "negligible" error in the present case. The derivation of Equations [4] and [1] is of course only valid for a laminar flow, but with this restriction it is not clear why the assumption of a stationary flow such that $\partial \boldsymbol{q}/\partial t =$ 0 is not rigorously correct for the flow under consideration.

The assumption of zero pressure drag, to which Dr. Zahm has called attention, has been the subject of many experiments which have led to rather contradictory conclusions. Fuhrman's experiments are quite out of line with practically all of the later tests in giving very high pressure drags (of the order of 50 to 60 per cent of the total drag). The investigations reported in

---

[10] Chief, Division of Aeronautics, Library of Congress, Washington, D. C.

N.A.C.A. Report 335, which gave pressure drag about 45 per cent of total drag, were on two-dimensional flow past strut forms and do not appear to have any immediate bearing on the present problem, which is concerned entirely with figures of revolution. The results printed in N.A.C.A. Report 291 and in certain of the early British reports give pressure drags of the order of 20 to 30 per cent of total drag. On the other hand, a rather extensive series of British investigations (cf. Reports and Memoranda 600, 801, 1169) in which careful allowance was made for wind-tunnel interference, static pressure drop along the tunnel, etc., indicated pressure drags so low as either to be not measurable or at most to be of the order of 6 or 7 per cent of total drag. The following excerpt is quoted from R. & M. 801: "When plotted . . . for longitudinal force, the same result was derived as was given in R. & M. 600; viz., at zero yaw, the form (pressure) resistance vanishes. . . . It would thus appear not only that the resistance of an airship envelope, neglecting interference of cars and fins, is entirely due to skin friction, but also that the longitudinal force at higher angles of yaw is also due to the same cause." It seemed to the present author that these conclusions furnished some justification for the assumption of zero pressure drag which underlies the present approximate theory, as well as those of B. M. Jones and Dryden and Kuethe.

The author wishes finally to comment briefly upon one point in the paper which, it has occurred to him, might cause some confusion. In section 3 the actual flow is approximated by assuming that outside of the boundary layer the flow is rigorously that given by the potential flow of an inviscid fluid about the body, and further that the boundary layer is so thin that the flow outside is identical with the potential flow which would exist at the surface. From this picture it follows that at $y = \delta$, $v = 0$; i.e., the normal component of velocity vanishes at the outer surface of the boundary layer. It appears to the author that this is an entirely consistent and permissible picture to use as an approximation to the true boundary layer flow. However, it differs somewhat from the picture given by Prandtl, which does not give $v = 0$ at $y = \delta$. It is easy to demonstrate, however, that Equation [6] is obtained unaltered whichever of the pictures is used. It will suffice here to outline briefly the course of the analysis when $v(\delta)$ is not assumed to vanish. Consider the left side of Equation [5] and write:

$$I = \int_0^\delta r\left(u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y}\right)dy$$

Then by partial integration

$$I = \int_0^\delta ru\frac{\partial u}{\partial x}dy + rvu\Big|_0^\delta - \int_0^\delta u\frac{\partial(rv)}{\partial y}\,dy,$$

and applying the continuity equation to the final term,

$$I = \int_0^\delta \left(ru\frac{\partial u}{\partial x} - u\frac{\partial(ru)}{\partial x}\right)dy + Ur(\delta)v(\delta)$$

$$= \int_0^\delta \frac{\partial(ru^2)}{\partial x}\,dy + Ur(\delta)v(\delta)$$

Using the continuity equation again,

$$Ur(\delta)r(\delta) = U\int^\delta \frac{\partial(rv)}{\partial y}\,dy = -U\int_0^\delta \frac{\partial(ru)}{\partial x}\,dy$$

Hence

$$I = \int^\delta \frac{\partial(ru^2)}{\partial x}\,dy - U\int^\delta \frac{\partial(ru)}{\partial x}\,dy,$$

and interchanging the differential and integral processes, using Leibniz's rule, the terms in $d\delta/dx$ cancel, and we obtain the left side of [6] just as before.

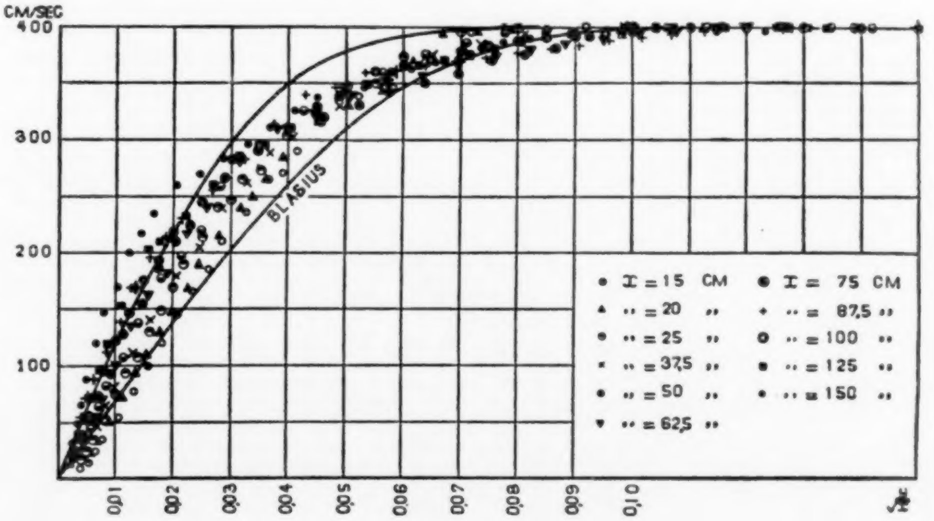

FIG. 11

(Air speed near a friction plane in a wind of 40 meters a second. Upper and lower graphs respectively delineate solutions of $\frac{\partial u}{\partial t} = \nu\frac{\partial^2 u}{\partial y^2}$ and $u\frac{\partial u}{\partial x} + v\frac{\partial v}{\partial y} = \nu\frac{\partial^2 u}{\partial y^2}$; dots denote Zijnen's measurements—see Bibliography reference 13.)

(The illustration accompanies Dr. Zahm's discussion on page 42.)

APM-54-4

On the Subcritical Speeds of the Rotating Shaft

By C. RICHARD SODERBERG,[1] EAST PITTSBURGH, PA.

Disturbances sometimes encountered at speeds above the fundamental whirling speed, having the fundamental frequency, are usually, and correctly, attributed to internal friction. Other disturbances frequently met with at speeds below the fundamental whirling speed, and when the motions also have the fundamental natural frequency, have been thought to be due to minute variations of the angular velocity of rotation caused by the eccentric application of gravity. The present paper discusses the latter group of phenomena, and aims to show that the cause assigned is incorrect.

THE phenomenon of shaft whirling has been extensively treated in the engineering literature of the last two or three decades, and to many who are familiar with the subject it may seem difficult to justify further discussion. There are, however, several phenomena which sometimes may appear mysterious. An important group of these are the disturbances which are sometimes encountered at speeds *above* the fundamental whirling speed, having the fundamental frequency. These are usually, and correctly, attributed to internal friction, but the exact mechanism of the motion is by no means clearly understood. Another group are the disturbances frequently encountered at speeds *below* the fundamental whirling speed, and where the motions also have the fundamental natural frequency. These were observed comparatively early by several investigators, and their cause was assigned to minute variations of the angular velocity of rotation caused by the eccentric application of gravity.[2] The fact that the vertical shaft did not exhibit this phenomenon was taken as a proof of this theory, and at the present time it is often believed to be correct. The present paper is a discussion of the latter group of phenomena, and it is intended to show that this nearly classical explanation is probably incorrect.

The purely academical aspects of the problem are hardly important enough to warrant lengthy discussions, but the problem actually does have an important practical aspect. Certain types of rotating machinery, notably certain groups of d.c. machines, are compelled to operate at or near one-half the fundamental whirling speeds. Many of these machines are sensitive to vibrations in the rotor, and the author has encountered a considerable number of cases where the elimination of these vibrations has presented an important problem.

NOMENCLATURE

Numerical calculations are carried out in the pound-inch-second system, where $g = 386$.

Symbol	Unit	Significance
k	lb. per in.	rigidity
m	lb./g	mass
n, p	......	number, order
r, s	in.	radii
x, y	in.	coordinates
y_0	in.	shaft deflection
ϵ, μ	radian	small angles
ξ, η	in.	components of s
θ, ϕ, ψ	radian	angles
χ	......	small number
ρ	in.	radius of gyration
ω	radians per sec.	angular velocity
ω_c	radians per sec.	critical angular velocity

The notations $\dot{r}$ and $\ddot{r}$ are used for dr/dt and d^2r/dt^2, etc.

CASES OF RESONANCE

The investigation concerns the simple system shown in Fig. 1. This consists of a massless, horizontal shaft in two bearings, on which is mounted a disk of mass m and radius of gyration ρ. If the rigidity (lb. per in.) of the shaft is denoted by k, the "critical speed" of the arrangement is given by the angular velocity

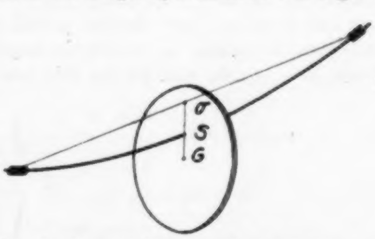

FIG. 1 SIMPLE SYSTEM CONSISTING OF A MASSLESS HORIZONTAL SHAFT RUNNING IN TWO BEARINGS AND CARRYING A SINGLE DISK

$$\omega_c = \sqrt{\frac{k}{m}} = \sqrt{\frac{g}{y_0}} \qquad [1]$$

where y_0 is the static deflection under gravity.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Disturbances are thus observed when the arrangement is rotated at the angular velocity ω_c, provided that there is a certain eccentricity of the disk. This type of resonance will be referred to as "fundamental resonance."

Experience shows, however, that measurable disturbances may occur at other speeds as well, particularly at $\omega_c/2$. The intensity of the disturbance depends on some "error" in the mounting of the disk. If the error is eccentricity, the phenomenon will be referred to as "subresonance due to eccentricity." If the error consists of variations in the deflection of the shaft, the phenomenon will be referred to as "subresonance due to variable elasticity." Other types of error, such as inclination of the disk, may also produce resonance phenomena, but these will not be considered in the present connection.

The object of the investigation is to compare the relative intensity of these three cases of resonance. Friction forces are often of importance in cases of resonance, but the inherent tendencies for motion of the system always depend on other properties; friction (unless it is excessive) merely restricts the motion to certain limits. Therefore the friction forces will be neglected in the following.

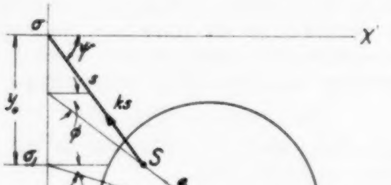

FIG. 2 ECCENTRICALLY MOUNTED DISK

A—FUNDAMENTAL RESONANCE ($\omega = \omega_c$)

The eccentrically mounted disk is investigated in Appendix No. 1. Fig. 2 shows a typical position of the disk. σ is the initial, unstrained position of the shaft center, σ_1 is the position in static equilibrium and S is the position at the moment under consideration. G is the center of gravity of the disk. The position of the disk is given by the coordinates r, θ, and ϕ, the first two locating G and the last giving the direction of $GS = e$, the eccentric radius. $\dot{\phi} = \omega$ is the angular velocity of rotation. When $\omega = \omega_c$, the solution for this case is found to be

$$\left.\begin{aligned}\phi &= \omega t\\ \theta &= \omega t - \frac{\pi}{2}\\ r &= \frac{e}{2}\,\omega t\end{aligned}\right\}\qquad [2]$$

Fig. 3 shows a typical position of the disk during this motion. It is evident that the center of gravity G will describe a spiral, the motion away from the center being linear with time.

The increment in the radius r after n revolutions ($\omega t = 2\pi n$) is

$$\Delta r = \pi n e \qquad [3]$$

B—SUBRESONANCE DUE TO ECCENTRICITY ($\omega = \omega_c/2$)

The solution for this case is also developed in Appendix No. 1. Introducing the small angle

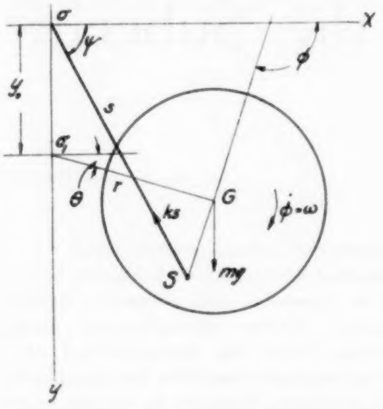

FIG. 3 TYPICAL POSITION OF DISK DURING ROTATION

$$\epsilon = \frac{ge}{\rho^2\omega^2} = 4\,\frac{y_0e}{\rho^2} \qquad [4]$$

the solution is found to be

$$\left.\begin{aligned}\phi &= \omega t - \epsilon\cos\omega t\\ \theta &= \omega t - {}^3/_8\,\epsilon\omega t\sin\omega t\\ r &= {}^4/_3\,e[1 - {}^3/_8\,\epsilon(2\sin\omega t + \omega t\cos\omega t)]\end{aligned}\right\}\qquad [5]$$

This motion is considerably more complicated than that at the fundamental resonance. The variation in angular velocity is small ($\epsilon\omega$), but the angle θ is subjected to periodic variations of increasing amplitude. The increment in the radius r is oscillating in nature, being positive when $\omega t/\pi$ is odd and negative when $\omega t/\pi$ is even. Putting $\omega t = 2\pi n$, the increment in the radius r, accumulated during n revolutions, is

$$\Delta r = \pm\epsilon\pi n e \qquad [6]$$

the plus sign corresponding to $n = 0, 1, 2, 3, \ldots$, and the negative sign to $n = {}^1/_2, {}^3/_2, {}^5/_2, \ldots$.

A similar condition of subresonance may be excited by subjecting the disk to a variable moment. If the moment may be written $M\sin p\omega t$, resonance will occur at the angular velocities $\omega = \omega_c/(p-1)$ and $\omega_c/(p+1)$. The nature of the motion is similar to that demonstrated above; in fact, the above solution is valid for the case that $p = 1$ and $\epsilon = M/(m\rho^2p^2\omega^2)$.

C—SUBRESONANCE DUE TO VARIABLE ELASTICITY ($\omega = \omega_c/2$)

The motion of a disk mounted on a shaft of variable elasticity is investigated in Appendix No. 2. The minimum rigidity of the shaft is denoted by k, the maximum rigidity by $(1+\chi)k$, where χ is a very small dimensionless quantity. The critical speed is still defined as $\omega_c = \sqrt{k/m}$; χ is assumed to be so small that the extension of the resonance range may be neglected. Resonance occurs when $\omega = \omega_c/2$; it is due to the raising and lowering of the center of gravity, which occurs twice every revolution.

Fig. 4 shows a typical position of the disk. The radius r now refers to the shaft center and is measured from the mean static position σ_m. The angle ϕ denotes the direction of the axis of maximum rigidity. When $\omega = \omega_c/2$ the solution is found to be

$$\left.\begin{aligned}\phi &= \omega t\\ \theta &= 2\omega t\\ r &= {}^1/_2\,\chi y_0\omega t\end{aligned}\right\}\qquad [7]$$

where $y_0 = mg/(1+\chi/2)k$ is the mean static deflection. In this case the motion of the shaft center is a spiral, the radius vector rotating with double angular velocity. Putting $\omega t = 2\pi n$, the increment in the radius for n revolutions is given by

$$\Delta r = \chi \pi n y_0 \ldots\ldots [8]$$

COMPARISON OF THE SOLUTIONS

The intensity of these three cases of resonance may now be compared by comparing the number of revolutions required to produce a certain increment of unity in the radius r. Denoting these numbers of revolutions by n_A, n_B, and n_C, respectively, we obtain from Equations [3], [6], and [8]

$$n_A = \frac{1}{\pi e}; \quad n_B = \frac{1}{\epsilon \pi e}; \quad n_C = \frac{1}{\chi \pi y_0} \ldots\ldots [9]$$

showing that

$$n_A : n_B : n_C = 1 : \frac{1}{\epsilon} : \frac{e}{\chi y_0} \ldots\ldots [10]$$

These quantities should be considered as indicating the tendency toward radial motion. The premises upon which the solutions were based may no longer be fulfilled after a large number of revolutions, but the actual number of revolutions required to attain a certain motion will always be greater than that indicated by these results.

Selecting a rotating system of "practical" proportions, we may put

$\rho = 10$ in. $\quad y_0 = 0.030$ in. $\quad \omega_c = 113$ rad./s

$e = 0.001$ in. $\quad \epsilon = 1.2.10^{-6}$ $\quad \chi = 5.10^{-3}$

These figures give

$$n_A : n_B : n_C = 1 : 833{,}000 : 6.7$$

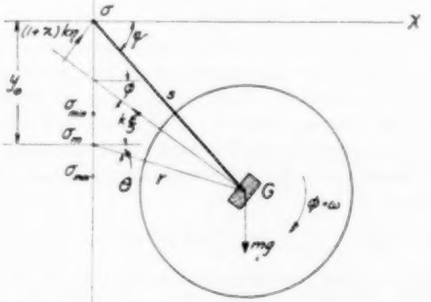

FIG. 4 TYPICAL POSITION OF ROTATING DISK MOUNTED ON A SHAFT OF VARIABLE ELASTICITY

showing that subresonance due to eccentricity is very improbable in comparison with the other two types. This conclusion would be valid even if the variation in angular velocity $\epsilon\omega$ were a thousand times greater than that assumed above. Subresonance due to variable elasticity, on the other hand, may be expected to occur in almost any horizontal arrangement. In the above set of figures it has been assumed that the shaft deflection varies 0.5 per cent, or about 0.00015 in. during a revolution. This amount would be difficult to demonstrate experimentally even by static measurements. Shafts having press fits or keys may frequently have considerably greater variation.

CONCLUSIONS

It has been shown in the foregoing that when subresonance at one-half the critical speed is encountered in rotating shafts, it is most probably due to minute variations in shaft deflection, and not to eccentricity. Therefore the most promising measure of correction of such cases, apart from the elimination of the resonance, is to eliminate the variation in the shaft deflection.

Appendix No. 1

SHAFT WITH ECCENTRIC DISK

THE GENERAL SOLUTION

CONSIDER a disk mounted symmetrically on a massless shaft, Fig. 1. The shaft is rotating in the horizontal position; Fig. 2 shows an instantaneous position. σ is the initial, unstrained position of the shaft center, σ_1 is the position in static equilibrium under the influence of gravity, and S is the actual position at the moment under consideration. G is the center of gravity of the disk. The quantities r, θ, and ϕ are clearly sufficient to specify the position of the disk; the solution required should give these quantities as functions of time and other known quantities. The radius vector r gives the distance of the center of gravity from the static center of rest σ_1, the angle θ gives the direction of this radius vector relative to the x-axis, and the angle ϕ gives the direction of the eccentric radius e relative to the x-axis. The total displacement of the shaft center is s, the resultant elastic force of the shaft is denoted by ks acting in the negative direction of s. This elastic force and the gravity are the only two external forces which will be considered.

Projecting all the forces parallel with and at right angles to the radius r, and taking moments around the point G, the following three differential equations are obtained.

$$m\ddot{r} - mr\dot{\theta}^2 + ks \cos(\psi - \theta) - mg \sin\theta = 0 \ldots\ldots [11]$$

$$mr\ddot{\theta} + 2m\dot{r}\ddot{\theta} + ks \sin(\psi - \theta) - mg \cos\theta = 0 \ldots\ldots [12]$$

$$m\rho^2\ddot{\phi} - kse \sin(\psi - \phi) = 0 \ldots\ldots [13]$$

ρ is the radius of gyration of the disk and m its mass. s and ψ may be eliminated from these equations by the relations

$$s \cos(\psi - \theta) = y_0 \sin\theta + r - e \cos(\phi - \theta) \ldots\ldots [14]$$

$$s \sin(\psi - \theta) = y_0 \cos\theta - e \sin(\phi - \theta) \ldots\ldots [15]$$

$$s \sin(\psi - \phi) = y_0 \cos\phi - r \sin(\phi - \theta) \ldots\ldots [16]$$

Introducing also the notations

$$y_0 = \frac{mg}{k} \ldots\ldots [17]$$

$$\omega_c = \sqrt{\frac{k}{m}} \ldots\ldots [18]$$

these differential equations become, after rearrangement,

$$\frac{d^2r}{dt^2} + r(\omega_c^2 - \dot{\theta}^2) = \omega_c^2 e \cos(\phi - \theta) \ldots\ldots [19]$$

$$\frac{d}{dt}(r^2\dot{\theta}) = \omega_c^2 er \sin(\phi - \theta) \ldots\ldots [20]$$

$$\rho^2 \frac{d^2\phi}{dt^2} + \omega_c^2 er \sin(\phi - \theta) = ge \cos\phi \ldots\ldots [21]$$

On account of the non-linearity of these equations, it is difficult to obtain an exact solution, but due to the fact that e and r are ordinarily very small as compared to ρ (for ordinary practical cases $r/\rho \cong 10^{-3}$), certain approximations are permissible.

Adding the last two equations and dividing by ρ^2 the following equation is obtained.

$$\frac{d}{dt}\left[\dot{\phi} + \frac{r^2}{\rho^2}\,\theta\right] = \frac{ge}{\rho^2}\cos\phi \qquad [22]$$

$\dot{\phi}$ and $\dot{\theta}$ have the same order of magnitude, at least as far as their mean values are concerned. The second term within the brackets may therefore be neglected, and the equation becomes

$$\frac{d^2\phi}{dt^2} - \frac{ge}{\rho^2}\cos\phi = 0 \qquad [23]$$

This is the ordinary differential equation for a mathematical pendulum of length ρ^2/e when ϕ is the angle of inclination to the horizontal. An exact solution would lead to elliptic functions, but due to the greatness of the length of the pendulum, no large error is committed if ϕ in the second term is replaced by ωt, where ω is the mean value of $\dot{\phi}$. This makes it possible to integrate the equation, whence

$$\phi = \omega t - \epsilon\cos\omega t \qquad [24]$$

where

$$\epsilon = \frac{ge}{\rho^2\omega^2} = \frac{y_0 e}{\rho^2}\,\frac{\omega_c^2}{\omega^2} \qquad [25]$$

is a very small angle.

The angular velocity $\dot{\phi}$ is thus nearly constant; the maximum deviation from the mean value being $\epsilon\omega$. It is reasonable to assume that $\dot{\theta}$ is also nearly constant, but this is not so easily proved. The term $\omega_c^2 er\sin(\phi - \theta)$ in [21] is certainly small, but it is not clear directly whether or not it is below the order $\omega_c^2 er$. In order to prove this assumption, put

$$\theta = \omega t + \mu\cos\omega t \qquad [26]$$

where μ is a small angle. This gives

$$\theta = \omega - \mu\omega\sin\omega t \text{ and } \dot{\theta}^2 = \omega^2 - 2\mu\omega^2\sin\omega t \qquad [27]$$

since μ^2 may be neglected besides unity. The angle $\phi - \theta$ now has the value $-(\epsilon + \mu)\cos\omega t$. Being a small angle, its sine may be replaced by the angle itself, and its cosine by unity. Equation [19] now becomes

$$\frac{d^2r}{dt^2} + (\omega_c^2 - \omega^2)r = \omega_c^2 e - 2\mu r\omega^2\sin\omega t \qquad [28]$$

If μ were zero, this equation would have a stationary solution

$$r = r_0 = \frac{\omega_c^2 e}{\omega_c^2 - \omega^2} \qquad [29]$$

a value which may be introduced as a close approximation into the last term. Equation [28] then yields the solution

$$r = r_0\left[1 - 2\mu\,\frac{\omega^2}{\omega_c^2 - 2\omega^2}\sin\omega t\right] \qquad [30]$$

This preliminary solution for r may be introduced into Equation [20], in order to determine the actual value of μ. Neglecting products and squares of the quantities ϵ and μ, the following value for μ is obtained:

$$\mu = -\epsilon\,\frac{(\omega_c^2 - \omega^2)(\omega_c^2 - 2\omega^2)}{\omega_c^2(\omega_c^2 - 4\omega^2)} \qquad [31]$$

The assumption that μ is small is thus correct, except when $\omega = \omega_c/2$. Barring this combination, the solution may be written

$$\phi = \omega t - \epsilon\cos\omega t \qquad [32]$$

$$\theta = \omega t - \epsilon\,\frac{(\omega_c^2 - \omega^2)(\omega_c^2 - 2\omega^2)}{\omega_c^2(\omega_c^2 - 4\omega^2)}\cos\omega t \qquad [33]$$

$$r = e\,\frac{\omega_c^2}{\omega_c^2 - \omega^2}\left[1 + 2\epsilon\,\frac{\omega^2(\omega_c^2 - \omega^2)}{\omega_c^2(\omega_c^2 - 4\omega^2)}\sin\omega t\right] \qquad [34]$$

SOLUTION WHEN $\omega = \omega_c$

The preceding solution fails when $\omega = \omega_c$ because the assumption of $\dot{r} \cong 0$ is no longer justified. The differential equations are

$$\left.\begin{aligned} \ddot{r} + r(\omega_c^2 - \dot{\theta}^2) &= \omega_c^2 e\cos(\phi - \theta) \\ r\ddot{\theta} + 2\dot{r}\dot{\theta} &= \omega_c^2 e\sin(\phi - \theta) \end{aligned}\right\} \qquad [35]$$

Assuming that $\dot{\phi}$ and $\dot{\theta}$ are to remain essentially constant $\cong\omega_c$ it follows that the angle $\phi - \theta$ also is constant. Then the equations can be satisfied only when $\phi - \theta = \pi/2$, and the solution becomes

$$\left.\begin{aligned} \phi &= \omega t \\ \theta &= \omega t - \frac{\pi}{2} \\ r &= \frac{e}{2}\,\omega t \end{aligned}\right\} \qquad [36]$$

when at the time $t = 0$ the point S agrees with σ_1, $\phi = 0$, $\dot{\phi} = \omega_c$ and $\theta = -\pi/2$. Any other set of boundary conditions would entail an intermediary period of adjustment, but there is not much doubt that the motion will ultimately follow Equations [36]. Fig. 3 shows an arbitrary position of the shaft during the resonance range.

SOLUTION WHEN $\omega = \omega_c/2$

The solution given by [32] to [34] fails when $\omega = \omega_c/2$ as well, because now the assumption as to the smallness of μ is found to be erroneous. There is nothing to invalidate the expression [24] for ϕ, however. Equation [33] indicates that when $\omega = \omega_c/2$ the angle θ will oscillate with increasing amplitude about its mean position. This suggests as a possible solution for θ, in place of [26],

$$\theta = \omega t + \chi\omega t\sin\omega t \qquad [37]$$

where χ is a small dimensionless quantity. It is of course necessary to restrict the discussion to values of time which make the angle $\chi\omega t$ small. By this restriction, the angle $\phi - \theta$ remains small, so that its sine may be replaced by the angle itself, and its cosine by unity. From [37] the following expressions are obtained:

$$\theta = \omega + \chi\omega\sin\omega t + \chi\omega^2 t\cos\omega t \qquad [38]$$

$$\ddot{\theta} = 2\chi\omega^2\cos\omega t - \chi\omega^3 t\sin\omega t \qquad [39]$$

$$\theta^2 = \omega^2 + 2\chi\omega^2\sin\omega t + 2\chi\omega^3 t\cos\omega t \qquad [40]$$

when higher powers than the first in χ are neglected. Introducing these values into [19] gives

$$\frac{dr^2}{dt^2} + r(\omega_c^2 - \omega^2) = \omega_c^2 e + 2\chi\omega^2 r[\sin\omega t + \omega t\cos\omega t] \qquad [41]$$

If χ were zero, this equation would have the stationary solution

$$r = r_0 = \frac{\omega_c^2 e}{\omega_c^2 - \omega^2}$$

This value of r may be introduced as a close approximation into the remaining term on the right-hand side of the equation.

The following solution is then easily obtained, when at $t = 0$, $r = r_0$:

$$r = r_0\left[1 + 2\chi\,\frac{\omega^2}{\omega_c^2 - 2\omega^2}\left(\frac{\omega_c^2}{\omega_c^2 - 2\omega^2}\sin \omega t + \omega t \cos \omega t\right)\right] \quad\ldots[42]$$

This gives for $\dot{r}$

$$\dot{r} = 2\chi\omega r_0\,\frac{\omega^2}{\omega_c^2 - 2\omega^2}\left[2\,\frac{\omega_c^2 - \omega^2}{\omega_c^2 - 2\omega^2}\cos \omega t - \omega t \sin \omega t\right]\ldots[43]$$

Introducing the value 2ω for ω_c, these equations become

$$r = r_0\,[1 + \chi(2 \sin \omega t + \omega t \cos \omega t)]\ldots\ldots\ldots[44]$$

$$\dot{r} = \chi r_0\omega[3 \cos \omega t - \omega t \sin \omega t]\ldots\ldots\ldots[45]$$

The constant χ is now to be determined by inserting the values of r and θ thus obtained in Equation [20]. Neglecting higher powers of χ, it is found that

$$\chi = -{}^3/_8\epsilon\ldots\ldots\ldots[46]$$

The complete solution for this case may thus be written, since $r_0 = {}^4/_3 e$.

$$\phi = \omega t - \epsilon \cos \omega t\ldots\ldots\ldots[47]$$

$$\theta = \omega t - {}^3/_8\epsilon\omega t \sin \omega t\ldots\ldots\ldots[48]$$

$$r = {}^4/_3 e[1 - {}^3/_8\epsilon(2 \sin \omega t + \omega t \cos \omega t)]\ldots\ldots\ldots[49]$$

The Case of a Variable External Moment

If the disk is subjected to an external moment of the form $M \cos p\omega t$, the same method of solution may be used with minor modifications. Neglecting gravity and putting

$$\epsilon_1 = \frac{M}{mp^2\omega^2\rho^2}\ldots\ldots\ldots[50]$$

the general solution is found to be

$$\left.\begin{aligned}
\phi &= \omega t - \epsilon_1 \cos p\omega t\\
\theta &= \omega t - \epsilon_1\,\frac{(\omega_c^2 - \omega^2)(\omega_c^2 - (p^2 + 1)\omega^2)}{[\omega_c^2 - (p + 1)^2\omega^2][\omega_c^2 - (p - 1)^2\omega^2]}\cos p\omega t\\
r &= e\,\frac{\omega_c^2}{\omega_c^2 - \omega^2}\left[1 + 2\epsilon_1\,\frac{\omega^2(\omega_c^2 - \omega^2)}{[\omega_c^2 - (p + 1)^2\omega^2][\omega_c^2 - (p - 1)^2\omega^2]}\sin p\omega t\right]
\end{aligned}\right\}\ldots[51]$$

In this case, a condition of resonance will prevail at the speeds

$$\omega_1 = \frac{\omega_c}{p + 1}\ldots\ldots\ldots[52]$$

and

$$\omega_2 = \frac{\omega_c}{p - 1}\ldots\ldots\ldots[53]$$

When $p = 1$, these two subcritical speeds merge into one, and the solution [51] is found to be identical with [32]–[34], when ϵ is replaced by ϵ_1.

The conditions at these subcritical speeds may be investigated by the same methods as those employed in the preceding section, but the results are somewhat lengthy and do not add many features of value beyond those given by [47]–[49].

Appendix No. 2

SHAFT WITH VARIABLE RIGIDITY

CONSIDER a system similar to that shown in Fig. 1, but where the eccentricity is zero and the rigidity of the shaft varies between a minimum value k in one direction and a maximum value $(1 + \chi)k$ in the other direction, where χ is a small positive quantity. Fig. 4 shows the disk in an arbitrary position. The shaft deflection s may be considered as the resultant of the components ξ and η in the directions of minimum and maximum rigidity, respectively. The external forces to be considered are thus $k\xi$, $(1 + \chi)k\eta$ and mg. The coordinates are still denoted by r, θ, and ϕ; their significance is obvious from Fig. 3. Projecting all forces on r, at right angles to r, and taking moments around G, the following equations are obtained.[3]

$$m\ddot{r} - mr\dot{\theta}^2 + k\xi \cos(\phi - \theta) - (1 + \chi)k\eta \sin(\phi - \theta) - mg \sin \theta = 0\ldots[54]$$

$$mr\ddot{\theta} + 2m\dot{r}\dot{\theta} + k\xi \sin(\phi - \theta) + (1 + \chi)k\eta \cos(\phi - \theta) - mg \cos \theta = 0\ldots[55]$$

$$m\rho^2\ddot{\phi} + \chi k\xi\eta = 0\ldots\ldots\ldots[56]$$

Introducing the values of ξ and η,

$$\xi = y_0 \sin \phi + r \cos(\phi - \theta)\ldots\ldots\ldots[57]$$

$$\eta = y_0 \cos \phi - r \sin(\phi - \theta)\ldots\ldots\ldots[58]$$

and putting

$$\omega_c = \sqrt{\frac{k}{m}}\ldots\ldots\ldots[59]$$

$$y_0 = \frac{mg}{\left(1 + \dfrac{\chi}{2}\right)k}\ldots\ldots\ldots[60]$$

these equations become

$$\ddot{r} + r[\omega_c^2(1 + \chi \sin^2(\phi - \theta)) - \dot{\theta}^2] = \frac{\chi\omega_c^2 y_0}{2}\sin(2\phi - \theta)\ldots[61]$$

$$r\ddot{\theta} + 2\dot{r}\dot{\theta} - \frac{\chi\omega_c^2}{2}r \sin 2(\phi - \theta) = -\frac{\chi\omega_c^2 y_0}{2}\cos(2\phi - \theta)\ldots[62]$$

$$\ddot{\phi} + \frac{\chi\omega_c^2}{2\rho^2}[y_0^2 \sin 2\phi + 2y_0 r \cos\theta - r^2 \sin 2(\phi - \theta)] = 0.\,[63]$$

In order to obtain a reasonably simple solution, it is necessary to restrict the analysis to values of r which are small in comparison with y_0, the mean static deflection. The quantity χ is already assumed to be small. The equations may then be simplified to

$$\ddot{r} + r(\omega_c^2 - \dot{\theta}^2) = \frac{\chi\omega_c^2 y_0}{2}\sin(2\phi - \theta)\ldots\ldots\ldots[64]$$

$$r\ddot{\theta} + 2\dot{r}\dot{\theta} = -\frac{\chi\omega_c^2 y_0}{2}\cos(2\phi - \theta)\ldots\ldots\ldots[65]$$

$$\ddot{\phi} + \frac{\chi\omega_c^2}{2}\,\frac{y_0^2}{\rho^2}\sin 2\phi = 0\ldots\ldots\ldots[66]$$

The last equation shows that $\dot{\phi}$, the angular velocity of rotation, will be essentially constant, even for appreciable values of χ.

Considering first the case that $\dot{\phi} = \omega$ is very small, it is obvious that the shaft center will be raised and lowered twice every revolution. An investigation into the statics of the problem will reveal that, when χ is small, the shaft center will describe a circle with radius $\frac{\chi\omega_c^2}{2}y_0$ around the position of static equilibrium. Under these circumstances, it is obvious that the radius r will make two revolutions for every revolution of the disk

---

[3] In writing the moment equation, the reactions on the bearing supports must be taken into account.

($\theta = 2\omega$). It is reasonable to assume that the same general conditions will be approximately true at higher speeds, so that we may put in Equation [65] $\ddot{\theta} = 0$ and $\dot{r} = 0$. This gives

$$\theta = 2\omega t - \frac{\pi}{2} \ldots\ldots\ldots\ldots [67]$$

Making $\theta = 2\omega$ in Equation [64], then gives

$$\frac{d^2r}{dt^2} + r(\omega_c^2 - 4\omega^2) = \frac{\chi\omega_c^2}{2}y_0 \ldots\ldots\ldots\ldots [68]$$

This equation gives the following stationary solution:

$$r = \frac{\chi y_0}{2}\,\frac{\omega_c^2}{\omega_c^2 - 4\omega^2} \ldots\ldots\ldots\ldots [69]$$

This solution is restricted to the case that $2\omega \neq \omega_c$, however, because when $2\omega = \omega_c$ the above assumption as to the smallness of $\dot{r}$ is no longer justified.

If it is assumed that $\dot{\phi} = \omega$ and $\dot{\theta} = 2\omega = \omega_c$ are essentially constant, the equations to be satisfied are

$$\left.\begin{aligned} \ddot{r} &= \frac{\chi\omega_c^2 y_0}{2}\sin(2\phi - \theta) \\ 2\dot{r}\,\omega_c &= -\frac{\chi\omega_c^2 y_0}{2}\cos(2\phi - \theta) \end{aligned}\right\} \ldots\ldots [70]$$

which demand that

$$2\phi - \theta = 0 \ldots\ldots\ldots\ldots [71]$$

whence

$$\left.\begin{aligned} \phi &= \omega t \\ \theta &= 2\omega t \\ r &= \chi\,\frac{y_0}{2}\,\omega t \end{aligned}\right\} \ldots\ldots\ldots\ldots [72]$$

is the solution for the special boundary conditions $\phi = \theta = 0$, $r = 0$ when $t = 0$. The rate of increase of r will thus be the same as under the influence of an unbalance corresponding to the eccentricity $\chi y_0/2$.

Discussion

David Robertson.[4] The author has already published several excellent articles on the vibration and whirling of shafts, and a further contribution from him is very welcome.

The effects of the irregularity of angular velocity induced by the gravitational torque have already been investigated by Rodgers,[5] who makes the same fundamental assumptions, but uses rectangular coordinates and leaves his result in that form. However, his result may be simply expressed by saying that the motion of the c. g. is the resultant of two circular motions; one is the steady whirl of the same frequency as the shaft rotation and the other is one of double frequency going the same way round. Relative to the steady whirl, the subsidiary whirl has a frequency equal to the shaft rotation.

This agrees with the author's solution, except that the radius of the subsidiary whirl derived from his equations is four times that obtained from Rodgers' work. The discrepancy is accounted for by an omission on Rodgers' part to allow for the variation of the angular velocity when deducing the coordinates of the elastic center from those of the center of gravity.

Rodgers does not recognize that he is dealing with a very special case and that his results do not apply generally. The author does definitely state that he considers no external forces except those due to the elastic resistance to bending and to the weight of the shaft, but he does not call attention to the consequences of this restriction, which amounts to assuming that there are no elastic forces due to torsion of the shaft. This is the same thing as assuming that the ends of the shaft are not coupled to anything possessing inertia. If either or both ends of the shaft were coupled to a driving motor or load of some sort, the inertia of that apparatus would exert a torque opposing any change of angular velocity which would, as a rule, greatly exceed that due to the elastic resistance to bending, unless the torsional stiffness of the shaft were so small that it would be incapable of transmitting any useful torque and of driving a load. Equation [25] would then be very far wrong.

Thus the whole of this paper would apply roughly to a rotary converter, but it is quite inapplicable to most other machines.

There is no doubt about the smallness of μ as a general rule, but Equation [31] can hardly be regarded as a proof that this is so, for this equation was derived by assuming it to be true.

The solution for $\omega = \omega_c$ has nothing to do with the gravitational torque, but merely shows how the shaft runs out when it is steadily run at the critical speed, with very special initial conditions. Rodgers gives the same result, but expressed in rectangular coordinates, in his Equations [26] and [27], before he begins to allow for any variations of angular velocity. Jeffcott[6] also deals with this problem.

When $\omega = {}^1/_2\omega_c$, Rodgers' form of the solution gives an infinite radius for the secondary whirl. He does not deal with the initial motion corresponding to Equations [47]–[49] of the paper.

Rodgers also studies the shaft with variable rigidity, both without and with unbalance, on page 136 of his paper. With no unbalance, he finds a main whirl and a subsidiary whirl of double frequency, and his value for the radius of the latter agrees with the author's equations.

Rodgers gives a separate solution when there is unbalance, but here he is quite wrong. Unbalance makes no difference.

The writer thinks that the author has not quite expressed his meaning in the statement on the second page about frictional forces, as he surely will agree that the friction is not merely "often," but is *always* important in the neighborhood of the critical speed. In fact, it then becomes the most important factor of all.

J. N. Goodier.[7] In spite of the already extensive literature of the subject, it is clear that this paper is an important one and heartily to be welcomed. The evidence presented for attributing subresonance to minute variations in shaft elasticity is most emphatic, and the author is to be congratulated on the series of judicious approximations which enabled him to extract his conclusions from the differential equations.

Of the two cases of subresonance discussed, it appears that one—that due to eccentricity—is accompanied by angular oscillation (equation for ϕ in [5]), while the other proceeds without disturbing the uniform rotation. If the system were coupled to another, rotating uniformly, subresonance due to eccentricity would accordingly induce torsional vibration. It would be interesting to know whether, in a system of practical proportions, this could be a source of resonant torsional vibration.

J. P. Den Hartog.[3] Two years ago the writer conducted some tests which seem to be a verification of the author's analytical result. A model shaft, carrying a disk in the middle, was run in rigidly supported ball bearings. The disk contained balancing holes, so that the eccentricity e could be varied. The usual critical speed was observed; its amplitude being roughly proportional to the unbalance e. But the resonant amplitude at the subcritical speed proved to be entirely independent of the unbalance. With the best obtainable balance, the amplitude at half critical speed was four times as large as at the critical speed itself. While by changing the unbalance the amplitude at the critical speed was varied from 25 per cent to 200 per cent, the amplitude at half critical speed remained 100 per cent throughout.

A non-uniformity in the rigidity of the shaft was looked for, but could not be detected. At the time it was not appreciated that such a very small amount of non-uniformity could be responsible for the effect. Taking the rate of increase observed in the experiment and substituting it into the author's formula [8], it is roughly estimated that the non-uniformity of the shaft rigidity was $^1/_{400}$; an amount which was too small to be detected with the means used at the time.

It is possible to derive the three main formulas [3], [6], and [8] in a somewhat simpler manner, as follows: In all three cases the shaft is supposed to rotate without any vibration whatever. Then the oscillating force on the disk can be easily calculated. This force is then made to act on the non-rotating disk, giving a linearly increasing vibration.

In the case of fundamental resonance the force acting on the disk is the centrifugal one of the amount $m\omega_c^2e$. Its component in any direction, for instance the vertical one, is $m\omega_c^2e \cos \omega_c t$.

In the case of a non-uniform shaft the gravity mg of the disk is counteracted by the shaft elasticity ky_0. However, this elasticity varies between the values ky_0 and $ky_0 (1 + \chi)$ with the mean value $ky_0 (1 + \chi/2)$. Therefore the pulsating force on the disk in the vertical direction is $^1/_2 ky_0\chi \cos 2\omega t$. At half critical speed $\omega_c = 2\omega$, so that the force is $^1/_2 ky_0\chi \cos \omega_c t$.

In the case B—Subresonance Due to Eccentricity, the conditions are somewhat more complicated. When there is no vibration, the center of gravity G describes a circular path of radius e about σ_1 as center. While G is moving downward, gravity exerts on the disk an accelerating moment; while G is moving upward, the moment is decelerating. From this it is seen at once that this action of gravity on the eccentricity is completely equivalent to the action of a non-uniform driving moment on the shaft. The pulsating force on the disk now is due to the inertia reaction of the motion of the center of gravity.

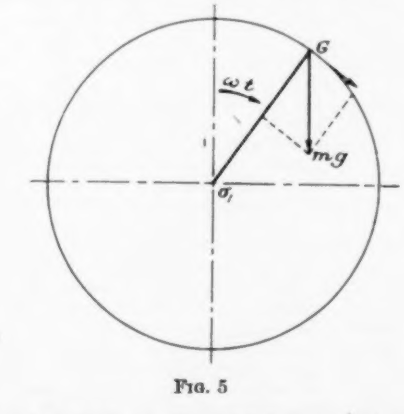

Fig. 5

Fig. 5 shows the tangential component of gravity to be $mg \sin \omega t$; the moment is $mge \sin \omega t$; the angular acceleration $ge \sin \omega t/\rho^2$; the tangential acceleration $ge^2 \sin \omega t/\rho^2$. The vertical component of this is $ge^2 \sin^2 \omega t/\rho^2 = -ge^2 \cos 2\omega t/2\rho^2 +$ const. The inertia reaction of this on the disk is $mge^2 \cos 2\omega t/2\rho,^2$ or at half resonant speed, $mge^2 \cos \omega_c t/2\rho^2$.

In all three cases, therefore, we have a pulsating force acting on the disk of frequency ω_c and of amplitude, say, P. The differential equation $m\ddot{\chi} + k\chi = P \cos \omega_c t$ has the well-known solution:

$$\chi = \frac{P}{2k} \omega_c t \sin \omega_c t$$

from which

$$\Delta\chi = \Delta r = \frac{P}{2k} \cdot \omega_c t.$$

Substituting the expressions for P in this in each of the three cases leads to the results [3], [5], and [8] with the exception of a factor 4 in formula [5], which, however, does not affect the order of magnitude of the result.

Author's Closure

Professor Robertson, in his discussion, concludes that the results of the paper apply only to a system having no connected rotating masses, such as a rotary converter, but would be quite inapplicable to most other machines. If a torsional system were connected with that of Fig. 1, adding one or more degrees of freedom, there are three alternative consequences. First, the connecting shaft may be very rigid, so that the natural frequency of the corresponding mode of motion is very high in comparison with the frequency of rotation. Then, no other modification than a certain increase of the radius of gyration of the disk is required in order to reduce the combined system to that of Fig. 1. Second, the connecting shaft may be very flexible, making the corresponding natural frequencies very low. In this case no appreciable influence is caused by the added torsional inertia. Third, the connecting shaft may be so proportioned that torsional resonance takes place. In general, the result will now be an increase in the effect of torsional impulses in the system; that is, the eccentricity of the disk would appear to be increased. The exact type of motion will now be very complicated, and Professor Robertson's statement may in a sense be correct. In no case can the influences of the unbalance, with regard to lateral amplitudes, be increased very materially, however, since some of the available energy will now go to a building up of the torsional vibrations. No reference has so far been made to the fact that the addition of torsional modes of vibration would also modify the system with regard to the modes of lateral vibrations. Such modifications, if excessive, would of course invalidate the entire arguments upon which the paper is based. It is worth noting, however, that the results obtained will surely hold for more complicated systems, in so far as the fundamental mode of motion is concerned.

Professor Robertson's criticism that Equation [31], which is derived on the assumption that μ is small, cannot be used to prove the same fact is undoubtedly justified. However, the only use of the assumption that μ is small, which is made in Equation [31], is to neglect higher powers than the first of μ and ϵ, the latter being known to be small. If the neglected terms in μ^2 and $\mu\epsilon$ were retained, another more complicated expression for μ would be obtained. It is easily verified that this expression converges toward [31] when ϵ is small.

Mr. Goodier's question is partly answered by the foregoing reply to the discussion by Professor Robertson. Such a state of resonance is theoretically possible, although no such experiments are known to the author. The available energy is so small, however, that no real phenomenon of resonance with the impulses due to gravity appears possible. Certainly, this phenomenon, even if it could be induced under well-controlled laboratory conditions, need not be looked upon as another source of torsional vibrations.

The author is much indebted to Dr. Den Hartog for his reference to experiments which seem to verify the conclusions of the paper. These experiments are of the same nature as the practical difficulties encountered in direct-current machines, to which reference has been made in the paper. In both cases, the attempts to eliminate the vibrations by reducing the eccentricity failed.

Dr. Den Hartog's suggestion for arriving at the results in a simpler manner is indeed a good one. This method would have been used but for the fact that the assumption upon which it is based is not so easily seen in problems of the type covered by the paper. The author is referring to the method of evaluating certain inertia forces, under the assumption that no vibrations take place, and then determining the amplitude of vibration by the aid of these (somewhat imaginary) inertia forces. This method is nothing but an application of relative motion, but it was felt that its truth is not directly obvious for systems of the type shown in Fig. 1. It does give the right results, however. In the case of sub-resonance due to eccentricity the disk is assumed to rotate with the point S rigidly held at σ_1. The coordinates (x, y) of G are then:[9]

$$x = e \cos \varphi = e \cos \omega t + e\epsilon \sin \omega t \cos \omega t$$
$$y = e \sin \varphi = e \sin \omega t - e\epsilon \cos^2 \omega t$$

where the angle ϕ is as given in [5] and the quantity ϵ is small in comparison with e.

The second terms of these expressions give inertia forces of the frequency $\omega_e = 2\omega$ and maximum value $^1/_2 me\epsilon\omega_e^2$. The resulting amplitude determined in accordance with the method suggested by Dr. Den Hertog is $^1/_4 e\epsilon\omega_e d$, which agrees with that given by [5] when it is remembered that $\omega = \omega_e/2$.

The Strength of Thin Plates in Compression

By THEODOR VON KÁRMÁN,[1] ERNEST E. SECHLER,[2] AND L. H. DONNELL,[3] PASADENA, CALIF.

The stability of thin plates has been investigated by many authors. However, in aeronautical structures, thin metal sheets are often used beyond the stability limits, and the load which can be carried by the structure is determined by the ultimate strength in compression. A recent series of experiments by the Bureau of Standards showed the ultimate load to be independent of width and length of the plate and approximately proportional to the square of the thickness. In the present paper an approximate theoretical analysis of this problem is developed, by which the "effective width" and the ultimate strength can be found. The result of this analysis shows the ultimate strength of a plate to be proportional to the square roots of the modulus of elasticity and the yield point of the material, and to the square of the thickness. This result gives a good check with the experiments mentioned.

THE problem of stability of thin plates has been investigated by many authors, S. Timoshenko having been especially successful in obtaining simple results for most of the cases which are of importance in engineering. However, in aeronautical structures, thin metal sheets are often used beyond the stability limits, and the load which can be carried by the structure is determined by the ultimate strength in compression. Recently a series of interesting experiments has been made by the Bureau of Standards, in cooperation with the Bureau of Aeronautics, Navy Department, for the purpose of determining the strength of plates under "edge compression." In these tests the edges parallel to the load were supported and the load was applied by rigid or nearly rigid beams perpendicular to the load. The ultimate load was found to be independent of the width and length of the plate, and approximately proportional to the square of the thickness.

Denoting the ultimate load by P and the thickness by t, the result of these experiments can be expressed approximately by the simple formula

$$P = Kt^2$$

where K is a constant depending on the physical properties of the material. From the theoretical point of view the question occurs how the physical characteristics of the material enter in the constant K, which obviously has the dimension of a stress. The following approximate analysis is a simple method of attacking this question.

Consider a thin sheet of length L and width b under a compressive load P. To simplify the calculations, let it be assumed that the entire load is carried by two strips of width w, one on each side of the sheet, and that the loading is uniform across these strips (Fig. 1). Each strip carries the load $P/2$. Then if σ is the stress in the material,

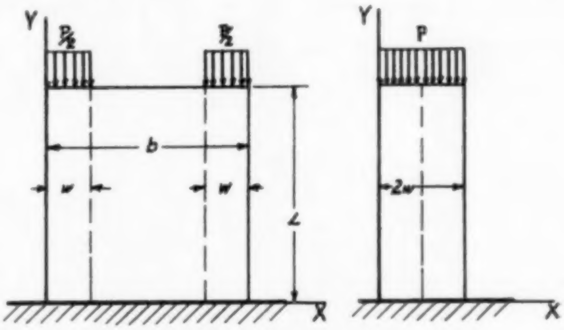

FIG. 1

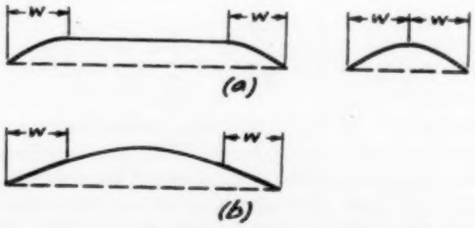

FIG. 2 ASSUMED CROSS-SECTIONS OF BUCKLED PLATES

$$P = 2wt\sigma \qquad \text{[1]}$$

Consider now the plate to be simply supported on the sides, so that the lateral deflection z along the sides is zero. For simplicity assume that the deflection is such that horizontal tangents at the inner edges of the two load-supporting strips are parallel to the X-direction, Fig. 2(a). Then the center of the sheet can be disregarded and the two strips can be handled as if they were together.

The lateral deflection z of such a strip under compression is given by the equation

$$\frac{Et^3}{12(1-\mu^2)}\left(\frac{\partial^4 z}{\partial x^4} + 2\frac{\partial^4 z}{\partial x^2 \partial y^2} + \frac{\partial^4 z}{\partial y^4}\right) + \sigma\frac{\partial^2 z}{\partial x^2} = 0 \qquad \text{[2]}$$

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. (The paper proper has been prepared by Dr. Von Kármán; the Appendix, by Messrs. Sechler and Donnell.)

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

where E is the modulus of elasticity and μ is Poisson's ratio for the material. A solution of this equation is

$$z = z_0 \sin \frac{\pi x}{2w} \sin \frac{\pi y}{l}$$

which satisfies the conditions that $z = 0$ and $\partial^2 z/\partial x^2 = 0$ when $x = 0$ or $2w$, and $z = 0$, $\partial^2 z/\partial y^2 = 0$ when $y = 0$ or any multiple of l. l then is the length of a half-wave of the deformation along the line $x = w$. Substituting this value for z in [2] and dividing through by $\sin \frac{\pi x}{2w} \sin \frac{\pi y}{l}$ gives:

$$\frac{Et^2}{12(1 - \mu^2)} \left(\frac{\pi^4}{16w^4} + \frac{2\pi^4}{4l^2w^2} + \frac{\pi^4}{l^4} \right) - \sigma \frac{\pi^2}{l^2} = 0$$

from which

$$\frac{\sigma}{E} = \frac{\pi^2 t^2}{12(1 - \mu^2)} \left[\frac{l}{4w^2} + \frac{1}{l} \right]^2 \qquad [3]$$

Assume now that the two strips carrying the load are at the limit of stability, corresponding to "the most dangerous wave length." This means that we must find the minimum value of σ/E. Finding the derivative of $\left[\frac{l}{4w^2} + \frac{1}{l} \right]$ with respect to l, and equating it to zero, we find

$$\frac{1}{4w^2} - \frac{1}{l^2} = 0$$

$$l = 2w$$

therefore

$$\frac{\sigma}{E} = \frac{\pi^2 t^2}{12(1 - \mu^2)} \left[\frac{1}{2w} + \frac{1}{2w} \right]^2 = \frac{\pi^2 t^2}{12(1 - \mu^2) w^2} \qquad [4]$$

from which

$$w = \frac{\pi}{\sqrt{12(1 - \mu^2)}} \sqrt{\frac{E}{\sigma}}\, t \qquad [5]$$

and

$$P = 2wt\sigma = \frac{\pi}{\sqrt{3(1 - \mu^2)}} \sqrt{\frac{E}{\sigma}}\, t^2 \sigma = \frac{\pi}{\sqrt{3(1 - \mu^2)}} \sqrt{E\sigma}\, t^2 \qquad [6]$$

Equations [5] and [6] give us the relation between effective width and the load carried by the plate. The equations hold in this form below the elastic limit. Beyond the elastic limit, it is necessary to replace E by the slope of the stress-strain curve E', and determine the maximum of the product $E'\sigma$. However, it is easy to see that this maximum value will not differ greatly from the product of the value of E below the elastic limit and the yield point σ_y. Hence the maximum load that can be sustained by the plate is:

$$P_{\text{ult.}} = \frac{\pi}{\sqrt{3(1 - \mu^2)}} \sqrt{E\sigma_y}\, t^2 \qquad [7]$$

In the experiments mentioned above, the average values of E and σ_y for the duralumin sheets tested were 10,500,000 lb. per sq. in. and 41,000 lb. per sq. in., respectively. Using these values and $\mu = 0.25$ in [7],

$$P_{\text{ult.}} = 1.23 \times 10^6 t^2$$

J. S. Newell[4] gives, as an empirical formula based on these experiments, the value of the maximum load for duralumin as

$$P_{\text{ult}} = 1.2 \times 10^6 t^2 - 3.0 \times 10^6 t^3$$

where the second term represents only a small correction for usual thicknesses. A more exact checking of the experimental results is given in the Appendix by Messrs. Donnell and Sechler.

These results have also been applied to the case of plates supported by longitudinal stiffeners. It is assumed that the stresses in the stiffener and in the effective strip of the plate are the same when buckling takes place. It is then possible to determine the width w of the effective strips on each side of the stiffener and to calculate a strengthening factor, by which the strength of the stiffener alone is multiplied, to obtain the strength of the stiffener with its adjacent effective strips. However, it is desired first to check these results by experiments, and the authors expect to do this very soon. It is felt that the experiments on stiffened sheets mentioned by Newell did not have sufficiently definite end conditions for this purpose.

Stiffeners combined with curved plates can be investigated in the same way. Analyzing the effect of a small curvature $1/R$ of the plate, it is observed that the strengthening factor should increase with the curvature due to the increased stability of the curved strips. However, if the stiffeners are located on the concave side of the plates, as must usually be the case with aeronautical structures, the curvature also has an opposite influence on the strengthening factor, because portions of the curved plates are nearer to the neutral axis and hence contribute less to the resultant moment of inertia than corresponding portions of flat plate.

It is easy to show that for small curvatures, i.e., for large values of R, the increase of the strengthening factor is proportional to $1/R^2$, while the loss due to the last-mentioned effect is proportional to $1/R$. It is therefore concluded that if plates supported by stiffeners are curved, the strength decreases with the curvature at first. This fact, which is rather contrary to what one would expect at first sight, was found experimentally in the tests cited by Mr. Newell.

Appendix

THE formula derived by Dr. von Kármán for the ultimate compressive load on a sheet simply supported at the sides can be written

$$P_{\text{ult.}} = C\sqrt{E\sigma_y}\, t^2 \qquad [8]$$

Experience with other types of stability problems indicates that the ultimate compressive load on a sheet with other edge conditions—such as a sheet clamped along the sides or the portion of a sheet between stiffeners—can be expressed by the same formula [8], but with a different value of the constant C. In making his analysis, Dr. von Kármán, for simplicity, assumed somewhat artificial conditions, and hence it is not to be expected that the value of C given above is exactly correct even for the case of simply supported sides. The purpose of the derivation was to prove that the ultimate load was proportional to $\sqrt{E\sigma_y}t^2$, and it is intended to obtain the correct value of C, for any given edge conditions, from experimental evidence.

It is interesting, however, to compare the value of C found in experiments with the values calculated for certain extreme assumptions.

If a perfectly rectangular flat sheet is freely supported along the sides and compressed between rigid flat plates at the ends, the compressive stress will obviously be uniformly distributed. As the end plates are brought together, this compressive stress will increase, and when it reaches a certain critical value σ_b, lateral buckling deflections will occur all across the sheet, except at the edges, which are constrained from lateral movement. Just as the buckling begins, it can be assumed that the compressive stress is still uniformly distributed across the sheet. This is the classical theory of buckling; there is no reason to suppose anything wrong with it.

---

[4] "The Strength of Aluminum Alloy Sheets," *Airway Age*, November, 1930.

The thing that Dr. von Kármán has investigated is what takes place when the end plates are brought still further together. It is known from general experience with buckling that, in the middle part of the sheet, the compressive stresses will remain substantially constant as the buckling deflections increase. On the other hand, at the very edges buckling is prevented by the lateral support, so that the stress there must increase according to Hooke's law until it reaches the yield point of the material σ_y; general experience indicates that the maximum resistance of the sheet will be realized at about this time. At points near the edges the stress will be somewhere between the limits σ_b and σ_y. The distribution of stress along the sheet will now be something like that shown in Fig. 3(*a*). The total area under the curve is a measure of the total force on the sheet, while the shaded area shows the total force according to the classical theory.

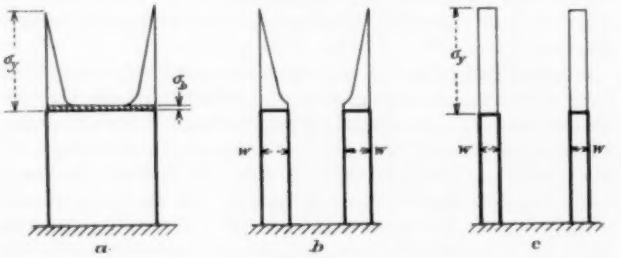

FIG. 3

For very thin sheets such as used in aeronautical work, σ_b is so small compared to σ_y that the middle portion can be neglected entirely. This reduces the problem to that of the buckling of two strips of unknown width w under a stress distribution something like that shown in Fig. 3(*b*). To facilitate calculations Dr. von Kármán makes a further simplification by assuming that the strips are under uniform stress σ_y, as in Fig. 3(*c*). This does not affect the final result as much as might be thought, because the width w is still to be solved for, and with the assumption of uniform distribution we will get a smaller value for w than we would with the distribution of Fig. 3(*b*); consequently the total force will be more nearly the same in the two cases.

We can now calculate w by exactly the same methods that are used in the classical theory to calculate the buckling stress; in that case the stress is unknown, but the width is known, while here the stress is known and the width is unknown. To make this calculation it is necessary to find or assume the shape of the buckled surface. In the derivation given in the main part of the paper it is assumed that buckled cross-sections of the sheet are as shown in Fig. 2(*a*), so that if the two effective portions are joined they form half a sine wave. With this assumption $C = \dfrac{\pi}{\sqrt{3(1-\mu^2)}} = 1.90$ for $\mu = 0.3$.

Another and perhaps more likely assumption would be that buckled cross-sections are as shown in Fig. 2(*b*) such that the portions w can be considered straight. It is shown later that with this assumption the ultimate load is found to be approximately

$$P_{\text{ult.}} = \sqrt{\frac{2}{1+\mu}}\sqrt{E\sigma_y t^2} = 1.24\,\sqrt{E\sigma_y}t^2,\ \text{for } \mu = 0.3 \ldots [9]$$

The actual buckled shape is probably somewhere between these two extremes and so one would expect to find experimental values of C somewhere between 1.90 and 1.24.

The Bureau of Standards experiments[5] previously mentioned were made on sheets of four materials of widely different physical properties: duralumin, stainless steel, monel metal, and nickel. Several widths were tested for each thickness (or nearly the same thickness), all widths giving nearly the same results. Table 1 shows the average ultimate load found for each average thickness, and also values of E and σ_y computed from the stress-strain curve given in the report for each thickness (or the nearest thickness). The yield point σ_y was taken as the stress for which the stress-strain slope is one-third the original elastic slope, as suggested in the report. In the last column of the table the values of $C = \dfrac{P_{\text{ult.}}}{\sqrt{E\sigma_y t^2}}$ (from Equation [8]) are calculated. These values are also shown plotted against the thickness in Fig. 4.

TABLE 1 TESTS MADE ON SHEETS OF VARIOUS MATERIALS

If Equation [8] is correct these values of C should all be the same. Considering the uncertainties of such tests and the fact that the physical properties varied very widely even for the same material and the indefiniteness of the yield point, the values of C obtained show remarkable constancy. It is also notable that there seems to be no systematic difference between the different materials, the average values for duralumin and stainless steel, for instance, being very nearly the same, in spite of the great difference in physical properties. This is convincing evidence of the correctness of Dr. von Kármán's conclusions that the effect of the physical properties of the material is measured by $\sqrt{E\sigma_y}$ (neglecting the slight influence of Poisson's ratio). There seems to be a slight systematic decrease in the value of C with the thickness. However, this might easily be explained by the fact that the flexibility of the testing jig used in the experiments would play a more important part when testing the thicker, and therefore stiffer, sheets.

The average value of C for smaller thicknesses is about 3/2. It is hoped soon to make a similar experimental determination of the value of C for the more important case, in practice, of portions of a plate between stiffeners.

Derivation of Equation 9: If it be assumed that cross-sections of the effective strip remain straight, the lateral deflection can be taken as

$$z = z_0 x \sin \frac{n\pi y}{L} \ldots\ldots\ldots\ldots\ldots\ldots [10]$$

Longitudinal elements of the strip shorten, due to buckling, by the amount $\displaystyle\int_0^L \frac{1}{2}\left(\frac{\partial z}{\partial y}\right)^2 dy$. The external work done by the load during buckling is therefore

[a] Stress on section between rivets attaching sheet to stiffener estimated from Bureau of Standards data on Flat Sheet.

$$V_1 = \int_0^L \int_0^w \sigma t dx \, \frac{1}{2} \left(\frac{\partial z}{\partial y}\right)^2 dy$$

The internal energy of bending and torsion in the strip after buckling is

$$V_2 = \frac{Et^3}{12(1-\mu^2)} \int_0^L \int_0^w \frac{1}{2} \left[\left(\frac{\partial^2 z}{\partial x^2}\right)^2 + \left(\frac{\partial^2 z}{\partial y^2}\right)^2 + 2(1-\mu)\left(\frac{\partial^2 z}{\partial x \partial y}\right)^2 + 2\mu \frac{\partial^2 z}{\partial x^2} \frac{\partial^2 z}{\partial y^2} \right] dx dy$$

Substituting [10] in these equations and setting $V_1 = V_2$,

$$\frac{\sigma}{E} = \frac{t^2}{12(1-\mu^2)w^2} \left[\frac{n^2\pi^2 w^2}{L^2} + 6(1-\mu) \right]$$

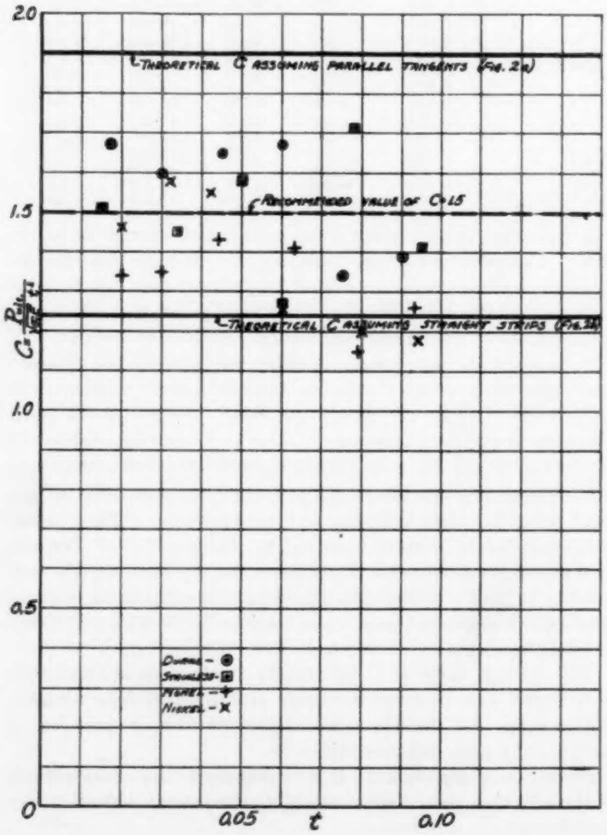

FIG. 4 VALUES OF *C* PLOTTED AGAINST THICKNESS *t*

To make σ/E a minimum, n should evidently have its minimum possible value, namely, unity. The first term in the brackets, $\pi^2 w^2/L^2$, can then be neglected in comparison with the second term if w is small compared to L, giving

$$\frac{\sigma}{E} = \frac{1}{2(1+\mu)} \frac{t^2}{w^2} \quad \text{[11]}$$

Equation [9] can then be obtained from [11] in the same manner that [7] was obtained from [4] in the body of the paper.

Discussion

Joseph S. Newell.[6] This paper is a timely and interesting contribution to the problem of all-metal airplane construction which is so vexing to designers at present. Equation [5] furnishes a rational means for determining the effective width of sheet which functions with the stiffener on a stiffened thin plate and will provide the numerous investigators who are cooperating on this problem a standard method for analyzing their data from this point of view.

It is, however, suggested that another assumption be considered by investigators of this problem of the stiffened thin plate in compression. The assumption is that the load which the combination of sheet and stiffener will carry is equal to the load which the sheet alone will take plus the load which the stiffener alone will take. To determine the load on the sheet one may use the data obtained by the Bureau of Standards[7] to determine the stress at maximum load on a sheet whose width is equal to the clear distance between rows of rivets connecting the sheet to the stiffeners.

This method of attacking the problem obviates the assumption that the stress in the sheet and in the stiffener are equal when maximum load is approached. In view of the fact that the effective EI of an assembly of sheet and stiffener, when tested as a beam, is not equal to but is normally appreciably less than the product of the modulus of elasticity of the material times the moment of inertia of the cross-section of the combined section, it would appear difficult to justify any assumption based on the homogeneity of the composite section. Furthermore, thin sheets normally wrinkle between the rivets attaching them to a stiffener as the load approaches the maximum that the combination will take. Under such conditions the strains of sheet and stiffener are obviously unequal; hence an assumption of equality of stress is hardly justifiable. The assumption of "effective widths" has long been employed in naval architecture and mechanical engineering. It may be the solution to this problem, but in view of the results shown in Table 2 the proposed scheme of taking the strength of the composite section equal to the sum of its parts appears to be worthy of further consideration.

Fig. 5 shows four types of stiffeners used on flat aluminum-alloy sheets for which more or less data are available. All of the tests have been on panels 12 in. wide. Most of them have been 12 in. long, but there are a few at 6 in. The data in Table 2 are a few taken from the results of investigations made at the Massachusetts Institute of Technology. Attention is invited to the agreement between "Predicted" and "Observed" values where the sheet carries about 12 per cent of the load on the combination, as well as where it carries nearly 75 per cent of the load. The agreement is too close to be the result of mere coincidence, hence appears worthy of the closest investigation.

The scheme in Table 2 is readily applicable for use in design, if later investigations justify its use at all, since one may determine

Fig. 5

the strength of a stiffener by test or analysis, add to it the load carried by a sheet of width equal to the distance between attachments of sheet to stiffener, and so obtain the strength of the combination. This strength, or total load, may be divided by the total area to obtain an "average" or "apparent" stress for the combination which may be used in analyzing the composite section.

Determining the maximum load to be taken by a stiffener involves the question of end conditions. Tests to date have been made on flat-ended sections as it has been felt advisable to obtain some working data which engineers having judgment could utilize. They are more in the nature of "guessing points" to be tempered by good judgment than exact scientific data. To obtain the latter means the use of knife edges or similar devices to get a true, pin-ended condition on the combination of sheet and stiffener. Since it is impossible to determine the effective centroid of the composite cross-section analytically, due to non-homogeneity of riveted assemblies, the determination of the axis of loading involves a trial and error method in the testing machine. This is practicable, but slow. Eventually it may be necessary to carry out investigations in which such a method will be used, if it proves difficult to obtain a correlating coefficient between the flat end conditions of these tests and the conditions obtained during static tests of actual airplanes, but the demand at present is for a set of approximate values obtained from tests to serve as values which a designer may modify to suit his problem.

Such values are admittedly temporary, and further investigations over a greater range of specimens may necessitate revising them completely. The present demand is for data with the limitations of the tests carefully stated in each case. Next comes the correlation of the data and the development of rational or empirical methods for predicting strengths of thin plates such as are used in aircraft. The present paper covers a possible method which is worthy of careful consideration, and the authors are to be congratulated on the clarity as well as the timeliness of their presentation.

AUTHORS' CLOSURE[8]

In answering Professor Newell's interesting discussion of the stiffened-sheet problem, it could be pointed out that rivet connections between sheet and stiffener may function quite differently when the sheet is tested in bending and in compression, and that if the rivets are not spaced closely enough to prevent wrinkling when testing in compression, then no simple theory can apply. However, this does not answer the arguments completely, and it is felt that there is not at present enough experimental data to decide what theory will fit most closely the conditions found in practice.

The objection to the experiments mentioned by Professor Newell was that flat-ended columns seem to lie somewhere between columns with perfect end fixity and pin-ended columns; this is also indicated by the results given for compression of the stiffeners alone. As fixed-end columns are supposed to have four times the resistance of corresponding pin-ended ones, it would seem that the effect of the sheet in increasing the width of the end, and hence the degree of end fixity, might be quite large compared to the effect which it is wished to measure. It may be possible to eliminate this factor more easily than by the method mentioned in the discussion, by arranging for a high degree of end fixity which will not be influenced by the presence of the sheet.

Flow of Steels at Elevated Temperatures

By F. P. Coffin[1] and T. H. Swisher,[2] Schenectady, N. Y.

Flow tests of steels at elevated temperatures, as carried on in the Research Laboratory of the General Electric Company, are described. The object of these tests is to predict the ability of materials to maintain dimensions under stress at operating temperatures for long periods of time. Various methods of testing are used. Some are for the purpose of obtaining a mass of information in the shortest possible time; here the rate of flow is measured for a series of successively reduced stresses at each of several successively increased temperatures. Others are designed to furnish more fundamental information regarding the nature of flow; here new specimens are subjected to constant stress at a constant temperature. A third is the constant-extension test where the stress is varied with time to maintain a constant total elongation (elastic plus plastic).

F. P. Coffin

T. H. Swisher

FLOW TESTS of steels at elevated temperatures are carried on at the General Electric Company in seven furnaces, five of which are shown in Fig. 1. Each furnace holds four horizontal test specimens. A 12-in. gage length is used. Test specimens are 26 in. long, with extension pieces welded to each end. The test bars are loaded in tension through a 100-to-1 lever system (see Fig. 2). For stresses under 40,000 lb. per sq. in. a 0.505-in.-diameter specimen is used; for stresses over 40,000 lb. per sq. in., a 0.375-in.-diameter specimen is used. Test specimens are supported by springs at each end of the furnace in such a way as to minimize the initial bending moment in the gage length. For a tensile load of 1000 lb. per sq. in., the maximum bending stress, after correction, is calculated to be 60 lb. per sq. in.; for tensile loads of 5000 to 40,000 lb. per sq. in., the maximum bending stress is 35 lb. per sq. in. When plastic flow occurs, the bending stresses decrease. Universal joints are used at the ends of the rods to insure a straight pull.

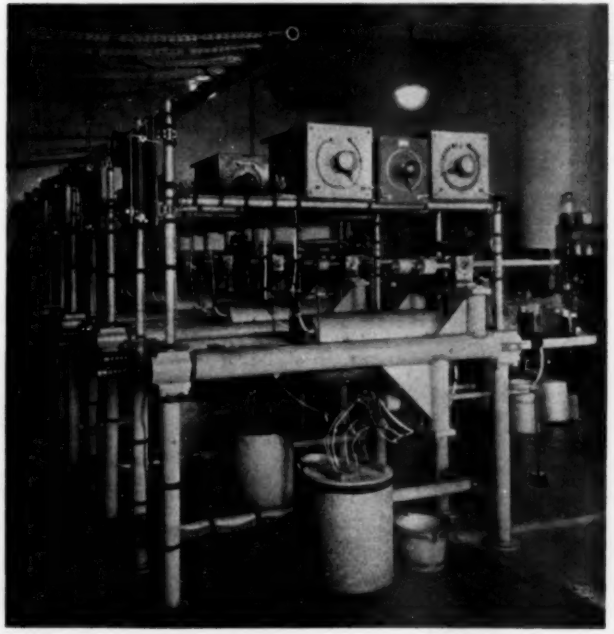

Fig. 1 Five Creep-Stress Testing Machines Having a Total Capacity of Twenty Test Specimens

Extension is measured by Ames dial indicators divided to the ten-thousandth part of an inch. The division marks are 2 mm. apart, and extensions may be read to the hundred-thousandth part of an inch. On a 12-in. gage length this makes it possible to distinguish magnitudes smaller than a millionth part of an inch per inch of length. Movement in the gage length is transmitted to the indicators through quartz rods. A rod of alloy steel is used along the gage length to minimize change in the gage reading due to change in temperature. Fig. 3 shows the universal joints, extensometers, and spring supports. Fig. 4 shows the extensometer clamps. The ends of the clamps are undercut so that they grip the test pieces for a length of $^1/_{16}$ in.

The clamping screws are extra long, and in addition sleeves having the same area as the screws are used to provide enough spring in the clamps to compensate for the decrease in diameter of the test bar caused by extension.

Temperature is controlled by special Leeds & Northrup controllers, the control thermocouples being located in the bottom

of the furnace 2 in. from the center. Fig. 5 shows the control thermocouple with the auxiliary heater used to obtain a short cycle of about 2 min. duration. During this cycle there is no measurable change of temperature in the test bars. The standard thermocouple is a 0.125-in. iron-copel X located in the bottom of the furnace 2 in. from the center, opposite the control thermocouple. Gage readings are taken when this thermocouple reads within 0.5 deg. cent. of the correct temperature. A $^1/_2$-in. dummy bar is located at the center of the furnace and extends out the ends. This bar has a temperature gradient approximately the same as the test bars. Three 0.040-in. chromel-alumel thermocouples are peened into this bar, one opposite each extensometer clamp and one at the center of the gage length. By means of a system of compensated windings and rheostats, it is possible to keep the temperature of the gage length uniform within 1 deg. cent. The difference in temperature between top and bottom of the furnace is small, of the order of 1 deg. cent. Temperatures are measured with a General Electric precision potentiometer sensitive to 1 millionth of a volt, which corresponds to $^1/_{60}$ deg. cent. The records on the Leeds & Northrup instruments are used for a check on the operation of the temperature control system and to record variations in tem-

perature caused by power interruptions or other irregularities. Fig. 6 is a diagram of the furnace arrangement, and Fig. 7 shows the precision potentiometer and one of the Leeds & Northrup instruments.

Method of Conducting Tests

The standard temperatures of testing are:

Deg. cent.	Deg. fahr.
400	752
450	842
500	932
550	1022

Various methods of testing are used. Many flow-rate tests have been made for the purpose of obtaining a bulk of information in the shortest possible time. Here the rate of flow was measured for a series of successively reduced stresses at each of several successively increased temperatures.

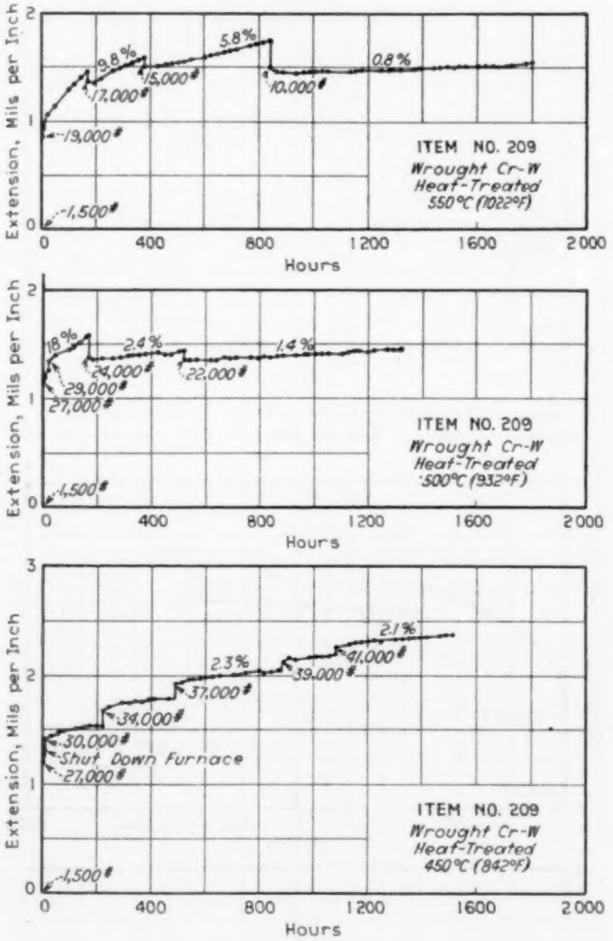

Fig. 8 Flow-Rate Tests of Item No. 209
(Composition: C, 0.36; Cr, 1.38; V, 0.19; W, 1.98; Mn, 0.30; Si, 0.19.)

Tests have been made to study flow under constant extension. The test specimens were loaded until the total elongation (elastic plus plastic deformation) reached a definite amount. As flow took place, the stress was lowered from time to time so as to maintain the total elongation approximately constant. These tests also yielded flow-rate information. The initial part of the tests showed that the stress decreased rapidly at first as flow took place.

In cases where more information of a fundamental nature is wanted on a particular steel, new specimens are subjected to a constant stress at a uniform temperature for long periods of time.

The following procedure was used for the flow-rate tests: The furnaces were brought up to temperature with the bars under a stress of 1000 lb. per sq. in. Then stresses were applied which were expected to produce a flow rate of approximately 10 per cent in 100,000 hours, after a flow of about 1 mil per inch had taken place. It was usually necessary to increase or decrease the stress in order to get a flow rate of the order of 10 per cent. After this flow rate was established by the flow remaining constant, say, for 200 hours, flow rates of about 3 per cent and 1 per cent in 100,000 hours were established. This gave flow rates for different stresses at one temperature. In some cases the same bars were tested at successively higher temperatures. The bars were generally stretched 1 to 1.5 mils per inch at each temperature.

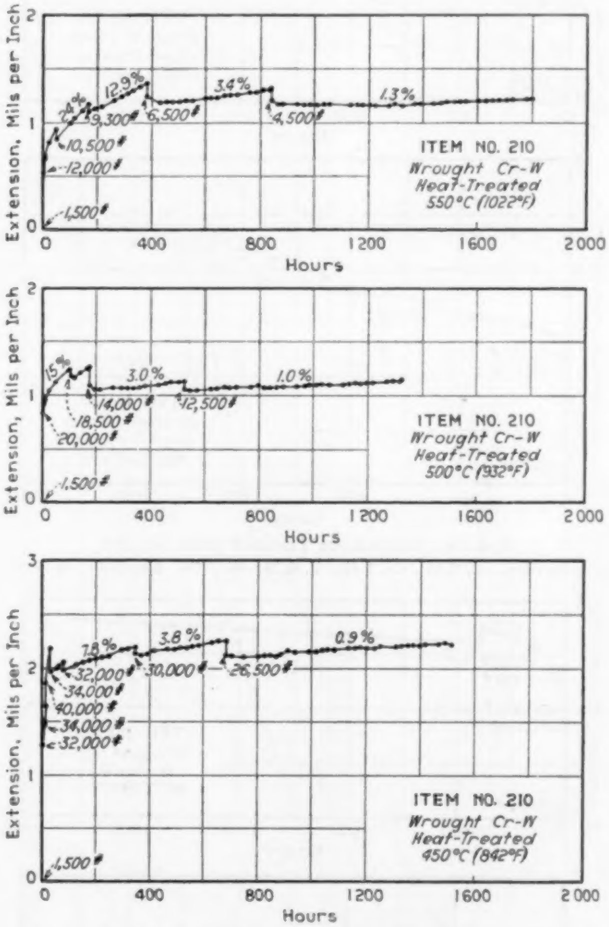

Fig. 9 Flow-Rate Tests of Item No. 210
(Composition: C, 0.42; Cr, 1.98; V, 0.20; W, 2.91; Mn, 0.34; Si, 0.24.)

When stress versus the flow rate, so determined, for a certain temperature, is plotted on logarithmic paper, the points generally fall close to a straight line drawn through them. This straight-line relation helps to extrapolate to the region of tolerable deformation.

It is desirable to conduct tests wherein the stress applied produces a flow rate of the order of magnitude that is permissible in practice; tests have been made as close to this region as time would permit.

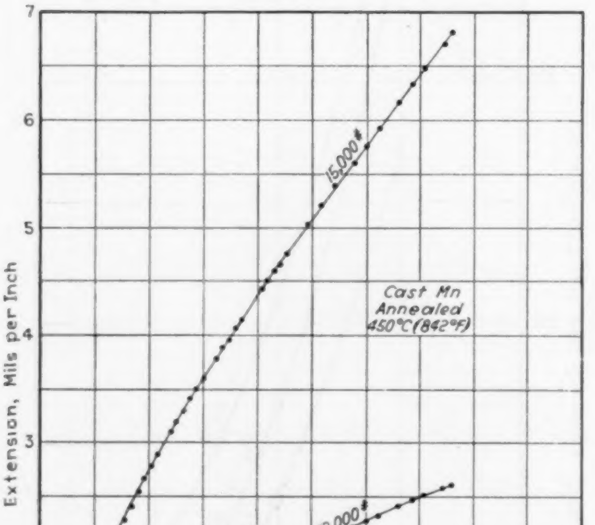

FIG. 18 CONSTANT-STRESS FLOW TEST OF FOUR BARS OF CAST-MANGANESE STEEL

(Composition: C, 0.31; Mn, 1.40; Si, 0.36. Heat treatment: 900°C., 6 hours, F.C.; 850°C., 4 hours, F.C.; 700°C., 4 hours. F.C.)

TEST DATA

Table 1 gives a summary of the results of a number of flow-rate tests.

Figs. 8 to 14 inclusive are flow-time curves of several of the tests summarized in Table 1. Stresses are given in thousands of pounds per square inch, and flow rates are expressed in per cent in 100,000 hours. Elastic extension is shown as well as plastic deformation. Fig. 16 gives logarithmic plots of stress versus flow rate. Fig. 17 shows the relation between temperature and the stress required to produce a flow rate of 1 per cent in 100,000 hours.

The following items are steels which were tested in both the annealed and in the heat-treated condition:

Annealed	Heat treated
265	264
252	253
246	240
123	122
259	257
114	115

These tests, and other tests listed in Table 1, where similar but not identical steels were tested in both the annealed and heat-treated conditions, indicate that frequently annealed steels resist flow at elevated temperatures better than heat-treated steels.

Fig. 15 is a test of a nickel-chrome-molybdenum steel, in which the (elastic plus plastic) extension was held approximately constant at 1 mil per inch. During the course of the test, 1340 hours, the stress was decreased gradually from 22,700 lb. per sq. in. to 15,000 lb. per sq. in., and the flow rate at the end of the test was 0.8 per cent in 100,000 hours.

Fig. 18 shows the results of a test in which four bars of the same cast manganese steel were held at 450 deg. cent. (842 deg. fahr.) with constant stresses of 15,000, 12,000, 9000, and 6000 lb. per sq. in. for 1514 hours (63 days). Tests of this nature provide data on total flow and on variation of flow rate with stress.

Appraisal of Results

The object of flow tests is to predict the ability of materials to maintain dimensions under stress at elevated temperatures for long periods of time, say, 5, 10, or even 20 years. From a family of curves as shown in Fig. 18, and in the light of flow rates established by stepdown loading, predictions may be attempted as to the probable flow in the course of, say, 100,000 hours. The analysis involving frankly a 20-to-1 or 40-to-1 extrapolation should be framed with due respect for metallurgical factors of vital importance. When long-time tests of a steel show a very small flow rate, decreasing as time goes on, it may be inferred with fair confidence that the extension-time curve will not suffer inflection.

Discussion

P. G. McVetty.[3] The demand for reliable creep data is increasing so rapidly that any possible simplification of the apparatus required is of great value. By putting four tests into one furnace the authors have greatly simplified the problem of controlling the temperatures of a large number of tests.

Another important simplification results from the use of the same specimen for several successive tests. There always has been some objection to this procedure because of the effect that strain hardening during a test may have upon those which follow it. The importance of this effect in comparison with that due to unavoidable differences among test specimens can be evaluated only after many more tests have been conducted.

From experience with creep curves, the writer has some doubts as to the reliability of rates determined in a period as short as 200 to 300 hours. If the rate continues to decrease as time goes on, the results obtained in a short test are on the safe side. In some cases, however, sudden increases of length are noted, with the result that the testing time is very much prolonged. It is evident that the analysis of the results depends greatly upon the decision as to when a creep rate representative of the stress has been obtained.

A study of the data given in Table 1 indicates the large effect upon safe working stresses which may result from what appear to be slight changes in analysis or heat treatment. For example, items 209 and 210 have similar analyses and identical heat treatments. The allowable stresses for the latter are appreciably lower in spite of a higher content of chromium and tungsten. Similar changes in results are observed when the same steel has different heat treatments. This leads to the conclusion that internal structure probably has an important effect upon creep phenomena.

The test represented by Fig. 15 is important in many applications. Instead of studying change of length at constant stress, it shows change of stress required to keep constant length. In practice this corresponds to the gradual reduction of stress in bolts due to creep. In the past very little has been done in this field of investigation.

In the concluding paragraph of the paper, the authors make the following statement, "When long-time tests of a steel show a very small flow rate, decreasing as time goes on, it may be inferred with fair confidence that the extension-time curve will not suffer inflection." This conclusion has not been proved, and it is open to some objection, especially at the higher test temperatures. For example, the test of item No. 210 at 550 deg. cent. and 4500 lb. per sq. in. indicates such an inflection. If we look upon creep as the net effect of the opposing actions of strain hardening and annealing and agree that annealing is a function not only of temperature but also of time of exposure, it seems inevitable that inflections will occur. This point can be settled by conducting creep tests over very long periods of time, and it is the opinion of the writer that a large number of very long tests at low stresses are necessary to explain creep phenomena.

F. H. Norton.[4] From what can be observed from the experimental curves it would seem that the precision in the measurement of temperatures and elongation is probably the best obtained by any experimenters on creep in this country. The comparatively long gage length of 12 in. is a distinct advantage in obtaining this precision. However, it is felt that this type of extensometer would not be as satisfactory for the higher temperature tests—that is, 1200 to 1500 deg. fahr.

It is interesting to observe that, where it is possible to make comparisons, the results obtained by the authors agree very well with our results, except for steel No. 209, where with a specimen of approximately the same composition we obtain approximately one-third of their value. Unfortunately we have very few tests at the temperature of 842, where most of the tests were reported in this paper.

Steels 117C and 119C, which are of approximately the same composition, show creep stresses in the ratio of 1.16 to 1.00 at 400 deg. cent., and approximately a three-to-one difference at 450 deg. cent.

The authors have plotted their results on logarithmic paper, and it is observed that in all cases the slope of the resulting curve is one in five, which agrees exactly with the results that we have been obtaining upon steels, although in this paper the results have been extended to somewhat lower rates than we have ordinarily obtained.

C. L. Clark[5] and A. E. White.[6] As each of the values given is the result of tests lasting hundreds of hours, it is evident that an enormous amount of time and effort was expended.

The writers have had occasion to investigate many steels of the type reported, and they are pleased to find that in general these results are in agreement with those obtained by them.

It is interesting to note that of the three chromium-tungsten-vanadium steels considered, Nos. 209, 210, and 211, the one having the lowest alloy content, No. 209, possesses the greatest creep resistance over the entire temperature range considered. This also is in keeping with the writers' findings and furnishes conclusive proof that increases in the alloying content do not necessarily increase a metal's high-temperature stability, as is believed by many, and may often have the opposite effect.

In this same connection, the writers recently prepared a series of nearly 100 heats in which the amounts of alloying elements present were gradually varied. The results of certain of these tests will be presented in a future paper, but it may now be stated that with many of the alloying elements, especially those of the chromium and tungsten types, definite amounts of each must be present in order to obtain the maximum high-temperature properties. Variations either above or below these critical amounts result in a marked decrease in the resulting high-temperature properties, especially in those measured by the proportional limit and the creep tests.

If one examines a large number of the creep values that have been reported for plain carbon steels, he will be surprised at the large variations in them. For example, at 850 deg. fahr., which corresponds fairly well to the 450 deg. cent. (842 deg. fahr.) temperature used by the authors, the writers have found the values to vary from 5000 to 20,000 lb. per sq. in. Many of these differences may be accounted for by variations in such factors as carbon content, test procedure, heat treatment, and method of presentation of results, but often the differences are large even when these various factors are about the same. The writers believe much of the difference in these latter cases may be due to the method and care employed in making the steel which was used in the tests. For example, they recently determined the creep values of two plain carbon steels at 850 deg. fahr., both of which had the same composition and heat treatment, and differed only in that one was made according to alloy-steel practice while the other was the usual run of commercial steel. For the carefully prepared steel they obtained a value of 11,000 lb., while with the ordinary one a stress of only 7000 lb. was required to produce the same creep of 1 per cent per 100,000 hours. For this reason, they believe that in all tables of physical properties, the source of the material—that is, whether it is open-hearth, electric, induction, etc.—should be stated whenever possible.

[6] Director, Department of Engineering Research, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

It is observed that in all the creep tests reported, either up-step or down-step loading was employed. The writers would like to ask the authors if the same material was ever subjected to both types, and if so, if the results were in agreement; also if single-step loading was ever used, and if so, if the results from this method compared favorably with those from the multiple-step procedure.

An interesting fact to be observed in connection with the down-step loading process is that all of the specimen's recovery does not always occur immediately upon removal of any given increment. We have observed this recovery lasting for periods of as long as 150 hours. The amount which does occur immediately upon removal of the load corresponds fairly well with the elastic deformation corresponding to that increment, while the remaining recovery seems to be at the expense of some of the plastic deformation which has previously occurred.

L. Levine.[7] The object of this discussion is to show the development and behavior of one mathematical expression involving the three variables, total flow, stress, and time, which fits the data given in Fig. 18 and affords some basis for further predictions.

TABLE 2 COMPARISON OF VALUES

t hours	Lb. per sq. in.	y calculated	y observed
100	6,000	0.132	0.13
	9,000	0.267	0.27
	12,000	0.540	0.53
	15,000	1.09	1.1
500	6,000	0.241	0.237
	9,000	0.560	0.57
	12,000	1.33	1.33
	15,000	3.16	3.19
1000	6,000	0.301	0.305
	9,000	0.767	0.77
	12,000	1.97	2.03
	15,000	5.07	5.07
1500	6,000	0.36	0.36
	9,000	0.96	0.95
	12,000	2.61	2.61
	15,000	7.06	6.76

The method of analysis used is "grapho-analytical." Relations between the variables are first found by plotting them on semi-logarithmic and logarithmic coordinates, and these later combined to give the complete expression:

$$y = \epsilon^{0.133\left\{St^{0.135} - \frac{32.4}{t^{0.046}}\right\}}$$

This gives the plastic extension y in terms of the stress S and the duration of stress t. That it is correct in the range covered by the available data is shown by Table 2, which compares the actual observed values for several different stresses and time intervals with values calculated from the foregoing empirical function.

Before commenting on this function, its limitations should be clearly recognized. All that is known is that for this particular steel, at this particular temperature, for stresses between 6000 and 15,000 lb. per sq. in. and a time duration of 1500 hours, the function expresses the behavior of the steel. That it will continue to do so over greater time intervals or for different stresses is not known. Nothing is said about other steels or other temperatures. But having this function, it is a matter of some curiosity to see how it behaves over a wide range. If the steel continues to follow it, well and good; if not, information must be sought in another direction.

1. When stress is zero,

$$y = \frac{1}{\epsilon^{4.3/t^{0.046}}}$$

This points to an increase of length even without stress—but only a slight increase. When t is 100,000, for example, y = 0.09 mil per in. Whether this is due to an error in the function, to actual physical growth of the metal, or to both, cannot be stated. In any case it is of small consequence.

2 When $t = 0$, $y = 0$, regardless of S. This is necessary because all flow is measured from the length at zero time.

3 When t is infinite, y is infinite for all positive values of S. This shows that the function does not approach an asymptote with time for any stress.

4 At a point of inflection the second derivative of y with respect to t is zero.

Some of the values of S which satisfy this relation are as follows:

S lb. per sq. in.	T hours	Y mils per inch
19,100	1,000	19
16,300	5,000	30
14,600	10,000	30
11,200	100,000	45
8,100	1,000,000	46

These results shown graphically would give a family of curves like Fig. 19.

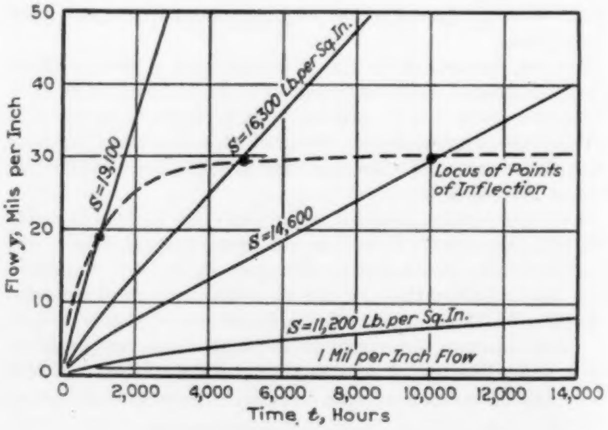

Fig. 19

---

[7] Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Jun. A.S.M.E.

The form of the equation indicates that there is an inflection in the curve for every stress. For the lower stresses, however, the inflection occurs at a time well beyond the life of any machine. This matter of points of inflection is an interesting one, for such points have been observed by various investigators.

5 Returning to the original flow function, we may note that when y = 1 mil per inch, the exponent of ϵ is zero. Therefore:

$$St^{0.173} = 32.4$$

Here is a matter which might deserve further investigation. If it were to be found that an expression of the form St^n = constant stated a necessary relationship between S and t for a total flow of 1 mil per inch, then by running tests on two or three bars at moderate stresses for a short time, the two empirical constants could be determined and the limiting design stress easily calculated. One cannot, of course, on the basis of this one test draw any conclusions on this subject. It is, however, an interesting subject for speculation.

E. L. Robinson.[6] The manner in which the authors have conducted their tests and presented the results makes them of particular value to designers of high-speed machines interested in maintaining dimensions over long periods of time.

These tests have been made on long test pieces, over long periods of elapsed time, at moderate stresses and extensions. These facts make for confidence in accepting the conclusions for application to actual behavior of machines.

Speed of measurement of flow rate could have been secured by causing the apparatus to magnify minute extensions occurring in a small gage length over a short time. But the results plotted in Fig. 18 show that flow rates based on a short elapsed time do not have the validity of rates based on longer periods of elapsed time.

In fact, with tests covering still longer periods, it may be necessary, for steady stress conditions, as suggested in the discussion by Mr. Levine, to find better methods for analytic interpretation than the logarithmic plots shown in Fig. 16 which characterize flow-rate tests under conditions of stress relief approximating constant extension.

The need for conducting tests showing behavior under different conditions of service is frankly recognized. In fact, the authors have not specifically pointed out that three of the flow-rate tests give curves for stress relief at constant extension similar to that shown in Fig. 15, while Fig. 15 itself constitutes a flow-rate test. Also among the flow-rate tests are three incidental steady stress tests of 500 hours' duration similar to those given in Fig. 18, which would be listed as "long time tests" by many other authors.

The futility of trying to judge relative dimensional stability of materials at high temperature on the basis of short-time strength tests at high stress is well demonstrated by the convergence of the lines in Fig. 16, for the 550 deg. cent. tests. The relative desirability of these materials would be reversed for short applications of high stresses.

Authors' Closure

Mr. McVetty is undoubtedly right in believing that anomalous behavior in creep may escape detection in tests of 200 to 300 hours. The time required to establish a flow rate depends upon the order of the magnitude of the rate. In our apparatus 200 to 300 hours will usually be sufficient time to establish a rate of 10 per cent in 100,000 hours. A run of at least 500 hours, however, is required ordinarily to establish a flow rate of the order of 1 per cent in 100,000 hours.

It also is true that the result of a flow-rate test depends upon the portion of the flow-time curve used to establish the flow rate. Fig. 18 shows that the rate of flow changes as flow takes place and as time goes on. In our usual flow-rate tests it is our practice to stretch the test bars 1 mil per inch before establishing the first flow rate, thereby putting the tests on an equal basis from the standpoint of the amount of flow.

In the last sentence of the paper it was implied that for the small stresses permissible in design the extension-time curve will not suffer inflection during the usual life of a machine. Whether such inflection may occur at some remote time cannot now be determined. Mr. Levine's discussion bears on this point. His equation, which is based on a single test (the one shown in Fig. 18), shows inflection points for small flow rates, but at distant points on the time axis.

Messrs. Clark and White also raise a point which has a bearing upon this matter of inflection. They point out that upon removal of a stress there is an elastic after-effect. We have frequently observed that this effect lasts for several hundred hours with no observable flow. (See item 210 at 550 deg. cent.) Sometimes there may be a partial recovery during this time, followed later by a change to a higher rate of flow. When using the step-down method, we have to use our judgment in regard to the length of time necessary to continue the test in order to be sure that we have passed this point of early inflection. By plotting three different flow rates on the same specimen at each temperature, we obtain a reasonably safe check in this regard.

Mr. F. H. Norton questions the applicability of the dial gage to flow tests at temperatures above 600 deg. cent. We have used them in tests made at temperatures up to 800 deg. cent. without any more difficulty than at lower temperatures.

The falling off in the ratio of the strength of the carbon steel 119 with respect to 117, at 450 deg. cent., is typical of the behavior of some quenched steels when compared with the same steels in the annealed condition. The high value shown for the steel 209 may be attributed to either or both of two factors: (1) The tungsten content may represent an optimum value, being approximately 2 per cent—we have been unable to get equally high values with tungsten contents of from 1.63 to 1.80 per cent, and Mr. Norton's specimen was 1.7 per cent; (2) steel 209 was hot-rolled to 0.5 in. in diameter, while our other specimens were rolled to 0.75 in. or greater in diameter; hence the amount of hot-working received by steel 209 was greater.

Messrs. Clark and White also comment on the optimum percentage of an alloying element such as tungsten. When we raised the tungsten content to 2.9 per cent, in steels 101 and 210 the strength definitely fell off at 500 deg. and at 550 deg. when compared to 209. As to the source of carbon steels we have confined our tests so far to open-hearth steels.

The results of the tests by Messrs. Clark and White, wherein a study of a series of steels of varying alloy content is being made, will be looked forward to with great interest, as systematic tests of this nature will be very useful.

Of the three methods used for loading the specimen, the step-up method is of least interest to our conditions of application, owing to the difficulty in judging the transition from the first stage to the second stage of the flow. When testing new types of steel, the most expeditious method for obtaining stable rates of flow is by first using the step-up method until a preliminary extension is obtained, amounting to about 1 mil per inch. The stress is stepped up with sufficient rapidity to obtain this extension in from three to seven days with flow rates as high as from 30 per cent to 70 per cent in 100,000 hours. The stress is then stepped down to obtain a flow rate of approximately 10 per cent for a sufficient length of time for it to become reasonably stable. It is then stepped down again to obtain, successively, rates of around 2 or 3 per cent, and finally around 1 per cent.

---

[6] Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

After sufficient preliminary exploration has been done by the step-down method to enable us to select particular types of steel for further investigation, we make confirmatory tests by the constant-stress method, as indicated in Fig. 18 in the paper.

We have run several constant-stress tests for periods of about six months, and then have plotted the final rates of flow against the stress on log-log paper. The four points usually fall fairly near a straight line, the deviations evidently being due to differences in strain hardening between the four bars. The rates of flow indicated by the straight line agree reasonably well with those obtained by the step-down method, provided we give preference to the points which represent the flow rates on the more highly stressed specimens.

The constant-stress tests, however, give information of a different character which is just as useful for design purposes as the flow-rate tests.

The Flexibility of Corrugated Pipes Under Longitudinal Forces and Bending

By L. H. DONNELL,[1] PASADENA, CALIF.

Pipes with circumferential corrugations are being used in expansion bends in steam lines and in other applications where the maximum longitudinal or bending flexibility is required. In the present paper the longitudinal flexibility is calculated for several types of corrugations, and from this a "reduced modulus of elasticity" is derived by which corrugated pipes can be calculated as if they were smooth. It is then proposed to use this same reduced modulus for calculating the bending of corrugated pipes. A set of experiments is described which check these results.

The flexibility of pipes with corrugations cannot be calculated by elementary methods because the change of radius during the bending of the corrugations produces circumferential tensile or compressive stresses which make the bending similar to that of a beam on an elastic foundation. By using the method of internal energy, a "reduced modulus of elasticity" has been computed for pipes with V-shaped corrugations (Fig. 1) and with semicircular corrugations (Fig. 3 when $h = b$), for longitudinal compression or extension of the pipe (see Appendix). A formula has been derived by analogy for the intermediate case of corrugations of parabolic or sine-wave shape (Fig. 2). In using these reduced moduli, calculations are to be made as if the pipe were not corrugated (but having the same average radius, length, and wall thickness) and had the reduced modulus as its modulus of elasticity.

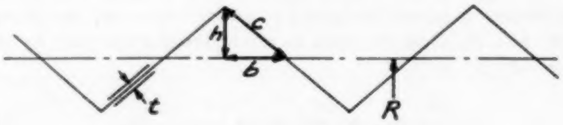

Fig. 1 V-Shaped Corrugations

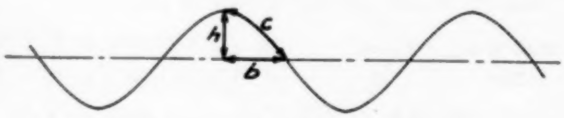

Fig. 2 Parabolic or Sinusoidal Corrugations

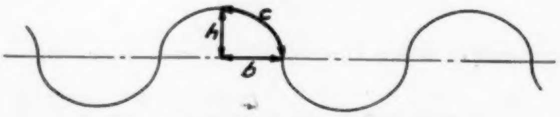

Fig. 3 Semielliptical Corrugations

It is assumed that the same reduced moduli can be used in computing bending deflections of corrugated pipe,[2] the calculations being made as if the pipe were not corrugated. There is no theoretical evidence to support this assumption, but it seemed reasonable, as the stiffness against transverse shearing of corrugated pipe is high, and it checked well with a set of experiments described in the Appendix. In computing deflections of pipe bends by this method it is not known what effect must be expected due to the flattening of cross-sections of the pipe, which flattening has been shown to have considerable influence in the case of plain pipe. It is probable that this flattening has much less effect with corrugated pipe than with plain pipe, as the resistance to flattening is greater and the forces producing it are smaller than with plain pipe.

In presenting the results below, the different types of corrugations have been dimensioned and treated in as similar a manner as possible. This leads to apparently unnecessary complications in some cases, but makes easier the comparison of the different types and the derivation of approximate formulas for intermediate types by analogy.

It is assumed that the depth of the corrguations is small compared with the radius of the pipe, and that the wall thickness is fairly small compared with the radius of curvature of the corrugations. However, the formulas developed should hold approximately if this is not the case.

Symbols

E = modulus of elasticity of the material
E' = "reduced modulus of elasticity," with which a plain pipe of the same length and wall thickness has the same flexibility
t = wall thickness
R = average radius of pipe
b, h, c = dimensions of corrugations as shown in Figs. 1–3
β = $(cb/Rt)^2$
u, v, w = longitudinal, radial, and normal displacements, respectively
s = distance measured along the curve.

The "reduced modulus" is then found to be

$$E' = \frac{E}{1 + \dfrac{4ch^2}{bt^2} K} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where K is a number depending on the corrugations. For V-shaped corrugations (Fig. 1):

$$K = \frac{h+b}{h+b} \, \frac{1}{1 + 2\beta - 0.14\,\beta^{1.5}} = \frac{1}{1 + 2\beta - 0.14\beta^{1.5}} \quad \ldots [2]$$

For parabolic or sinusoidal corrugations (Fig. 2) a very approximate formula is proposed:

---

[1] Research Fellow in Aeronautical Structures, Guggenheim Aeronautical Laboratory, California Institute of Technology. Mem. A.S.M.E. L. H. Donnell was born in 1895 in Maine. He is a graduate in Mechanical Engineering, University of Michigan, 1915; Doctor's degree, University of Michigan, 1930. He worked in the engineering departments of automobile companies (Franklin, Packard, Dodge) for seven years, and taught engineering mechanics as assistant professor, University of Michigan, for seven years.

Presented at the National Applied Mechanics Meeting, Purdue University, Lafayette, Ind., June 15 and 16, 1931, of The American Society of Mechanical Engineers. [The work described was carried out at the University of Michigan.]

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] S. Timoshenko suggested that this might be possible.

$$K = \frac{h + 1.6b}{h + b}\,\frac{1}{1 + 1.4\beta - 0.15\beta^{1.4}} \quad\ldots\ldots\ldots[3]$$

For semicircular or semielliptical corrugations (Fig. 3):

$$\left.\begin{aligned} K &= \frac{h + 2b}{h + b}\,\frac{1}{1 + \beta - 0.16\beta^{1.3}} \\ &= \frac{1.5}{1 + \beta - 0.16\beta^{1.3}},\ \text{if } h = b \end{aligned}\right\} \quad\ldots\ldots\ldots[4]$$

This formula has been proved only for the case when $h = b$, but it is probably roughly correct for semielliptical corrugations with h different from b.

Appendix

V-Shaped Corrugations. If h is small compared with R, Fig. 4, and the material has the same properties in tension and compression, we can assume without much error that points such as P and P' do not move radially (*vertically* in the figure), and we can use the average radius R in computing the width and elastic support of an elemental strip, such as that cut out by the planes M–N and M'–N'. Under these assumptions the points P and P' become points of inflection and the problem can be reduced to that of a bent strip (Fig. 5), of uniform width αR (where α is a small angle) under horizontal end loads $\alpha F/2\pi$ and a vertical elastic support proportional to the vertical displacements v (due to tangential stresses). The tangential strain will be the same as the radial strain or approximately v/R, making the tangential stress Ev/R, or a force per unit length of strip Etv/R. The resultant of such forces on each side of the strip will then be a vertical elastic supporting force $(Et\alpha/R)\,v = kv$ per unit length of strip.

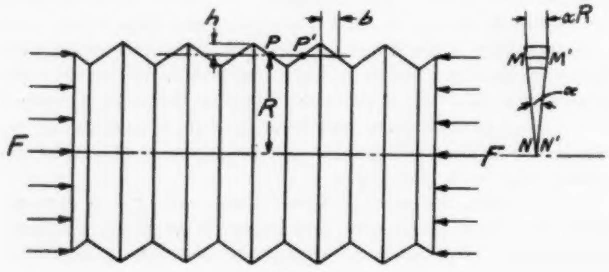

FIG. 4

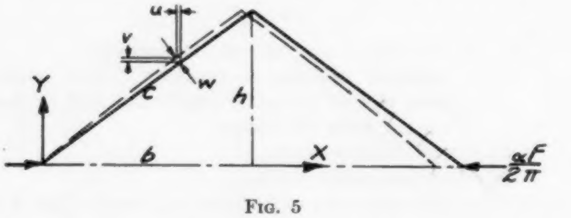

FIG. 5

In Fig. 5, u represents horizontal, v vertical, and w normal deflections, and s distances along the strip. Then:

$$ds = \frac{c}{b}\,dx,\quad dw = \frac{c}{b}\,dv \ \text{(for small deflections)}$$

Hence the bending moment is

$$M = EI\,\frac{d^2w}{ds^2} = \frac{b}{c}\,EI\,\frac{d^2v}{dx^2} \quad\ldots\ldots\ldots\ldots\ldots[5]$$

M and v are zero at the ends of the strip, and these conditions, as well as those of symmetry and continuity at the middle, are satisfied if:

$$v = \Sigma a_n \sin\frac{n\pi x}{2b} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots[6]$$

where n is odd only. Then, using [5]

$$M = -\frac{EI\pi^2}{4cb}\,\Sigma n^2 a_n \sin\frac{n\pi x}{2b} \quad\ldots\ldots\ldots\ldots\ldots[7]$$

The internal energy of bending is then

$$W_1 = \int_0^{2c}\frac{M^2 ds}{2EI} = \frac{EI\pi^4}{32cb^3}\int_0^{2b}\left(\Sigma n^2 a_n \sin\frac{n\pi x}{2b}\right)^2 dx$$
$$= \frac{\pi^4 E\alpha R t^3}{384\, cb^2}\,\Sigma n^4 a_n^2 \ldots[8]$$

The work done against elastic forces is, using [6],

$$W_2 = \int_0^{2c}\frac{kv^2 ds}{2} = \frac{E\alpha tc}{2Rb}\int_0^{2b}\left(\Sigma a_n \sin\frac{n\pi x}{2b}\right)^2 dx = \frac{E\alpha tc}{2R}\,\Sigma a_n^2 \quad\ldots\ldots[9]$$

The horizontal shortening due to bending is, from [6],

$$\Delta = 2(u_{x=b}) = 2\,\frac{h}{b}\,(v_{x=b}) = \frac{2h}{b}\,(a_1 - a_3 + a_5 \ldots) \ldots[10]$$

If the strip is given a small displacement from the position of equilibrium, produced by giving a_n an increment da_n, the change in W_1 and W_2 must be equal to the external work done by the force $\alpha F/2\pi$, or:

$$\frac{\partial W_1}{\partial a_n}\,da_n + \frac{\partial W_2}{\partial a_n}\,da_n = \frac{\alpha F}{2\pi}\,\frac{\partial\Delta}{\partial a_n}\,da_n \quad\ldots\ldots\ldots[11]$$

or, using [8], [9], and [10] and dividing by da_n,

$$\frac{\pi^4 E\alpha R t^3 n^4 a_n}{192cb^2} + \frac{E\alpha t c a_n}{R} = \pm\frac{\alpha F h}{\pi b}\begin{pmatrix} + \text{ for } n = 1, 5, 9 \ldots \\ - \text{ for } n = 3, 7, 11 \ldots \end{pmatrix}$$

$$a_n = \pm\frac{192\,Fhcb}{\pi^5 ERt^3}\,\frac{1}{\left(n^4 + \dfrac{192}{\pi^4}\,\dfrac{c^2b^2}{R^2t^2}\right)} = \pm\frac{2Fhcb}{\pi ERt^3}\,\frac{1}{n^4 + 2\beta}$$

approximately, where $\beta = (cb/Rt)^2$. Hence, using [10],

$$\Delta = \frac{2h}{b}\,(a_1 - a_3 + a_5 - \ldots) = \frac{4Fh^2c}{\pi ERt^3}\left(\frac{1}{1 + 2\beta} + \frac{1}{81 + 2\beta}\right.$$
$$\left. + \ldots\right) = \frac{\pi Fh^2c}{4ERt^3}\left(\frac{1}{1 + 2\beta - 0.14\beta^{1.6}}\right),\ \text{approx.}\ldots[12]$$

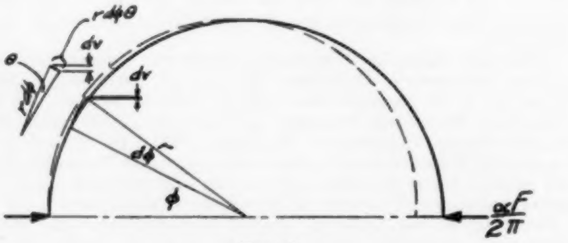

FIG. 6

The expression in the last parenthesis was obtained empirically after calculating values of the series it replaces for values of β from zero to 100.

Semicircular Corrugations. In a similar manner the case of semicircular corrugations may be reduced to that of an arched strip, as shown in Fig. 6. Due to bending of the strip there will be some rotations of cross-sections of the strip as indicated by the angle θ in the figure. This rotation will produce linear displacements of points in the strip. The change in radial displacements in a length $rd\phi$ of the strip, due to the rotation θ is $rd\phi\theta$, and the corresponding change in vertical displacement is:

$$\left.\begin{aligned} dv &= rd\phi\theta \sin\phi \\ \text{whence} \qquad \theta &= \frac{1}{r\sin\phi}\frac{dv}{d\phi} \end{aligned}\right\} \qquad [13]$$

The rotation θ is caused by bending, and the change in θ in an element of length $rd\phi$ (in other words, the relative angular displacement of the two ends of the element) is, just as in the bending of a straight beam:

$$d\theta = \frac{M}{EI}(rd\phi)$$

Hence, using [13],

$$M = \frac{EI}{r}\frac{d\theta}{d\phi} = \frac{EI}{r^2}\frac{d\left(\frac{1}{\sin\phi}\frac{dv}{d\phi}\right)}{d\phi} \qquad [14]$$

The bending moment is zero at the ends of the strip, and we can write

$$M = \frac{EI}{r^2}\Sigma a_n \sin n\phi \qquad [15]$$

where n is odd only, from symmetry. Substituting this in [14] we have

$$\Sigma a_n \sin n\phi d\phi = d\left(\frac{1}{\sin\phi}\frac{dv}{d\phi}\right)$$

Integrating both sides,

$$-\Sigma\frac{a_n}{n}\cos n\phi = \frac{1}{\sin\phi}\frac{dv}{d\phi} + C_1$$

When $\phi = \pi/2$ we have $dv/d\phi = 0$, from which $C_1 = 0$. Then

$$dv = -\Sigma\frac{a_n}{n}\sin\phi\cos n\phi\, d\phi$$

Integrating once more,

$$v = -\frac{a_1}{2}\sin^2\phi + \sum_{n=3}^{n=\infty}\frac{a_n}{2n}\left(\frac{\cos(n+1)\phi}{n+1} - \frac{\cos(n-1)\phi}{n-1}\right) + C_2 \qquad [16]$$

When $\phi = 0$ or π, $v = 0$, from which

$$C_2 = \sum_{n=3}^{n=\infty}\frac{a_n}{n(n^2-1)}.$$

Then from [15] the internal energy of bending is

$$W_1 = \int_0^\pi \frac{M^2 rd\phi}{2EI} = \frac{EI}{2r^3}\int_0^\pi(\Sigma a_n \sin n\phi)^2 d\phi = \frac{E\alpha Rt^3\pi}{48r^3}\Sigma a^2{}_n \qquad [17]$$

The work done against elastic forces is, using [16],

$$W_2 = \int_0^\pi \frac{kv^2rd\phi}{2} = \frac{kr}{2}\int_0^\pi v^2 d\phi$$

$$= \frac{Et\alpha r}{8R}\int_0^\pi\left[-a_1\sin^2\phi + \sum_{n=3}^{n=\infty}\frac{a_n}{n}\left(\frac{\cos(n+1)\phi}{n+1} - \frac{\cos(n-1)\phi}{n-1} + \frac{2}{n^2-1}\right)\right]^2 d\phi$$

$$= \frac{Et\alpha r}{8R}\int_0^\pi\left[\left(-\frac{a_1}{2} + \sum_{n=3}^{n=\infty}\frac{2a_n}{n(n^2-1)}\right) + \ldots\left(\frac{a_n}{n(n+1)} - \frac{a_{n+2}}{(n+1)(n+2)}\right)\cos(n+1)\phi\ldots\right]^2 d\phi$$

$$= \frac{Et\alpha r\pi}{16R}\left[2\left(\frac{a_1}{2} - \sum_{n=3}^{n=\infty}\frac{2a_n}{n(n^2-1)}\right)^2 + \ldots\left(\frac{a_n}{n(n+1)} - \frac{a_{n+2}}{(n+1)(n+2)}\right)^2\ldots\right] \qquad [18]$$

The horizontal shortening due to bending is, using [15],

$$\Delta = \int_0^\pi \frac{Mrd\phi}{EI} r\sin\phi = \frac{\pi}{2}a_1 \qquad [19]$$

Using [11] and [17], [18] and [19] and letting $r^4/R^2t^2 = \beta^1$, we find

$$\left(\frac{1}{\beta^1} + \frac{9}{4}\right)a_1 - \frac{a_3}{4} - 3\sum_{n=3}^{n=\infty}\frac{2a_n}{n(n^2-1)} = \frac{6Fr^3}{\pi ERt^3\beta^1} \qquad [20]$$

$$\left(\frac{1}{3\beta^1} + \frac{8}{n^2(n^2-1)^2} + \frac{2(n^2+1)}{(n-1)^2n^2(n+1)^2}\right)a_n - \frac{2a_1}{n(n^2-1)} + \frac{4}{n(n^2-1)}\sum\frac{2a_p}{p(p_2-1)} - \frac{a_{n+2}}{n(n+1)^2(n+2)} - \frac{a_{n-2}}{n(n-1)^2(n-2)} = 0 \qquad [21]$$

where p has all odd values but 1 or n.

The numbers a_1, a_3, a_5, etc., diminish rapidly in importance. By taking all above a certain one as zero the remainder may be found from [21]. Then using [19] and [20] we find

$$\Delta = \frac{3Fr^3}{ERt^3[1 + 2.25\beta' - 0.2(\beta')^{1.2}]} \qquad [22]$$

The expression in the brackets was obtained empirically after calculating values of Δ for values of β' from 0 to 100.

Formula [22] is put into a form where it is probably approximately applicable to semielliptical corrugations by the following reasoning. The quantity in the brackets of the denominator represents the effect of the elastic support, while the remainder is the formula for Δ if there were no elastic support. The last part can readily be calculated by elementary methods for the case of an ellipse (Fig. 3), and by combining the resulting formula with the parenthesis of [22] we obtain a form which is certainly true for $h = b$ and should be nearly true when h differs somewhat from b. To interpret the meaning of $\beta' = r^4/R^2t^2$ for the case of an ellipse we use an analogy with the previously calculated case of V-corrugations by setting

$$\beta' = \frac{r^4}{R^2t^2} = \frac{4}{\pi^2}\frac{\left(\frac{\pi}{2}r\right)^2 r^2}{R^2t^2} = \frac{4}{\pi^2}\frac{c^2b^2}{R^2t^2} = \frac{4}{\pi^2}\beta$$

All this has been done in deriving Equation [4].

Equations [1], [2], and [4] were obtained by setting the values of Δ in [12] and [22] equal to the value of Δ for a plain pipe with modulus of elasticity E'.

$$\Delta + \frac{F2b}{E2\pi Rt} = \frac{F2b}{E'2\pi Rt}$$

$$E' = \frac{E}{1 + \frac{\pi ERt\Delta}{Fb}}$$

The quantity $F2b/E2\pi Rt$ is the shortening of the corrugated pipe due to direct stress, which must be added to the shortening due to bending, previously calculated. This is of no importance except for very shallow corrugations, and its value then approaches that given.

Formula [3] is derived simply by analogy from [2] and [4], considering that the case of parabolic or sinusoidal corrugations is an intermediate one, about six-tenths of the way between V-shaped and semielliptical corrugations, as elementary calculations show would be the case if there were no elastic support.

Experiments. A piece of corrugated culvert pipe was tested in direct compression and in bending, as shown in Figs. 7 and 8. In the compression test extensometers were placed on both sides of the specimen to eliminate the effects of eccentric loading. In the bending test the pipe was supported at the ends and the load divided between two points equal distances from the ends, so that the center of the pipe was in a condition of pure bending. Deflections in the center portion were measured with the aid of unloaded bars hung from the pipe. Dimensions of the pipe were R=5.33 in.; t=0.065 in.; b=0.670 in.; h=0.235 in.; c=0.735 in. The shape of the corrugations was between the sinusoidal and V-shape—nearer the former. The reduced modulus E' calculated from the results of the direct loading test was 1,510,000 lb. per sq. in.; from the bending test it was 1,450,000 lb. per sq. in. The theoretical value of E' from Formula [2] was 2,250,000 lb. per sq. in.; and from Formula [3] it was 1,200,000 lb. per sq. in.

$E = 3 \times 10^7$

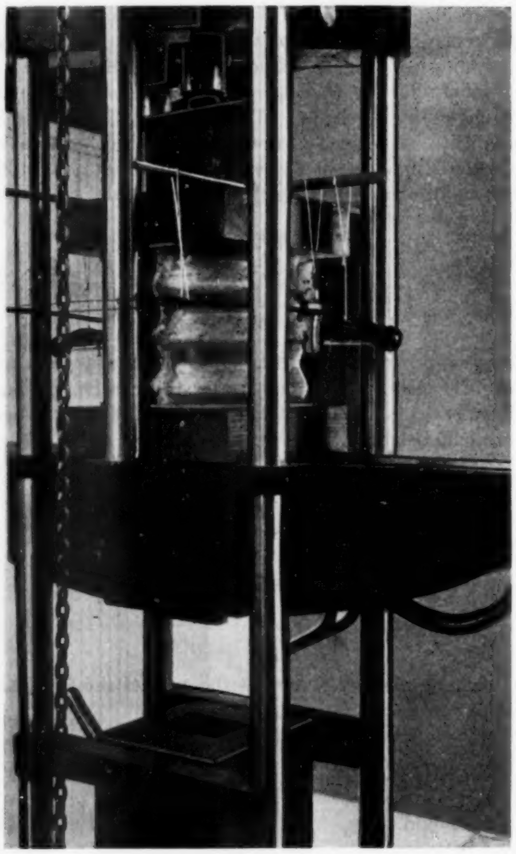

Fig. 7 Direct-Compression Test

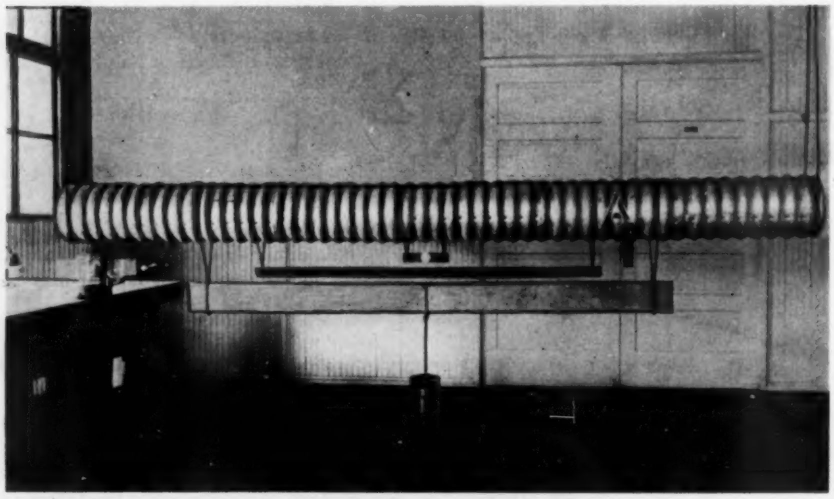

Fig. 8 Bending Test

Discussion

E. T. Cope[3] and E. A. Wert.[4] The author is to be congratulated upon the deduction of an empirical formula for the calculation of K', "reduced modulus of elasticity." Beyond a doubt this form of analysis is applicable to a corrugated pipe in which the profile of the corrugation is symmetrical, either parabolic, sinusoidal, or semicircular, and the thickness of pipe wall is small in comparison with the height of the corrugations. However, the writers are fearful lest the implication contained in the first sentence of the summary may lead to calculated results, when applied to available corrugated steam-pipe members, which are not in accordance with the results of tests.

During the summer of 1930 the writers conducted a series of tests to determine load-deflection relations for ten pieces of high-pressure steam pipe of 10 in. and 14 in. nominal diameter. Three of these pieces of pipe were smooth, five were corrugated, and two were creased. The corrugated pipes were made under the patents of P. Koffoski, of Poland.[5] As far as the writers know, this is the only kind of corrugated pipe now procurable for use in steam-power-plant installations. The results of these tests, together with the mathematical calculations of load-deflection relation for smooth-pipe members of the same dimensions as the corrugated pipe, were published in a paper entitled "Load-Deflection Relations for Large Plain, Corrugated, and Creased Pipe Bends," by the writers.[6]

[4] Drafting and Surveying Bureau, The Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

Figs. 9 and 10 show the corrugated pipe on which tension loading was applied. In Fig. 10 the tension loading was applied only on the straight part of the pipe member. Elongation was measured over the corrugated portion only. Figs. 11 and 12 show dimensioned drawings of these two pipes, and Figs. 13 and 14 the profiles of the corrugations of these pipes, as nearly as it was possible to measure them.

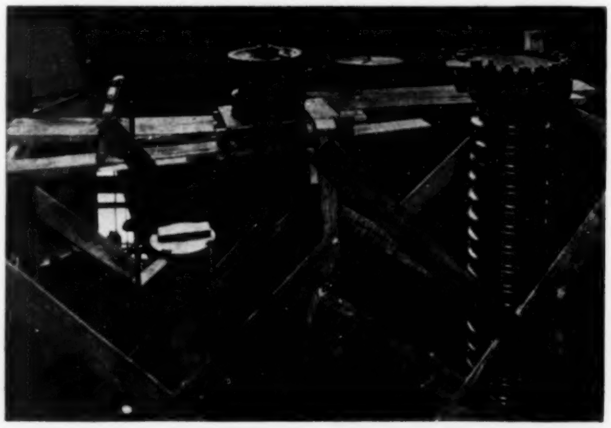

FIG. 9 CORRUGATED PIPE ON WHICH TENSION LOADING WAS APPLIED

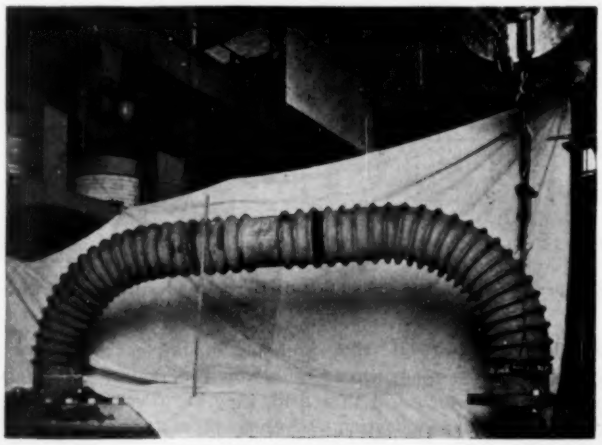

FIG. 10 TENSION LOADING APPLIED ONLY ON STRAIGHT PART OF PIPE MEMBER

It should be remembered that the corrugations on commercial corrugated steam pipe such as those shown are not of exact form. The method of fabrication results in each separate corrugation being an individual. The corrugations are not symmetrical curves such as those pictured in the paper. Again, the wall thickness is likely to be large in comparison with the radius of the corrugation. The 14-in. pipe, it will be noted, had a $^1/_2$-in. wall and the mean radius of the crest of the corrugation was 1 in. It appears that the validity of the empirical formula deduced depends upon the fact that the radius of trough and crest of the corrugations are equal. This makes its application to commercial corrugated steam pipe of questionable value.

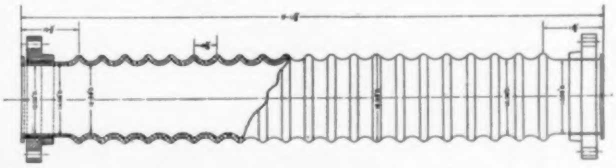

FIG. 11 DIMENSIONAL DRAWING OF 14-IN. CORRUGATED TANGENT PICTURED IN FIG. 9

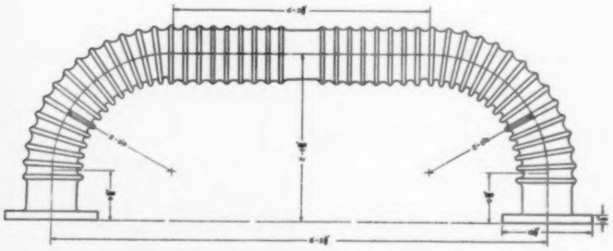

FIG. 12 DIMENSIONAL DRAWING OF 10-IN. CORRUGATED EXPANSION U-BEND PICTURED IN FIG. 10

(Mean outside diameter at ends, 10.36 in.; mean thickness of wall at ends, 0.22 in.; mean inside diameter at ends, 9.22 in.; mean outside diameter of crests of corrugations, 12.11 in.; mean outside diameter of troughs of corrugations, 10.25 in.)

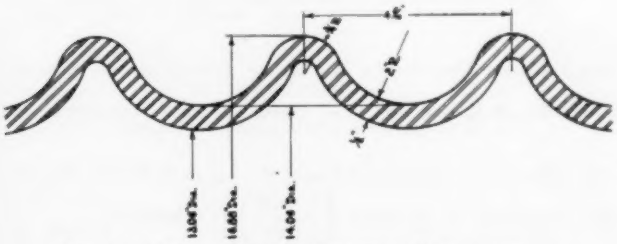

FIG. 13 PROFILE OF PIPE SHOWN IN FIGS. 9 AND 11

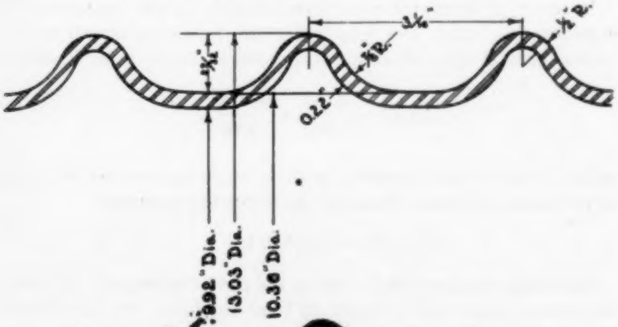

FIG. 14 PROFILE OF PIPE SHOWN IN FIGS. 10 AND 12

The load-deflection relations under axial loading of the two corrugated pipes which the writers have tested are shown in Figs. 15 and 16. On the same sheets are shown the calculated load-deflection relations of smooth-pipe members of the same major dimensions.

Further study showed that the elongation of such a corrugated pipe as either one shown, due to thermal expansion, cannot be taken up by the compression of the pipe unless a large axial restraining force was applied. As an example, consider the corrugated tangent such as the straight portion of Fig. 10. In Fig. 16 the elongation in tension is seen to be 0.005 in. in 19.47 in. of length when an axial load of 9000 lb. was applied. The coefficient of thermal expansion for mild steel is, according to Halborn and Day, equal to $0.006212\left(\frac{t-32}{100}\right) = 0.001623\left(\frac{t-32}{100}\right)^2$, where t is the temperature of the steel in degrees fahrenheit.

---

[5] Corrugated pipe, according to the Koffoski patent, is made in England by Aiton & Co., Ltd., Derby, and in Germany by Seiffert & Co., Düsseldorf.

TABULATED RESULTS

FORCE	Δ TEST CORR.	Δ THEORY PLAIN	R = Δ-CORR / Δ-PLAIN
5,000#	0.0020"	0.00077"	2.59
10,000#	0.0115"	0.00154"	7.46
15,000#	0.0140"	0.00231"	6.06
20,000#	0.0195"	0.00308"	6.33

FIG. 15 LOAD-DEFLECTION RELATIONS UNDER AXIAL LOADING OF 14-IN. PIPE

(Comparison of elongation of 14-in. smooth pipe tangent having the same major dimensions as a 14-in. corrugated tangent.)

If the pipe temperature (steam, liquid, or air temperature) were 500 deg. fahr., one may write the following equation between thermal elongation and compression due to axial loading:

$$19.47 \times \frac{3.58}{1200} = \frac{0.005}{9000}P$$

where P is the axial thrust in pounds necessary to hold the pipe in its initial position. Solving the foregoing equation:

$$P = 104,550 \text{ lb.}$$

Obviously such an axial thrust could not be tolerated. If, now, the steam temperature should be 1000 deg. fahr., the axial thrust would be much larger than that calculated. It is the practice of designers of steam piping [illegible]e tangents in bending rather than in compression. The corrugated tangent in bending is a highly flexible member which should find wide application in piping design.

By way of a summary, it may be remarked that a mathematical formula, either rational or empirical, applicable to the load-deflection relations for corrugated tangents (and bends also) would be of considerable value to the designer of power-plant steam piping. This is particularly true in stations in which higher steam temperatures are being contemplated. It must not be forgotten, however, that the form of corrugation obviously should be that which can be commercially produced at a price within the reach of the prospective user.

AUTHOR'S CLOSURE

It is not quite correct to call the formulas developed in the paper "empirical." The formulas for V-shaped and semicircular corrugations are admittedly approximate, but they are based entirely on theory and not on experiments. This has the important significance that, while they probably do not cover a certain field of application as accurately as would an empirical formula based on experiments in that field, they are presumably quite general in their application—covering all materials, sizes, and proportions, up to such very extreme proportions as would make the approximate assumptions on which the theory is based of major importance. They should therefore be valuable to designers in this new field of engineering, as indicating the general influence and importance of each of the various physical quantities involved, even if the final result is not very exact. And if experiments show serious discrepancies, then at least these formulas should be ideal bases for empirical formulas, using the same general form, but modifying the constants to conform to experiment.

FIG. 16 LOAD-DEFLECTION RELATIONS UNDER AXIAL LOADING OF 10-IN. PIPE

(Comparison of elongation of 10-in. smooth pipe tangent having the same major dimensions as a 10-in. corrugated tangent.)

As to the formulas given for parabolic and elliptical corrugations, their only justification lies in the fact that at the present state of the subject they are probably better than nothing. By giving formulas for these progressively different types of corrugations it was felt that a good basis was given for estimating other intermediate shapes of corrugations.

As to corrugations which are not symmetrical, there is no reason to suppose that a fair estimate cannot be obtained from the formulas by using average values of the dimensions, at least if the asymmetry is not extreme. Thus for the 10-in. and 14-in. corrugated pipes tested by Messrs. Cope and Wert, using one-half the total depth and width of the corrugations for h and b, formulas [1] and [4] for elliptical corrugations give values for E/E' of 8.04 and 7.13, respectively. The results from the experiments with axial loads, found from the slopes of the test curves given in the discussion, were about 8.7 and 6.6.

APM-54-8

Celluloid as a Medium for Photoelastic Investigation

By R. H. G. EDMONDS[1] and B. T. McMINN,[2] SEATTLE, WASH.

R. H. G. Edmonds

This paper deals with the physical properties of celluloid and their bearing on its use in the photoelastic method of stress determination. The authors present curves and test data on American-made celluloid, showing stress-strain and time-creep relations. Their results indicate that the physical constants for this material are not fixed, but have a consistent variation with speed of loading. Their work shows that celluloid is not perfectly elastic under any condition of loading. They point out some important peculiarities in the interrelation between photoelastic color and stress and strain.

B. T. McMinn

THE nitrocellulose compound called celluloid and sold under trade names such as pyralin, viscoloid, xylonite, etc., is one of the most common materials used by photoelastic investigators for the manufacture of models. This material is easily obtained in sheets of uniform thickness and quality and it has many characteristics that recommend it for photoelastic use. It is readily machined and worked into complicated shapes and models. It has a low modulus of elasticity, which permits large strains with moderate loading. Its flexibility and toughness add to the ease with which it can be handled. There are, however, certain peculiarities in the physical and optical properties of this material which, in the opinion of some scientists, render the photoelastic results obtained somewhat inaccurate.

Other investigators are quite firm in their belief that the use of celluloid in photoelastic work is quite satisfactory.

Because of this difference of opinion and because information on American-made celluloid is rather meager, it seemed highly desirable to run a rather extensive series of tests on the physical and photoelastic properties of this material.

This paper contains a brief review of papers already published on the subject, together with a report on tests run by the authors.

For details regarding the photoelastic method or for information regarding other materials that can be used, the reader is referred to the bibliography at the close of this paper.

Review of Previous Work

Very complete data on the physical and optical properties of this material have been published by Coker and Chakko (3).[3] Their tests were made on xylonite of British manufacture. The following information taken from their paper is of interest in connection with the present investigation. The elastic limits are not tabulated in the table of physical constants, but in the text it is found that the values range between 1600 and 2500 lb. per sq. in. The moduli of elasticity range from 250,000 to 350,000. Many data are given regarding the optical properties of this material. These authors state in their conclusions that: "The whole of the evidence appears to show that the transparent celluloid examined obeys a linear stress-optical law which holds up to approximately twice the range of the elastic limit of stress; and that within this range optical determinations of stress distribution may be relied upon."

Filon and Jessop (8) in their interesting paper on "Stress-Optical Effects in Transparent Solids Strained Beyond the Elastic Limit," describe some highly important results. The celluloid (British xylonite) which they examined showed definite optical and strain creep. In their summary of conclusions they say: ". . . Optical creep is comparatively large and may easily amount to 10 per cent of the initial value in a few minutes. . . . This has an important bearing on stress determinations from observations of artificial double refractions in celluloid. . . . The stretch of celluloid follows laws closely similar to those of the optical retardation." The title of their paper would indicate that the writers were dealing with effects beyond the elastic limit, but just what they consider the elastic limit is not made clear. Strain creep apparently begins at much lower stresses than optical creep. They show strain-creep and recovery curves for a specimen loaded to 60 kg. per sq. cm., which is equivalent to 853 lb. per sq. in.; also similar results for a stress of 86 kg. per sq. cm., or 1220 lb. per sq. in. Optical-creep observations were made on specimens at somewhat higher stresses. This indicates the importance of these observations, as it would seem almost impossible to keep stresses within such limits when making photoelastic tests.

[3] Numbers in parentheses refer to items in the appended bibliography.

extended experimental investigation, have severely criticized the use of celluloid models for exploring the stresses in engineering structures. Their work was carried out on German celluloid.

As has been already stated, published test data on the properties of American-made celluloid are very meager. In 1923 Heymans and Allis (4) made tests on two different kinds of celluloid. Camphor celluloid (made by du Pont) gave an elastic limit of 3900 lb. per sq. in. and a modulus of elasticity of 363,000. Naphtha celluloid (manufacturer not given) showed an elastic limit of 5400 lb. per sq. in. and a modulus of 365,000. The stress-strain curves were not shown.

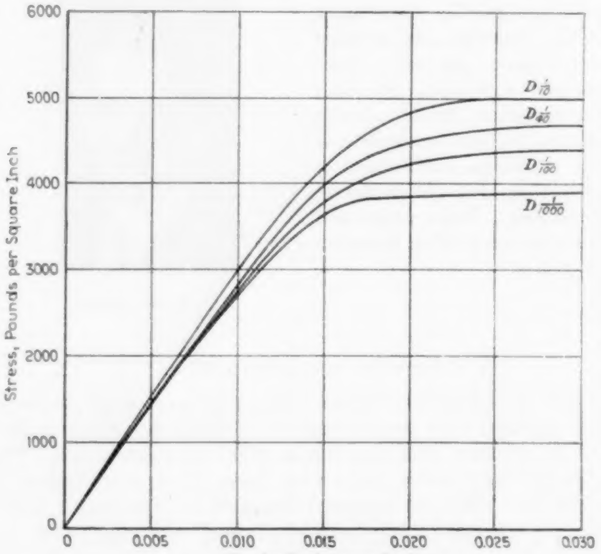

Fig. 1 Stress-Strain Curves—Material "D"
(Thickness of material, 0.250 in.; speeds, 0.001 in. to 0.1 in. per in. per min.)

Timoshenko and Dietz, in connection with their paper on "Stress Concentration Produced by Holes and Fillets" (5), ran some tests on du Pont celluloid and placed the elastic limit at 1700 lb. per sq. in. and Young's modulus at 302,000.

Very often the statement is made that so long as the stresses in the celluloid model are kept within the elastic limit, the results are satisfactory. There seems to be a difference of opinion as to the location of the elastic limit.

Tests on the Physical Properties

Material for these tests was obtained from the du Pont Viscoloid Co. and was of seven different thicknesses, as listed in Table 1. This material was of quite uniform thickness and quality. The purchases were made at five different times over a period of five years.

The test specimens were of a simple type for testing in tension. They were all made of approximately the same width of $^5/_8$ in., and of sufficient length to use a gage length of 10 in.

TABLE 1 PHYSICAL CONSTANTS OF THE MATERIAL TESTED

Material index	Thickness, inches	Speed, inches per inch	Modulus of elasticity	Elastic limit, lb. per sq. in.	Ultimate strength, lb. per sq. in.	Brinell hardness number
1	0.130	0.1	292,000	4200	5400	11.8
A	0.130	0.001	270,000	2900	4200	11.8
B	0.155	0.1	410,000	5800	7460	13.7
B	0.155	0.001	380,000	4600	5900	13.7
C	0.165	0.1	310,000	4000	5500	10.9
C	0.165	0.001	270,000	2900	4400	10.9

F	0.340	0.001	274,000	3060	3720	9.9
G	0.157	0.025	400,000	5500	7300	14.3
G	0.157	0.001	388,000	4300	6000	14.3

A series of tension tests were run, using a pendulum-type machine provided with an autographic arrangement. Early in this work it became apparent that the speed of loading should be taken into account. It was decided that four different speeds, based on the rates of elongation, should be used, namely, 0.100, 0.025, 0.010, and 0.001 in. per in. per min. Sufficient runs were made to get four curves for each thickness and type of celluloid available. Fig. 1 shows one set of these curves and is typical of the whole series. The complete stress-strain diagram is not shown. Each specimen was tested to the breaking point, however. The general tendency was for the stress, after passing the elastic limit, to drop off gradually till just before the point of rupture, when it rose slightly. The total elongation was somewhat less for high speeds than for low.

These stress-strain curves (Fig. 1 and the others taken) indicate definitely that the nominal elastic limit and the ultimate strength increases with an increase in the speed of loading. There also seems to be a change in the modulus of elasticity.

In order to investigate these matters more precisely a mirror extensometer was used, with which it was possible to secure reliable and consistent results, even at light loads. The data ob-

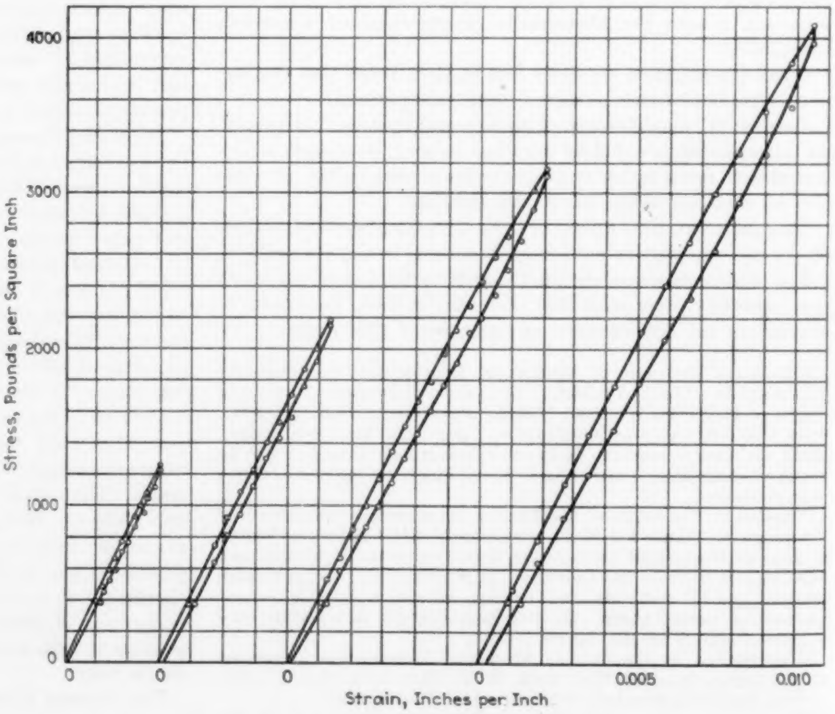

Fig. 2 Hysteresis Loops—Material "G"
(Thickness of material, 0.157 in. Loaded from 0 to maximum stresses of 1000 to 4000 lb. per sq. in. up and down at uniform rate of speed of 0.001 in. per in. per min.)

tained in this way were used to verify the correctness of slope and curvature of the stress-strain curves already obtained on the tension machine.

An additional series of tests were made to show more definitely the effect of time on strain readings. Runs were made at all stated speeds up to certain maximum stresses and back to zero at uniform rates of elongation and recovery. The plotted curves enclosed a definite hysteresis loop, even at low stresses and high speeds. Fig. 2 shows a typical set of these curves. Here again all different samples of the material were tested and showed the same general characteristics. The hysteresis loop, while differing in width, was always present.

The gradual increase in strain as a constant load is applied on a member may be termed "creep." This characteristic was very apparent in the celluloid examined. In order to find how creep varied with the amount of stress and time, readings were taken over a long period. Fig. 3 shows the results graphically for one specimen. It is interesting to note that even for the strongest material and the low stress of 1000 lb. per sq. in. there was a measurable creep in a relatively short period of time.

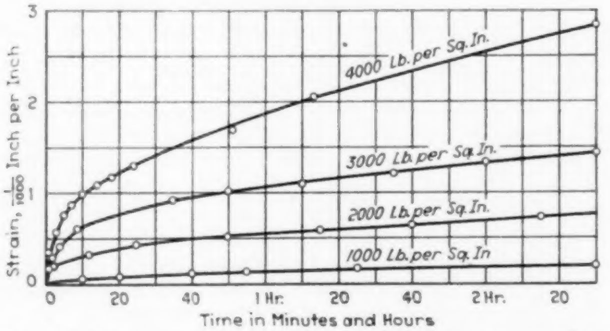

FIG. 3 TIME-CREEP CURVES SHOWING INCREASE OF STRAIN WITH TIME—MATERIAL "G"

(Stress kept constant at values given.)

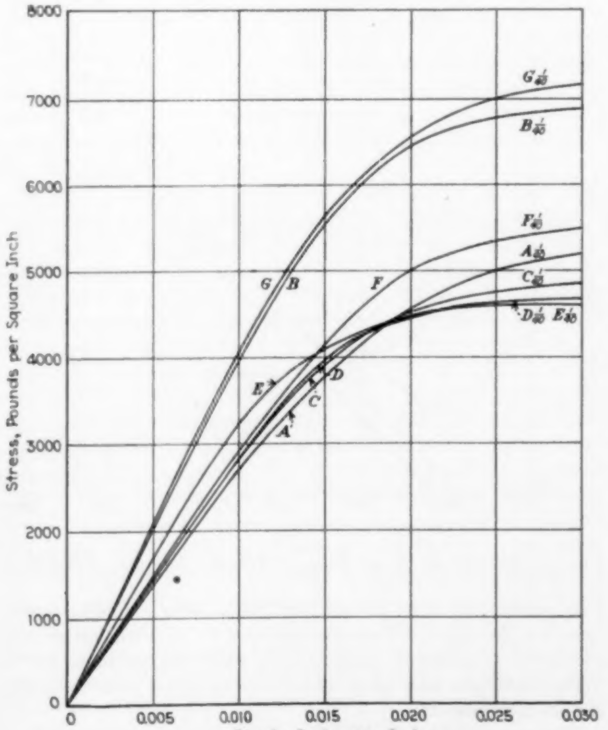

FIG. 4 STRESS-STRAIN CURVES FOR DIFFERENT MATERIALS AT THE SAME SPEED

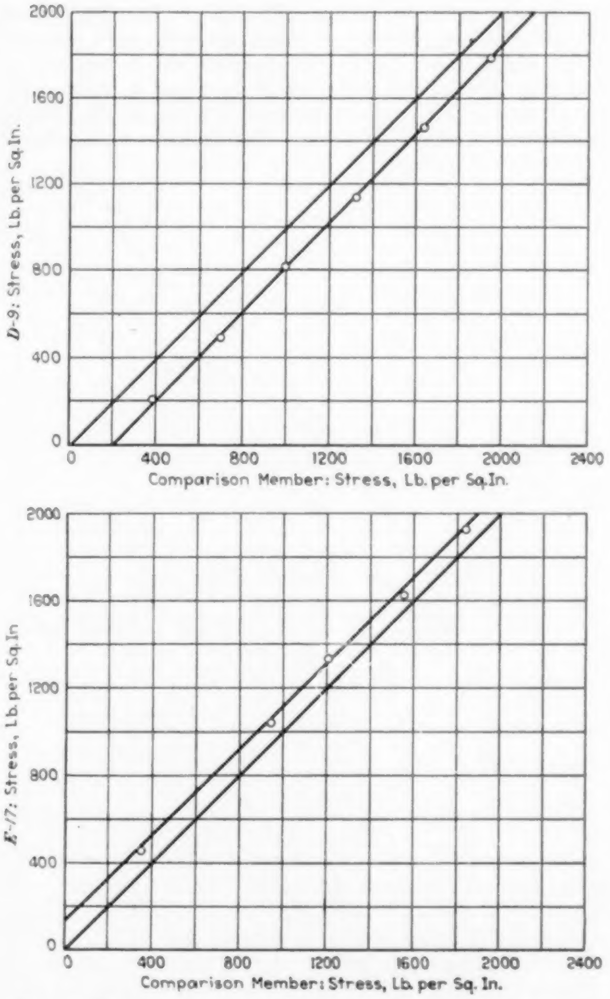

FIG. 5 EFFECT OF INITIAL STRESS DUE TO INITIAL COLOR

Observations on the rate of recovery after the load was removed were not plotted. It was noticed, however, that for low loads the recovery was quite rapid. For stresses approaching the nominal elastic limit, the time of recovery was a matter of days, but unless the stresses were very high the material would recover in time.

A critical examination of Figs. 1–3 indicates that a true proportionality between stress and strain does not exist under any condition of loading. The effect of creep and time of loading is very apparent. The modulus of elasticity, the nominal elastic limit, and the ultimate strength all increase with the speed of loading.

Physical constants for the different thicknesses of material at maximum and minimum speeds of loading are shown in Table 1. The modulus of elasticity was taken as the mean slope of the nominally straight portion of the stress-strain curve. The elastic limit was uncertain. For the purpose of measurement, it was taken as the unit stress at a point on the curve where the slope was two-thirds of that taken for the modulus of elasticity. The ultimate strength was taken from the original load-deformation curves.

Fig. 4 shows the stress-strain curves for all different materials at the same speed of loading. Material G has the greatest strength and the highest modulus of elasticity, with B a close second and E next. These three materials are in the order of their age, G being five years old, B four, and E three. The rest of the curves were well grouped, the age of the material ranging from 6 months to a year. This indicates an increase in strength with age. No other conclusions seem possible. There is no consistent variation with thickness. According to the statement of the manufacturer, no change was made in chemical composition or the method of manufacture.

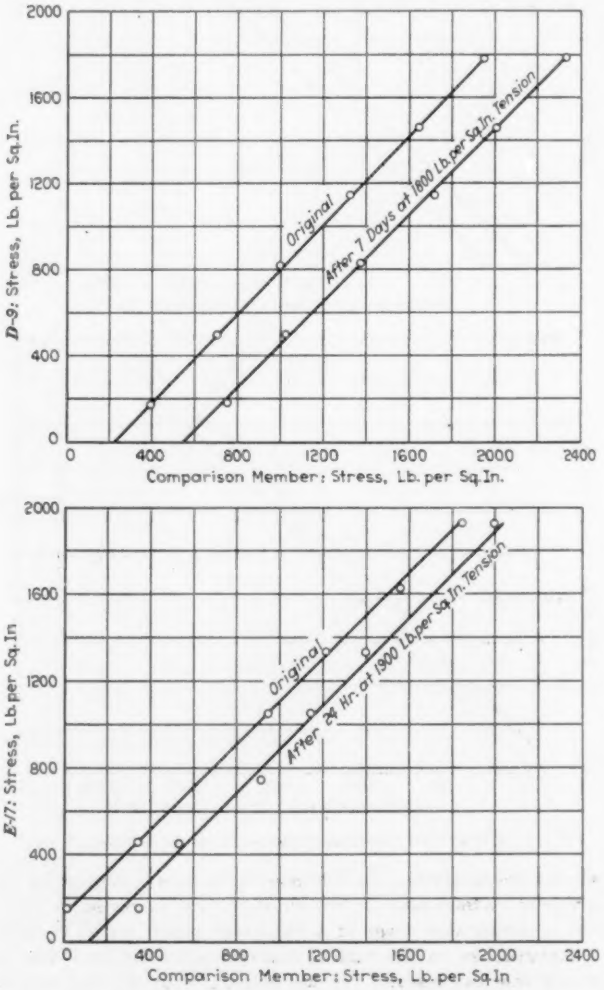

Fig. 6 Effect of Continuous Load on Stress Due to Residual Color

Photoelastic Tests

The materials whose physical properties were investigated in the earlier part of this work were further investigated to ascertain their photoelastic characteristics. The test specimens, with two exceptions, had a nominal width of $^{5}/_{8}$ in., and a 10-in. gage length available for strain measurements. The comparison members, and in two cases the test specimens, had a nominal width of $^{1}/_{4}$ in. and a uniform section for 5 in. of length. The specimens were made with great care and finished by hand, to eliminate as far as possible the strains due to shaping.

The curves of Fig. 5 were obtained by reading the respective dynamometers for crossed tension members with the common image extinguished for loads as shown. For both curves the comparison members were carefully selected so as to be free from initial color. The main member for the upper curve was selected because it had an initial color effect indicative of a simple tensile stress, while the one for the lower curve was selected because it had initial color indicating a simple compressive stress. The lines of 45 deg. slope through the origin were drawn to facilitate comparison of slope and "set-over."

The tests yielding the curves of Fig. 6 were obtained by making observations of dynamometer readings for extinction of the common image of crossed members, for increasing loads to the maximum value shown, then maintaining the load on the specimen by deadweights for the times shown—the comparison member being unloaded during that period—and then making a run of dynamometer readings for extinction up to the previous maximum. The comparison members for both curves were carefully selected so as to be free from initial color. The test specimen for the upper curve was selected to have an initial color indicative of a simple tensile stress, while the specimen for the lower curve was selected so as to have an initial color indicating simple compression.

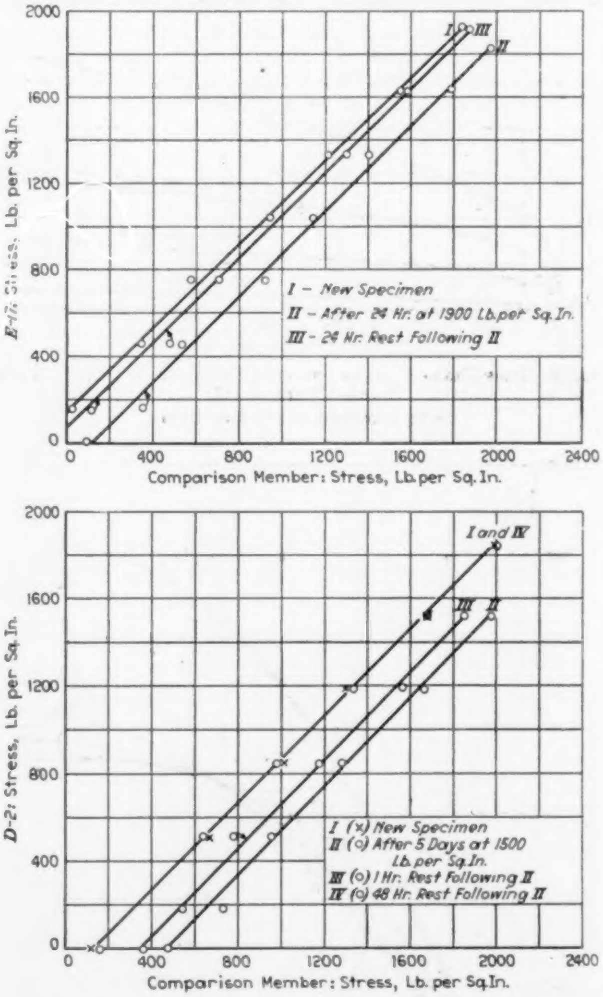

Fig. 7 Effect of Rest Period After Continuous Loading

The tests plotted in Fig. 7 were similar to those of Fig. 6, except that after a period of rest following a continuous load another set of readings of comparison-member stress versus test-specimen stress for extinction was obtained and plotted to the same coordinates. In the lower curve, runs at two intervals of rest are plotted.

Fig. 8 is the result of a test in which simultaneous readings of stress and strain in the test specimen and stress in the comparison member to produce extinction of the common image were measured. The stresses in the comparison member necessary to produce extinction were plotted as ordinates, with abscissa values in one case the measured stress in the test specimen, and in the other, the measured strain in the test specimen.

In all the above-mentioned curves the data were selected from not less than several runs in each case; the values and consistency shown are typical of all the runs made, and it was deemed that the inclusion of more curves of the same types of tests would be but duplication.

It is obvious that if two tension members selected for freedom from initial color be "crossed" and loaded to produce extinction of the common image in suitable polarized light, the plot of the dynamometer readings to coordinates, as in Fig. 5, would be a straight line of 45 deg. slope through the origin. The curves of Fig. 5 deviate from such a curve by constant values of stress, the apparent significance being that the test specimen of the upper curve has an initial tensile stress of 210 lb. per sq. in., and the one of the lower curve an initial compressive stress of 140 lb. per sq. in., to which is algebraically added the applied load at any time to produce the total. This apparent significance requires interpretation. The apparent initial stress is due to the initial color, and it is obvious from considerations of equilibrium that the initial stress cannot be a simple uniform tension or compression. But it is reasonable to assume that the initial color, read by means of a comparison member and expressed in terms of a simple tensile or compressive stress, could represent a complex condition in which different layers of the material are stressed to different degrees, and possibly in different directions. Such a complex condition of initial stress, and corresponding initial strain, is easy to conceive of, in view of the nature of the process used in the production of this material. For convenience of reference hereafter, the photoelastic stress equivalent (stress read from the comparison member when the common image is extinguished) of the initial color will hereafter be called the "apparent initial stress."

While it cannot be true that the apparent initial stress indicated in Fig. 5 is the actual stress, the effect of initial color on later loading and photoelastic observation is obviously the equivalent of the apparent initial stress being algebraically additive to the applied load, as typified by the curves of Fig. 5.

The first part of this work showed that celluloid exhibits a residual strain after a continuous load. The curves of Fig. 6 show a similar phenomenon in terms of residual color, which is read photoelastically in terms of residual stress. In the upper curve of Fig. 6 the test material at the start had an apparent initial tension of 230 lb. per sq. in. After seven days of continued loading at 1800 lb. per sq. in. it showed an apparent initial tension of 550 lb. per sq. in., together with residual strain. In the lower curve of the same figure, the original specimen had an apparent initial compressive stress of 130 lb. per sq. in., while after 24 hours at 1900 lb. per sq. in. tension it had an apparent residual tension of 120 lb. per sq. in. Study of the curves shows that the effect of the apparent residual stress on stress determined photoelastically (by comparison member with extinction of the common image) thereafter, is identical with that of the apparent initial stress; i.e., it is algebraically additive to the applied stress to produce the photoelastically determined stress.

The augmented initial color remaining in a specimen after a cycle of loading, producing the apparent residual stress just discussed, if produced by moderate maximum values of load, disappears gradually, as does the residual strain accompanying it, if the specimen is left unloaded. In the upper curves of Fig. 7, photoelastic tests of the original material produced curve I, showing an apparent initial compression of 150 lb. per sq. in. After a continuous load of 1900 lb. per sq. in. for 24 hours, the curve obtained was II, indicating an apparent residual tensile stress of 120 lb. per sq. in. The specimen was allowed to rest unloaded for 24 hours, and then yielded values given in curve III, showing an almost complete loss of the residual color introduced by the continued load, and an almost complete reassumption of the original condition of initial compression.

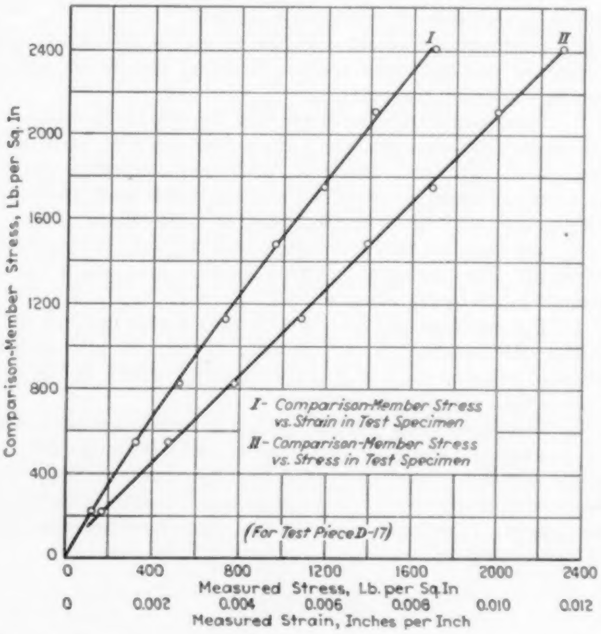

Fig. 8 Comparison-Member Stress Vs. Strain and Stress in Test Specimen

In the lower figure of Fig. 7, similar relative changes are exhibited, except that the specimen started with an apparent initial tensile stress of 110 lb. per sq. in., and readings were made after periods of rest of one hour and 48 hours. Curve IV shows complete recovery from the effects of the continued load.

The logical inference from a study of these curves is that for tests immediately following the acquisition of apparent *residual* color and stress, they may be considered as affecting the results as do apparent *initial* stress and color, but that *residual* stress and color from a cycle of loading are temporary in nature and disappear as a function of time, while the *initial* color and apparent stress are of a more permanent and stable nature.

The series of tests from which the data for Fig. 8 were selected were run to demonstrate that, for the maximum loads chosen, the creep characteristic of celluloid, developed in the first part of this work, does not vitiate the proportionality between stress and photoelastic color. In Fig. 8 the stress equivalents of photoelastic color, as obtained by use of a comparison member, are plotted as ordinate values, while measured stresses and strains in the test specimen are plotted as abscissa values. Curve I is similar to the stress-strain curves of the first part of this work, showing a slight curvature and indicating the same lack of perfect proportionality between photoelastically measured stress and strain as was previously shown for measured stress versus strain.

Curve II of Fig. 8 is of the same nature as those shown in the several previous figures and is of 45 deg. slope, exclusive of a slight observational error, and has a slight "set-over" due to initial color.

CONCLUSIONS

On the basis of these tests the following conclusions can be drawn in regard to the celluloid examined:

1 The physical constants for celluloid are not fixed but have a consistent variation with speed of loading, the higher speeds having the higher constants.

2 There seems to be evidence that for celluloid a true proportionality between stress and strain does not exist under any condition of loading. Therefore, while one may call a certain point on the strain-strain curve a nominal elastic limit, there is a very grave doubt as to the existence of a true elastic limit.

3 Age seems to have a bearing on the physical properties of celluloid. The undesirable characteristics were much more marked in the newly made material.

4 The results of the photoelastic tests herein reported lead to the conclusion that, within the range of the tests, photoelastic color in celluloid models is proportional to stress, but is not strictly proportional to strain.

5 The photoelastic method applied to celluloid models may be expected to yield satisfactory results where proportionality of stress and strain have no critical bearing on the problem, but where such proportionality is an important factor the results will be in error. This error is due to the complicated interrelation of stress, creep, and time, and may reach a high value.

Discussion

Max M. Frocht.[4] This paper deals with the mechanical properties of American-made celluloid and aims at a reexamination of the fundamental stress-optic law of a material which made photoelastic investigations practicable.

The present tendency is away from celluloid and toward more sensitive materials such as bakelite. It would thus be of basic importance to conduct such investigations as reported in this paper also for bakelite. Should such an investigation be undertaken, it is suggested that more sensitive methods be used to determine the stress-optic law. Instead of the tension compensator, a Babinet compensator might be used, and the phase difference directly determined against the known loads. It would also be of interest to examine somewhat more complicated stress systems than those in pure tension, such as a disk under diametral compression. The photoelastic results could then be compared with the values of the available theoretical solutions. The writer has worked with both celluloid and bakelite, and in his opinion the readings from the tension compensator with celluloid may vary 5 per cent or more. Fig. 9 shows the relative optical sensitivities of celluloid and bakelite. The models were of the same dimensions and under identical loading. (See Fig. 10.) It will be observed that for the one fringe in the celluloid beam there are five in the one of bakelite, which means an advantage of 5 to 1 in favor of bakelite.

Kinematography in Photoelasticity

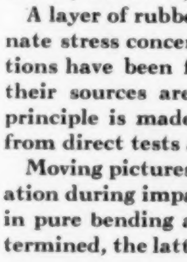
By MAX M. FROCHT,[1] PITTSBURGH, PA.

Photoelasticity is one of several methods for stress analysis. Kinematography in photoelasticity was made practicable by the introduction of the monochromatic method and should be found useful in the study of gear action, tool cutting, impact stresses, and in the phenomenon of failure.

Moving pictures of 15 models in 29 set-ups are presented which show a variety of stress-distribution patterns and their formations. Stress concentration can spring from various sources such as holes, grooves, notches, sharp curves, scratches, and the edges of flat steel dies.

A layer of rubber, lead, or wood has been found to eliminate stress concentration due to a die. Stress concentrations have been found to be mutually destructive when their sources are many and close. Application of this principle is made to the design of a thread and results from direct tests are shown which substantiate it.

Moving pictures are presented showing the stress fluctuation during impact, and from these the increase of stress in pure bending and the time of stress oscillation are determined, the latter being in good agreement with theory.



THERE are several ways in which to study stress distribution. There is the purely mathematical method, which starts with the laws of equilibrium and the assumption of continuity and derives by logical processes conditions for stress functions. There is also the purely experimental method, which aims to measure local stresses directly by means of refined and sensitive strain gages. In the field of two-dimensional stress systems there is a third method, namely, the optical or photoelastic method, whose singular merit consists of giving a definite visual stress pattern to each stress system, from which the shear stresses can always be read directly. The photoelastic method has until recently been based upon the color effect which a stressed element of a corresponding celluloid or Bakelite model produces. These color effects are obtained when white light is taken as a source. In recent years, however, it has been found desirable to substitute monochromatic light. This change has numerous merits, one of which is that, when combined with a sensitive material such as Bakelite or phenolite, it makes kinematography of stress formation practicable.

Moving pictures of stress formation were made by Dr. Ziro Tuzi, of the Physical Chemical Institute, Tokyo, Japan, and were shown by him at the International Congresses of Applied Mechanics and Metallic Structures held last year at Stockholm and Liége, respectively.

The application of kinematography to photoelasticity carries interesting possibilities. It provides an excellent means of recording the history of stress formation and of bringing these results to the classroom or lecture hall, thus being of educational value. Kinematography should also prove useful in the study of gear action, and will probably add to our understanding of tool cutting. The pictures of group 5 (Figs. 43–45) show that kinematography has potential possibilities in the study of impact stresses and the phenomenon of failure.

It is the object of this paper to present moving and static pictures of stress-distribution patterns and their formations in a variety of models and under diverse loading which will bring home to the reader a concentrated demonstration of the things one sees in the polariscope, and to interpret these pictures non-mathematically from the point of view of stress concentration. It also deals with fluctuations of stresses during impact, and shows that there are possibilities in that direction.[2]

THE APPARATUS USED

It is assumed that the reader is familiar with the essentials of photoelasticity.[3] The apparatus used and its optical arrangement are shown in Figs. 1 and 2. The polariscope is one made by the Winkel-Zeiss firm, of Göttingen, Germany, and uses Ahrens instead of Nicol prisms. The loading, except in impact, was continuous and uniformly increasing, and was obtained by connecting a rubber hose to a nearby faucet and allowing a steady stream of water to fall into a large bucket suspended from the lever of the straining frame. Loading by means of flowing water has decided merits over deadweights. One can sit at the screen and leisurely watch the fringe formation as the load increases. This can be repeated as many times as necessary in order to determine the fringe order for any particular model. All pictures except some in impact were taken at the rate of 16 per second, this being the fixed speed of the DeVry camera which was used throughout the work. The models were all of Bakelite and were annealed by the author's method, which is discussed in another paper.[3] The monochromatic light was obtained from a mercury-vapor lamp and the use of a No. 77 Wratten filter.

MOVING PICTURES

Moving pictures were taken of 15 models in 29 different setups. For convenience these were divided into five groups, as follows:

1 Central compression
2 Bending
3 Die on a large plate
4 Angles, disks, and square plates
5 Experimental impact pictures.

In interpreting these pictures it is well to bear in mind three points: first, that a fringe is a locus of points of equal maximum shear; second, that the crowding of fringes accompanied by

[1] Associate Professor of Mechanics, Carnegie Institute of Technology. Dr. Frocht received the degree of B.S. in Mechanical Engineering from the University of Michigan in 1922, M.S. in Physics from the University of Pittsburgh in 1925, and Ph.D. in Engineering Mechanics in June, 1931, from the University of Michigan. From 1912 to 1920 he was associated with various automobile concerns, including the General Motor Research Laboratories at Dayton, Ohio. He has been a member of the faculty of the Carnegie Institute of Technology since 1922. During a leave of absence in 1930 he made a study of the functional and structural organization of the Ford Motor Company for the Autostroy, a U.S.S.R. corporation.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] The work described in the paper was carried out in the Photoelastic Laboratory of the Mechanics Department in the University of Michigan, Ann Arbor, Mich.

[3] For a brief statement of these essentials, see author's paper on "Recent Advances in Photoelasticity," Trans. A.S.M.E., 1931.

sharp curvatures is evidence of stress concentration; and third, that the points where fringes start such as the four dots in Fig. 39 are points where yielding begins, and this may be of significance in ductile materials since these are points of maximum shear. With this in mind we are able to make certain general and at times useful observations from the mere inspection of the photographs.

We see that a single concentrated load, even if it is small, produces large local stresses in the immediate vicinity of the load (Fig. 3). We also see that in a long prismatic bar compressed by two concentrated forces (Fig. 4) the ends are under high and variable stresses, even though the middle portion be under uniform and moderate stress. The center of the bar in Fig. 5 is of a uniform degree of darkness or brightness, showing a uniform distribution of stresses, whereas the ends show evidence of stress concentration.

Figs. 6, 7, 8, and 9 show rather complicated fringe patterns which are evidence of a variable stress distribution across a horizontal section of symmetry. Fig. 10, however, shows a remarkable exception to this group. It will be observed that the central portion across nearly the whole length is uniformly dark, and is thus under a uniform distribution of stress except in the immediate proximity of the notches. Thus stress concentrations at close intervals are mutually destructive, and the effect of many is much smaller than the effect of one. We shall return to this point in group 2. Referring now to group 2 (Figs. 12–18) we first of all observe the beam in pure bending, Fig. 12. Here the fringes are straight, parallel, and equidistant, from which it is comparatively easy to deduce the well-known linear law of stress distribution. This is true everywhere except in the neighborhood of the points of application of the loads and reactions. In the small intervals between the loads there is no neutral axis as is assumed in the elementary engineering theory.

Fig. 14 shows graphically why Bakelite and not celluloid was chosen as the material for models. It will be seen that there are about five times as many fringes in the Bakelite beam (upper halves of pictures) as there are in the corresponding celluloid beams. It must be remembered that the two beams are of the same dimensions and under identical loads. This has been accomplished by using the set-up shown in Fig. 11.

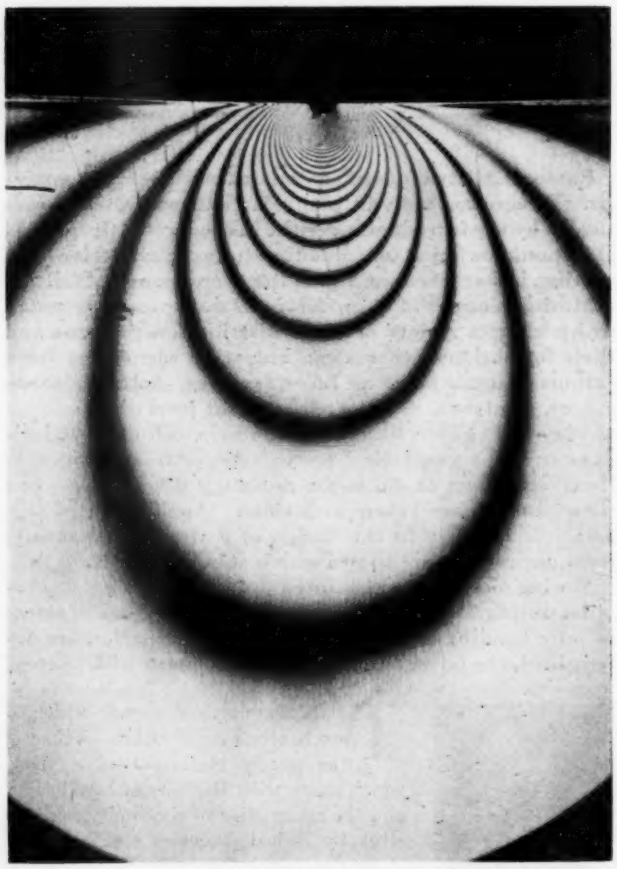

FIG. 3 EFFECT OF CONCENTRATED LOAD

Fig. 13 shows the stress concentrations due to large semicircular grooves. It will be observed that the disturbances due to such grooves are felt throughout the length and depth of the whole beam, and that in such a case the assumption of linear distribution is undoubtedly at variance with actual conditions.

Attention is next called to Fig. 23, which vividly shows the effect of the size of the fillet upon stress concentration. This should impress the designer with the need for avoidance and elimination of sharp corners wherever possible.

FIG. 4

Figs. 20, 21, and 22 are particularly interesting. Here, as in group 1, it is seen that stress concentrations emanating from points close together mutually destroy each other, or that one notch has a greater weakening effect than many. This is of importance in the design of screws. In this connection the author wishes to quote from a report by Prof. S. Timoshenko and W. P. Irwin to the Westinghouse Electric and Manufacturing Company, who, in making an investigation on the relative strengths of two systems of threads, came to the conclusion that "if instead of a single groove a thread such as that shown in Fig. 19 be taken, the weakening effect will be much less than for the case of a single groove." To reduce stress concentrations at the extremities of the thread, fairly large fillets were employed as shown. Their conclusions were arrived at on the basis of a series of fatigue tests using a cantilever fatigue-testing machine. Some fatigue tests for establishing the weakening effect of V-grooves were also made by the Aeronautical Research Committee, England,[4] which established the following formula for

calculating the weakening effect of a single groove:

$$k = 1 + 0.45\sqrt{\frac{d}{r}}$$

in which d is the depth of the groove, r the radius at the bottom of the groove, and k the factor of stress concentration. This formula gives results in good agreement with those of the above-quoted report. A point of considerable interest here is that the photoelastic conclusions drawn from a two-dimensional system are also true in the corresponding three-dimensional case. There are other cases in which this is true, so that the usefulness of photoelasticity extends beyond the boundaries of the two-dimensional system.

As a corollary to the principle of mutual destruction of stress concentrations we conclude that a scratch on a polished surface is of greater potential danger than one on a rough surface, and that a deep scratch on a polished surface may be more detrimental than an entirely rough surface.

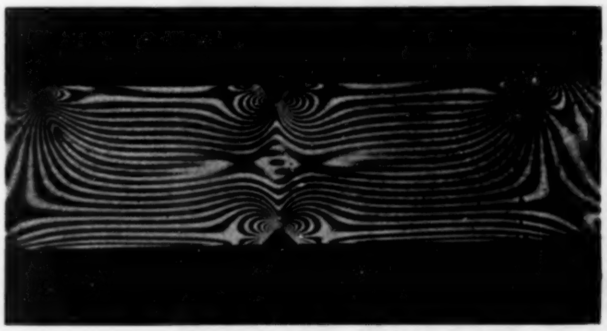

FIG. 20 BEAM WITH ONE NOTCH. PURE BENDING

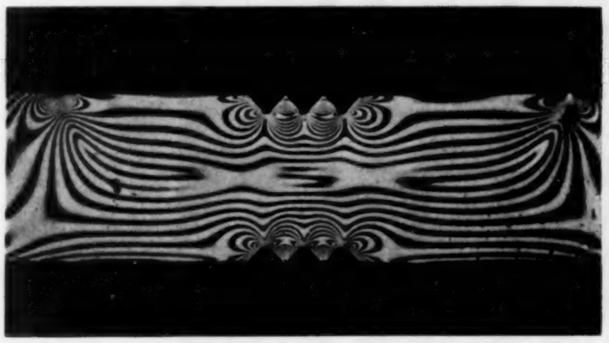

FIG. 21 BEAM WITH THREE NOTCHES. PURE BENDING

Turning to group 3 (Figs. 24–28), which deals with stress concentrations caused by dies,[5] let us first examine Fig. 29. It is seen that the pressure under the die is not uniform and that there are pronounced stress concentrations at the edges.[6] Fig. 30 shows the effect of a layer of rubber placed between the die and the plate. Two things stand out: first, the total vanishing of the stress concentrations and a nearly uniform pressure distribution; and second, a shifting of the maximum shear zones from points A and B to region C.

Similar results can be obtained with lead and wood, as is shown in Figs. 26 and 28. These photographs furnish practical suggestions to engineers. To the civil engineer they suggest the danger of placing a flat-end steel column on a concrete floor. To the mechanical engineer and shop men it suggests that the same danger exists in the mounting of machinery on foundations. In all these cases local stresses can be eliminated and the life and safety of the foundation increased by placing blocks of wood or lead between the steel and the concrete.

At the suggestion of Professor Timoshenko the steel die was coated with a layer of paraffin, thereby reducing the friction forces between the die and the plate. It was found that under small loads the action of the paraffin is the same as that of rubber, lead, or wood, but that under larger loads its action is negligible. Rounding or chamfering the corners of the die proved of no help in eliminating stress concentration.

Fig. 27 shows the action of a Bakelite die on a Bakelite plate. It suggests the possibility of investigating photoelastically the stress phenomenon in the die as well as in the plate.

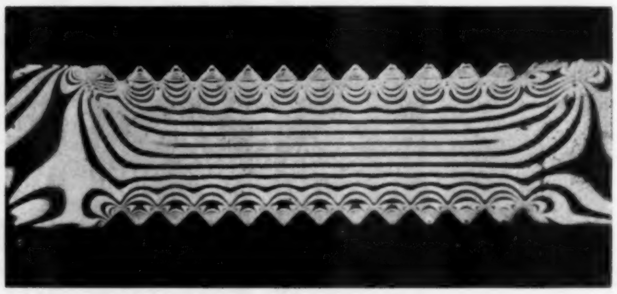

FIG. 22 BEAM WITH MANY NOTCHES. PURE BENDING

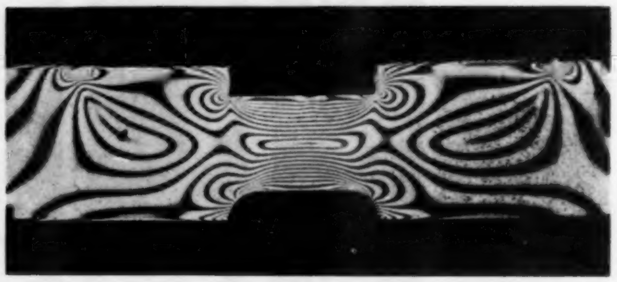

FIG. 23 COMPARISON OF STRESS CONCENTRATIONS DUE TO SHARP CORNERS AND ROUNDED FILLETS. PURE BENDING

Fig. 31 shows the action of a steel die with a single V-notch in the center. It is seen that the notch becomes an additional source of stress concentration although of smaller magnitude than the edges. However, when the number of notches is increased to cover the whole die, the principle of mutual destruction again operates and no additional stress concentrations are set up. On the contrary, it seems that they may even tend to counteract the bad effects at the edges. (See Fig. 32.)

In group 4, miscellaneous set-ups are shown. The two angles of Fig. 36 are of the same size and under identical loads, and again demonstrate the influence of the size of the fillet upon stress concentration. It will be seen that the angle with the sharp corners has more fringes than the corresponding angle with the large fillet, and that they are of greater curvature.

In the solid disk shown in Fig. 38 the stress-distribution pattern is fairly simple, and the first fringe seems to be approaching the boundary without ever reaching it, the boundary acting as a neutral curve of zero stress except in the vicinity of the concentrated loads.

---

[5] The theoretical aspects of this problem have been gone into by several investigators: namely, J. H. Mitchell (London Math. Soc., Proc., vol. 32, 1900, p. 35), M. Sadowski (*Zeit. f. angew. Math. u. Mech.*, vol. 5, no. 8, 1928, p. 107), and Gustav Mesmer (Doctor's Dissertation, Georg-August-Universität, Göttingen, 1929).

[6] For a good celluloid photograph substantiating these results see Gustav Mesmer's Dissertation mentioned in the preceding footnote.

Group 3—Die on a Large Plate

Fig. 39 shows the pronounced disturbances produced by drilling a hole in the center of the disk.[7]

Group 5 (Figs. 43–45) deals with stress fluctuations during impact. Here the kinematographic method is of primary importance as static pictures of stress fluctuations are evidently impossible. This is a pioneer field in which the equipment and technique are still to be developed. To the best of the author's knowledge the pictures shown in this group are the first of their kind. Three models were photographed: a large plate under a concentrated load, a beam in pure bending, and a disk under vertical loads. Due to the limitations of the camera it was decided to start the work with slow impact, and this was accomplished by inserting a spring in the loading arrangement (see Fig.

---

[7] This problem has recently been investigated by Dr. Billewicz. See his dissertation for the Doctor's Degree at the University of Michigan, 1931.

40). Most of the energy of impact was thus diverted to the elastic system of the apparatus and only a small part of the energy went toward increasing the stresses in the models. Photographs were taken at the rate of 16, 32, and 64 exposures per second, the latter being the limiting speed of the camera available.[8] Many of the photographs show the fringes due to impact quite clearly. Fig. 41 shows the stress fluctuations in pure bending due to the drop of a 5-lb. weight about 2 in. The data for this curve were taken from a strip of film which was projected upon the screen and the fringes counted.

The curve shows that the maximum stress due to impact of the falling weight is at least $6^1/_2$ times larger than the static stress caused by the same weight.[9] From the photographs it was found that the disturbances due to the shock were felt for a little over one second with the spring, and about half that time without the spring. To check the reliability of the photoelastic results, the time of one stress oscillation was computed from the known value of the spring constant and compared with that furnished by Fig. 41.[10]

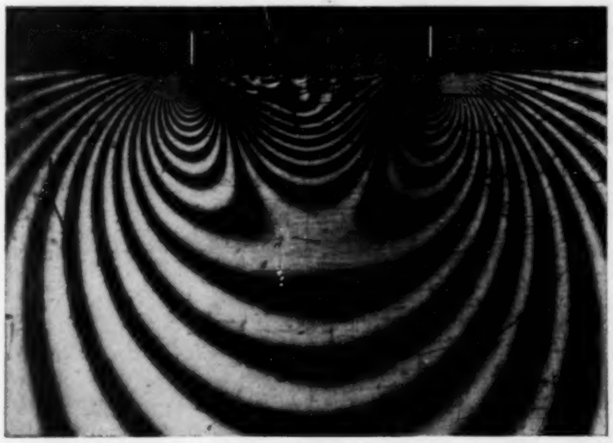

Fig. 29 Steel Die

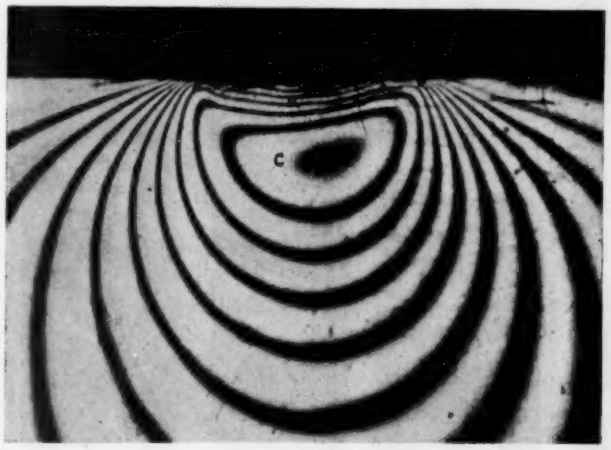

Fig. 30 Steel Die Acting Through Layer of Rubber

By direct experiment the spring constant was found to be 90 lb. The rod and platform were found to weigh 5 lb., so that when the impact weight of 5 lb. was dropped the spring was oscillating under a 10-lb. load.

Let τ be the period of oscillation of the spring and δ_{st} the statical deflection caused by the oscillating weight, then[11]

$$\tau = 2\pi\sqrt{\frac{\delta_{st}}{g}}$$

This gives

$$\tau = 2\pi\sqrt{\frac{10 \times 1}{90 \times 12} \times \frac{1}{32}} = 0.106 \text{ sec.}$$

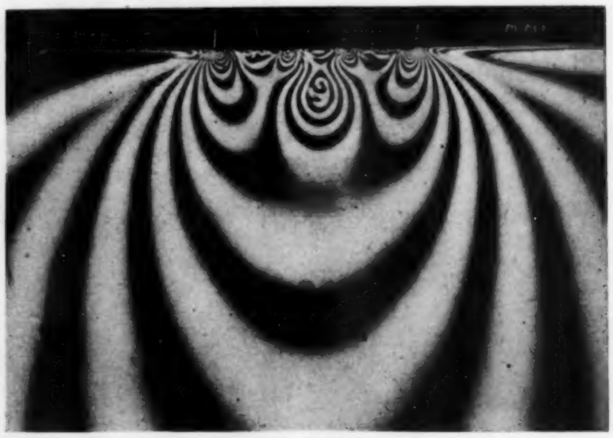

Fig. 31 Steel Die With V-Notch in Center

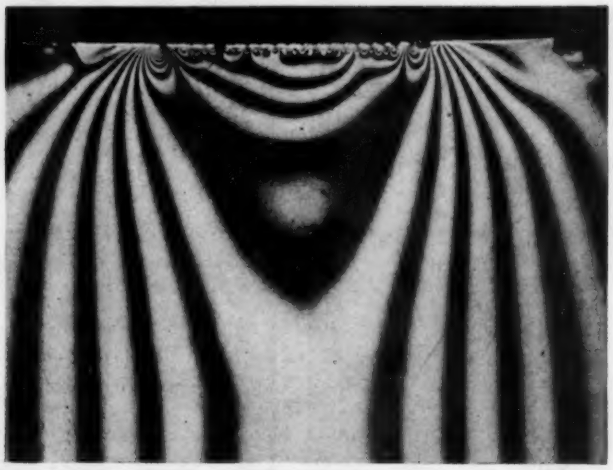

Fig. 32 Steel Die With Many Notches

Fig. 41, which is based on a film taken at the rate of 64 pictures per second, shows an average of 7 pictures per stress oscillation. This gives for the period of oscillation

$$\tau = 7 \times \frac{1}{64} = 0.119 \text{ approx.}$$

which is in good agreement with the theoretical value—especially so since the deflection of the lever has been neglected in the former computation.

To utilize Bakelite to limits beyond its maximum strength, it is suggested that the model be subjected to a negative initial

---

[8] A Victor camera was used for pictures taken at 32 and 64 exposures per second.

[9] From the curve it is seen that the initial stress was 4 fringes, the maximum stress $10^1/_2$ fringes, and the final stress 5 fringes. The falling weight therefore caused a static stress of $5 - 4 = 1$ fringe, and an impact stress of $10^1/_2 - 4 = 6^1/_2$ fringes.

[10] This was suggested by Professor Timoshenko.

[11] See "Vibration Problems in Engineering," by Timoshenko, p. 2.

bending moment, thereby doubling the range of the possible stress due to impact.

The time of direct impact has been measured at various times and found to be of the order of 0.001 sec. This suggests the need of a high-speed camera capable of taking several thousand pictures per second. When such high-speed equipment becomes available the problem of stress fluctuation during impact, as well as the phenomenon of failure, will lend itself to photoelastic investigation.

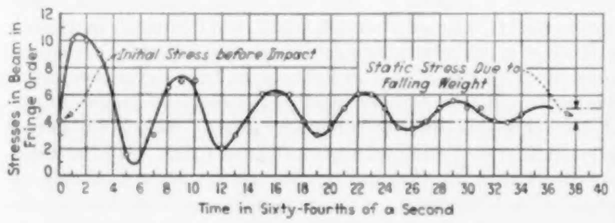

FIG. 41 FLUCTUATION OF STRESS IN PURE BENDING UNDER IMPACT (64 exposures per second.)

ACKNOWLEDGMENT

The author wishes to express his indebtedness to Prof. S. Timoshenko for the interest shown in this work and for valuable advice. It was he who suggested the study of impact stresses. The author is especially grateful for permission to quote from his unpublished report. The author also wishes to thank Prof. E. L. Ericksen, Head of the Department of Mechanics at the University of Michigan, for cooperating in the work by providing funds for supplies and materials; Prof. O. W. Boston, Director of Engineering Shops of the University of Michigan, for allowing him the use of the DeVry camera; and Dora Lipkin-Frocht for valuable laboratory assistance during the filming of the pictures.

Discussion

RAYMOND J. ROARK.[12] The writer, after reading papers on photoelasticity and the application of the mathematical theory of elasticity, regrets that the results secured are not more definitely correlated with the results of tests to destruction on the actual materials of construction. Both the general theory of elasticity and an experimental procedure such as is employed in photoelasticity are essentially techniques; both have been carried to a high state of development by their exponents, and both are powerful and useful tools. But they are alike in being strictly limited by the assumptions upon which they are based, and the results which they yield are for that reason not infrequently of less significance than might be supposed. The elastician and the experimenter are of course quite aware of these limitations, but the average engineer may not be; and impressed by mathematical wizardry or experimental ingenuity, he is likely to accept too literally the apparent implications of such investigations.

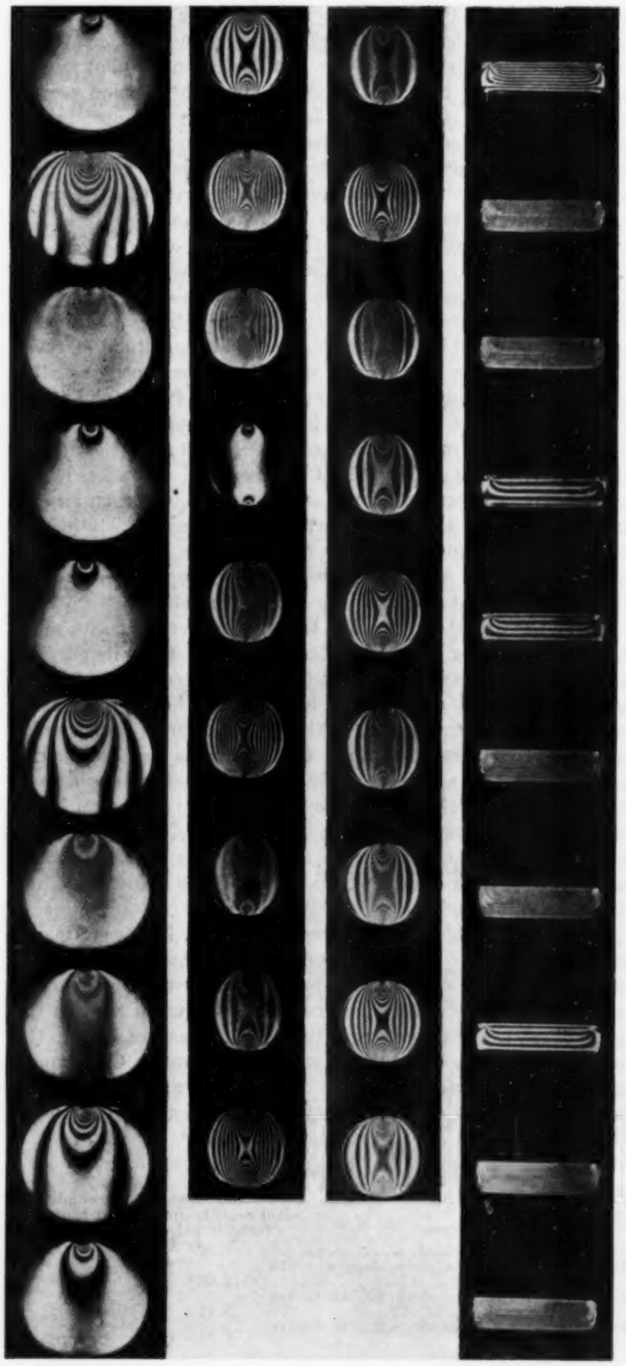

Fig. 43 (a) Fig. 44 (b) Fig. 45

[(b) is a continuation of (a).]

GROUP 5—FLUCTUATION OF STRESS DURING SLOW IMPACT

For example, as Mr. Frocht and others have shown, the presence and intensity of stress concentrations due to peculiarities of form are beautifully demonstrated by photoelasticity. For many cases the theory of elasticity can also be effectively applied. Now the conditions indicated by either technique are such as to lead the inexpert to an exaggerated opinion of the seriousness of such stress concentrations. Even for cases involving fatigue of ferrous metals, where little if any plastic action can be counted on, it is well known that the weakening effect of holes, notches, scratches, etc., is much less than might be surmised from the photoelastic indications. For cases of static loading, where some plastic action inevitably occurs before failure in even the most brittle materials, the effect of such stress raisers may reasonably be expected to be even less. Indeed, it appears to be an open question as to whether the relative ultimate strength of elements of various forms can be reliably predicted from a study of the intensity and distribution of elastic stresses alone.

---

[12] Professor, University of Wisconsin, Madison, Wis.

There are many structural elements, especially castings, the form of which is necessarily such as to lead to stress concentrations of greater or less severity. Photoelasticity provides a means of ascertaining the distribution and magnitude of these stresses within the elastic limit; but does it necessarily afford a criterion for judging as to the actual margin of security against failure, and does it conclusively indicate the most advantageous among a number of available designs? Is it, to put the matter differently, safe to assume that if an element *A* shows less intensity of stress concentration within the elastic limit than an element *B* of different form, *A* is better fitted to resist a static load or has a greater factor of safety? The writer is inclined to be skeptical of this. Perhaps a few definite examples will serve to illustrate the point and be of interest in themselves.

The writer, together with Mr. R. S. Hartenberg,[13] has for some time been carrying on an investigation which has for its purpose the study of stress concentration (especially as concerns effect on ultimate strength under static loading) by the use of plaster models and the correlation of the results secured with results obtained when cast iron and other materials are used. The plaster used gives an almost straight-line stress-strain curve up to the ultimate, and might therefore be expected to be as sensitive to the effects of stress raisers, or to be as "tender," as any material of construction. Of the many different tests that have been made and that are contemplated, a few will be selected to illustrate the point made.

Beams 1 in. wide, $1^1/_2$ in. deep, and 14 in. long were made; some of these were left as molded, some were notched and some were drilled. All were tested to failure, and the nominal modulus of rupture of each form was calculated in the usual way, on the basis of the net cross-section at the point of fracture. From the results so secured, the factor of stress concentration *C* for conditions at failure was determined. The results are given in Table 1, together with the calculated factors of stress concentration for elastic conditions.

TABLE 1

Description of beam	*C* for conditions within elastic limit (calculated)	*C* for conditions at rupture (experimental)
Plain rectangle as molded	1.00[a]	1.00
One 72° V-notch $^1/_4$ in. deep, sharp as could be made	<11.00[a]	2.24
One 72° V-notch $^1/_4$ in. deep, 0.05 in. radius at point	5.47[a]	2.02
One 72° V-notch $^1/_4$ in. deep, 0.15 in. radius at point	2.55[a]	1.76
One saw cut $^1/_4$ in. deep	...[c]	2.34
Many saw cuts $^1/_4$ in. deep, $^1/_4$ in. apart	...	1.62
One vertical hole 0.0625 in. diameter	2.82[b]	1.23
One vertical hole 0.500 in. diameter	2.00[b]	1.21

[a] By Inglis formula: $C = 1 + 2\sqrt{(d/\rho)}$.
[b] By Coker's formula: $C = 3K/(K + 1)$.
[c] Coker found, by photoelastic analysis, a stress-concentration factor of 2.78 for a rectangular notch with rounded corners.

It is not the fact that the experimentally determined coefficients are much smaller than the calculated coefficients that is to be remarked; such a disparity is to be expected, because even with the brittle material used, some plastic action is present. What is noteworthy is the fact that the difference in the strength of the several types of specimen is so much less than the difference in intensity of elastic stress would lead one to expect—whether determined by mathematical analysis or photoelasticity. Only a small number of tests have so far been made on cast-iron beams of this sort, but these showed smaller coefficients and less difference in coefficients than the plaster beams.

Again, circular plates, 12 in. in diameter and $^1/_2$ in. thick, were tested with edge support and concentrated center loading, the diameter of the circular area over which the load was applied being varied from 0.2 in. (the least that could be used without local crushing) to 1 in. Table 2 gives the relative magnitude of the loads that caused failure and, for comparison, the relative magnitude of the loads which, according to the theory of elasticity, would have caused a given stress within the elastic limit. Again it appears that elastic stress is not alone a sufficient index to relative ultimate strength.

TABLE 2

Diameter of loaded area, in.	Relative strength (from test to failure), per cent	Relative load to produce a given elastic stress (calculated), per cent
1.00	100.0	100.0
0.50	87.5	82.2
0.20	89.2	66.7

In general, it appears probable that any analysis of stress within or even slightly beyond the elastic limit, whether mathematical or photoelastic, is likely to lead to exaggerated ideas of the importance of stress raisers, and to indicate, at least to the inexpert, a greater disparity in static strength as between one design or form of element and another than actually exists. This is not meant to imply that such analyses are not of great value. It is intended to suggest that, by themselves, they do not always provide an adequate basis for design and that it is important that they should be correlated with the record of materials in service and in tests to failure.

F. L. EVERETT.[13a] A field of study considerably greater than has previously been known is revealed by the paper. The presentation of further possibilities of stress analysis by the use of photoelasticity such as a study of impact and of failure is particularly interesting.

The photoelastic method can very profitably be extended beyond that suggested up to the present time to investigate the failure of materials due to fatigue. Until now the precise manner in which fatigue cracks are produced finds explanation based only on observations of the final fracture. The fractured surface consists of two regions, one at the point of greatest stress, which is believed to form relatively slowly, and the other represented by the remainder, which breaks suddenly and as a brittle material due to the inability of the reduced section to sustain the entire load.

It is of interest to study the history of the fatiguing action, particularly during the gradual formation and growth of the initial cracks. The usual design of fatigue specimen does not lend itself to study by photoelastic means, since the method requires a two-dimensional system. A two-dimensional type of fatigue specimen, however, together with a schematic drawing of a suitable apparatus designed to give a constant maximum bending moment over the length of the specimen, is shown in Fig. 46.

In applying this apparatus, the axis of the polarized beam would pass through the model in a direction normal to the plane of the drawing. The source of light could be a Neon lamp operated as a stroboscope, synchronized with the apparatus producing the fatigue stress, or a monochromatic of polychro-

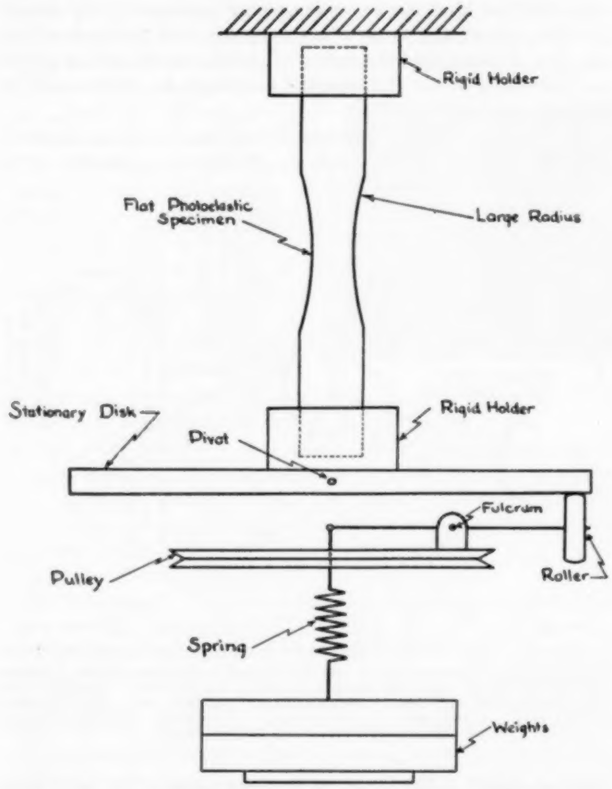

FIG. 46 FATIGUE APPARATUS FOR PHOTOELASTIC STUDY

matic light and mechanical stroboscope may be used. Stress concentration resulting from various-shaped notches in fatigue specimens could of course be readily studied.

The resulting behavior could be observed at any desired magnification by throwing the picture on a screen or preserved for future study, according to the scheme described and used by the author, by utilizing the motion-picture camera.

ARSHAG G. SOLAKIAN.[14] To the knowledge of the writer, this is the third attempt ever made in applying kinematography to the photoelastic study of stresses produced by moving loads. It is very pleasing to see the author's success in obtaining excellent patterns of stress fringes, developed under the action of dynamic stresses.

Of all the possible applications of kinema-photoelasticity, the study of dynamic stresses is of the greatest importance, and it is hoped that in the near future photoelasticity will greatly facilitate the formulation of a comprehensive and satisfactory theory concerning the disputed phenomenon of failures of materials under moving loads, such as is the case in gear action, tool cutting, centrifugal forces, repeated stresses, impact stresses, etc. Of all these different problems, the writer wants to emphasize the importance of photoelasticity in the study of impact stresses.

In the investigation of the behavior of materials in impact tests, the abrupt change of cross-section producing a non-uniform distribution of stress across a section of the specimen or near that region has not yet been considered to its full merit and cared for in the design of the elements of machines or structures. The ordinary mechanical tests register only the total energy required for causing failure of the material, usually represented graphically by the area under a complete stress-strain curve. The final tabulation of the results representing the resistance of the material against dynamic stresses is usually in terms of the amount of energy absorbed per unit area of cross-section in failure or unit volume of material withstanding the impact. The determination of the total effective volume of material by mechanical means is an impossible proposition, and the results obtained by various ingenious methods should be looked upon very cautiously with regard to their accuracy of principles. Only photoelasticity can tell us something definite and of convincing character through the study of stress fringes, all over the region affected by impact.

In static-stress problems, isochromatic or monochromatic fringe photographs of stress concentrations have positively demonstrated the fact that stress distribution across a section in the neighborhood of holes, notches, or similar discontinuities of boundary lines, etc. is of a varying character. Coker and Heymans have demonstrated in 1922 that, with specimens 10 mm. square in cross-section, notched halfway through with notches having different radii at the bottom, the stress at the bottom of the notch increases from two to six times the average stress, as the radius of the notch is decreased from 10 to 0.6 mm. Such stress concentrations as a matter of fact exist also during the application of the moving loads and are of seriously harmful character, on account of their being mostly responsible for the initial starting of a crack line or yielding of the material at the most stressed point.

The various impact machines used in the past are of either of pendulum type (Izod, Charpy, Amsler, Olson, Russell), or drop-hammer (Page, Fremont, Hatt-Turner), or rotating flywheel (Guillery), or repeated-impact (Stanton, Natsumura). The pressure produced by impact in the specimen is determined by time-position, or deflection, or deformation, or elastic-stretch methods. None of these testing machines with their elaborate accessories is adapted for the determination of the internal stresses and strains produced during the action of the pressure. On the other hand, total energy measurements are not of a conclusive character in telling the whole story of impact phenomena. Besides, there are numerous factors influencing greatly the accuracy of the results obtained in a mechanical test, such as the effect of the size and velocity of the moving mass on the resilience of the specimen, the amount of the kinetic energy of the mass lost before impact in producing vibrations and overcoming inertia and frictional resistances, etc. That is why impact tests in general have been, on certain occasions, of opposite nature in their conclusions, depending upon the kind of the machine, the type and size of the specimen, and the notch adopted by different investigators.

Photoelasticity is fortunately free of these complications. It is simple in principle and operation. The recent introduction of stress-cured bakelite for models and the use of isochromatic or monochromatic fringes of stresses, combined with the further development of kinematrography for high-speed exposures, will considerably facilitate the solution of a great many theoretically indeterminate problems in general and the investigation of dynamic stresses in particular.

J. P. DENHARTOG.[15] The beautifully sharp pictures obtained by the author lend themselves very well to an experimental study of the location of the so-called "singular points" of the two-dimensional stress distribution. This is especially striking when seeing the loading gradually applied, as in the moving picture.

Though the printed illustrations give but an imperfect idea of the beauty of the moving picture, it will be attempted to describe the point in hand with the aid of Fig. 23 of the paper. In the middle, between the two fillets at the right (one sharp, one round), there are two black curves just touching each other. The detail of this is shown schematically in Fig. 47*a*. With increasing loading, the moving picture passes through the stages *a*, *b*, *c*, *d*, then *a* again, etc. The intersection point of the two curves of Fig. 47*d* is a "singular point." The theory of these points has recently been published by Prof. L. Föppl, of Munich, Germany.[16] It is apparent that for a study of this important phenomenon, the monochromatic method of the author is superior to the usual polychromatic one.

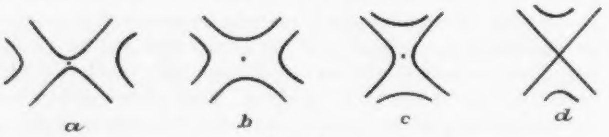

FIG. 47

On the subject of the impact pictures taken by the author, the writer cannot be quite as enthusiastic as on the rest of the paper. It is not seen what possible use can be derived from such tests or from results such as those shown in Fig. 41. The stress multiplication due to impact can be made as large as desirable by dropping the weight from a sufficient height.

Ziro Tuzi.[17] On reading the paper the writer is pleased to know that the fringe method which he once recommended[18] has been adopted for practical use with such splendid results. He desires to pay his respects to the technical skill of Dr. Frocht in getting such beautiful films as shown in Figs. 5 to 39. They seem to be wonderfully clear and excellent for demonstration purposes.

The problem of the material available for photoelastic work is always rather difficult on account of the lack of uniformity of the sensitive materials, and the author was very fortunate in being able to obtain such good bakelite free from persistent initial stress. About this problem the editor of *Engineering* (London) states in the articles[19] discussing the writer's fringe method that Mr. H. T. Jessop could eliminate the initial stress of bakelite successfully. Mr. I. Arakawa[20] also states that he has succeeded fairly well in annealing bakelite specimens. The writer has repeated these methods with various kinds of bakelite, made in our country, the majority of which resulted unsuccessfully. Phenolite is practically the same material as bakelite, with only a difference in the process of production. Manufacturing it by ourselves lately, we have had much difficulty in obtaining uniformity, free from obstinate mottle, though very recently we found a sure way to obtain good ones. Upon these experiences the writer is of the opinion that the problem of annealing depends not on the method but on the material plate itself. It seems that there are two kinds of initial stresses in the baked plate of such organic compounds: one is similar to the stream lines in the optical glass, displaying discontinuous mottle, the other being a mere continuous tint. So far as the writer has experienced, the former can never be removed by any means, while the latter is very easily eliminated by a simple annealing process in an air bath of 65 to 90 deg. cent., with slow cooling, as mentioned in the writer's previous publication, and it is better to embed the sample in refractory powder. Therefore in case the raw material belongs to the second kind, though accidentally, the elimination of the initial stress is rather easy, whether it is bakelite or phenolite, but with the first kind the annealing seems hopeless by any means. For the present, the writer is not quite sure how to obtain a good one, but it seems that the purity of the chemicals such as phenol or formalin is one of the essential conditions to obtain optically uniform plates.

The results of the experiments of the falling weight, as shown in Figs. 40 to 45, are very interesting. Really the application of the photoelasticity to the study of dynamic stress is the most striking problem. Concerning this, the very ingenious photoelastic results of Mr. K. Sekiguti have been introduced in Dr. J. Obata's paper[21] read at the World Engineering Congress, Tokyo. In his experiment the fringes of a section of a bakelite beam under vibration were photographed with a falling plate camera parallel to the reaction force measured by a piezoelectric dynamometer, as reproduced in Figs. 48 and 49. The writer recently has also tried the same kind of experiment (not published), endeavoring to shorten the time of exposure down to 1/2500 sec., with a film running at a speed of 2.5 m. per sec. and a slit of 1 mm. Fig. 50

shows the variation of fringes at the central section of a curved beam when struck by a hammer. From the photograph it can be concluded that the exposure of 1/2500 sec. is not short enough to analyze such a change. To catch the elastic wave in a solid is no doubt a very interesting problem; but assuming the Young's modulus and the density of phenolite to be $E = 35{,}000$ kg. per sq. cm. and $\rho = 1.26$ gr. per cu. cm., respectively, the sound velocity in phenolite can be calculated to be about 1650 m. per sec., with the formula $U = \sqrt{(E/\rho)}$. It seems the exposure in photographing the wave front should be, at most, shorter than 1/1650000 sec., admitting for the displacement of 1 mm. of a fringe during the exposure. Such technique, however, seems rather difficult for the present, and yet the writer thinks that such a problem is not only very interesting, but very important and worthy of future efforts.

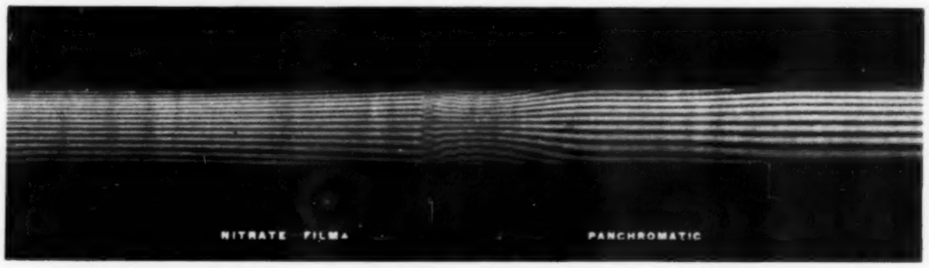

Fig. 50 Variation of Fringes at Center of Curved Beam Struck by a Hammer

H. F. Moore.[22] Professor Frocht's demonstration that stress concentration due to several notches close together is less than that due to a single notch is very interesting. This lessening of effective stress concentration in the case of screw threads was shown by R. R. Moore,[23] and his work was checked by tests at the University of Illinois. Such a lessening of stress concentration finds a rough analogy in the bending stresses in rails under closely spaced wheel loads as shown by Talbot[24] and by Timoshenko and Langer.[25]

In connection with the photoelastic method of stress determination and other non-mathematical methods, such as the soap-film method, the brittle-material method, the endurance-limit method, the "yield point by scaling" method, etc.[26] it is well to note that the theoretical stress concentration is always found to be worse than the effective stress concentration as shown by tests to failure and that various materials differ widely in the degree of effective stress concentration developed by a given notch, hole, or other "stress raiser."

Author's Closure

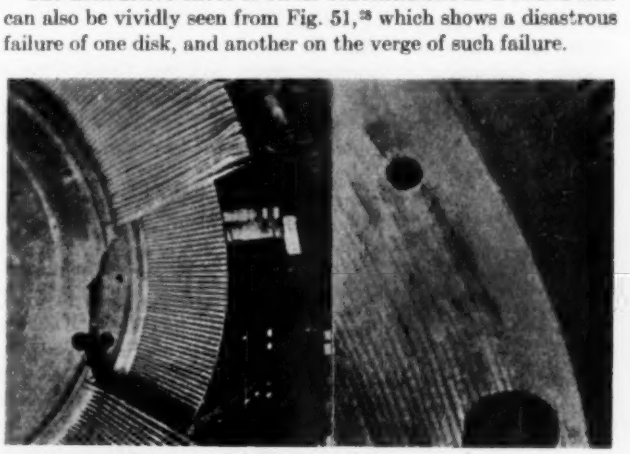
Broadly speaking, there are three aspects to the science of strength of materials: one dealing with stress analysis, another with mechanical properties of materials and tests to destruction or failure, and a third with theories of failure.

Professor Roark's comments pertain to the fact that to date we have not evolved a satisfactory, comprehensive theory to explain the failure of materials under stress. He does not question the correctness or validity of the results of stress analysis, but rather their significance and bearing on the question of behavior of materials at failure.

He calls attention to the importance of correlating stress data with records of materials in service and with tests to failure. There is no doubt that the designer cannot shape or dimension his machine parts and structural members from a knowledge of stress distributions alone. The mechanical properties of the materials, their degree of homogeneity and isotropy, the kind of loading, and the rate of loading must be known as well, in order to make a rational design. The author also agrees that under static conditions of loading the significance of stress concentration is rather small.

Professor Roark goes, however, beyond the limits justified by available experimental evidence when he says: "The seriousness of stress concentration is exaggerated even for cases involving fatigue of metals where little if any plastic action can be counted on." On this point the author wishes to quote an eminent authority. Professor S. Timoshenko says: "Under the action of reversal of stress, small cracks often start at points of stress concentration, and the majority of fractures of machine parts in service can be attributed to such progressive cracks."[27]

The destructive effect of stress concentration at a round hole can also be vividly seen from Fig. 51,[28] which shows a disastrous failure of one disk, and another on the verge of such failure.



a b

Fig. 51

The investigation which Professor Roark reports should prove interesting and useful. It is hoped that materials other than cast iron will be used. It has already been shown that this material is less affected by discontinuities than, say, high-carbon steel.

Table 2, it would seem, provides as much data against as for Professor Roark's contention that there is a large disparity between actual failing loads and those predicted by the mathematical theory of elasticity.

Professor Roark seems to have set out to caution the inexpert or average engineer "against a too literal acceptance of the apparent implications of stress concentration factors," and to reassure him that "the seriousness of these stress raisers has been exaggerated." The experimental evidence available today shows, however, that greater harm may come from attempts to lull the average engineer into a false sense of security than is likely to result from the meager efforts to call attention to the existence, value, and significance of stress concentration.

Dr. DenHartog points out that photoelasticity can be successfully applied to the study of "singular points." This point might, perhaps, be better illustrated by referring to Fig. 39, instead of Fig. 23, which clearly shows two permanently dark spots on the horizontal diameter near the large circle. The dark point shown in Fig. 47 is not found in the corresponding Fig. 23, and the erroneous impression was undoubtedly gained during the hurried showing of the film.

Dr. DenHartog cannot see what possible use can be derived from impact tests. Numerous uses have been mentioned in the paper, and others have been added by Drs. Everett, Solakian, and Tuzi. In addition to these, other impact problems might be added such as impact of air, steam, or water on the opening of a valve.

The study of "singular points" is undoubtedly interesting, but is it more useful than the problem of stress intensity during impact? Being an engineer himself, the author appreciates and shares the desire for practical application of all knowledge. Nevertheless, he would like to see greater freedom given to the research worker and lesser demands made to justify his work by immediate useful application. The history of science abounds in evidence of pure research finding uses and application totally unforeseen at the time when the work was done.

The author was particularly pleased to hear from Dr. Tuzi. If there is an initial stress in bakelite which cannot be removed by any annealing process, the author was fortunate not to have encountered such in his work. He has worked with a variety of samples containing pronounced green and red bands. Some difficulty was encountered with the material close to the edges. Aside from that, the material responded to treatment. It is, however, likely that the manufacturing process should have an influence on the problem of annealing.

The author was glad to learn of the interesting work by Messrs. Sekiguti and Obata. He shares Dr. Tuzi's opinion that it would be instructive to photograph the elastic wave, and wishes him success in any such attempts.

In an oral discussion Dr. Nádai criticized the author's work and method. (1) He called attention to the fact that the curves of Fig. 3 are ovals or ellipses and not circles, as they should be theoretically, and criticized the author for not obtaining a closer agreement between photoelasticity and theory. (2) He similarly criticized Fig. 30, claiming that under uniform pressure the fringes must be circles passing through the edges of the die (points A and B in the figure). (3) He further said that while the author was unsuccessful in obtaining such circles, Dr. Mesmer, of Göttingen, did obtain the circles in question. (4) And lastly he said that in 1929 Dr. Mesmer had discovered a process of annealing of bakelite and criticized the author for not acknowledging his work.

In reply to (1), the curves in question are evidently not circles. It is also true that under certain conditions the fringes should be circles. Dr. Nádai has failed, however, to mention these conditions. Only in the case of a load acting on an infinite plate could the fringes be expected to be circular. No claim, however, is made in this paper that Fig. 3 refers to such a plate. Furthermore, no claim was made that Fig. 3 was intended as a photoelastic corroboration of any mathematical prediction. The only comment on this figure in the text was that a single concentrated load, even if small, produces large local stresses in the immediate vicinity of the load. The model in this case was a fairly oblong plate about 4 in. by 6 in., and the purpose of Fig. 3 was to furnish photographic evidence of stress concentration. If it is desired to compare the shape of the fringes for this plate with those of an infinite plate, it would be necessary to restrict ourselves to the fringes in the immediate vicinity of the concentrated load. If that is done, then the fringes are seen to be as close to circles as those obtained by Dr. Mesmer.[29]

The situation is similar in regard to Fig. 30. It is true that for an infinite plate and under uniform pressure the fringes may be expected to be circular. But the author did not claim to be working with such a plate, nor to have corroborated any mathematical theory, nor to have secured *perfectly* uniform pressure under the die. The only claim made was that the effect of a layer of rubber is to remove the stress concentrations, to produce a *nearly* uniform pressure distribution, and to shift the maximum shear zone from points A and B to point C. These claims are believed to be warranted by the stress pattern shown in Fig. 30.

Referring now to the circles obtained by Dr. Mesmer, it is the author's opinion that they prove exactly nothing. It is interesting to note how these circles were obtained. Dr. Mesmer tells us that he produced the isochromatics for this case by preparing a special die of celluloid with two carefully rounded corners which was pressed against the test piece.[30] In other words, the circles were not obtained by applying a known uniform pressure and then observing the formation and shape of the isochromatics, but by carefully filing and rounding the edges of an initially flat die until after numerous trials approximately circular isochromatics were obtained. Such results are a bit forced. The author fails to see how manipulations of this kind establish the relation between the isochromatics and uniform pressure which is claimed by Dr. Nádai. It is evident that by continuing this process of "carefully rounding" the edges of the die an infinite number of other isochromatics can be obtained as well.

The author regrets that in his paper on "Recent Advances in Photoelasticity" he failed to mention Dr. Mesmer's attempts to anneal bakelite. At the time of writing the paper he was not familiar with Dr. Mesmer's valuable work. Proper acknowledgment was made to the sources that were known to the author. He thus acknowledged the work of Mr. Jessop,[31] who it was claimed had discovered a process of annealing bakelite as far back as 1923. Such unintentional omissions unfortunately occur. We thus find G. Mesmer, working under Dr. Nádai in 1929, failing to acknowledge Mr. Jessop's work of 1923.

With respect to Dr. Mesmer's annealing method, the author regrets to have to quote from memory, as he was unsuccessful in obtaining a copy of his paper in Pittsburgh. His annealing experiments were carried out in paraffin oil and not in an air bath and at a temperature much lower than that used by the author. This process left stresses which Dr. Mesmer estimated as 35 kg. per sq. cm., which in our units amounts to about 500 lb. per sq. in. In terms of fringes for bakelite $^1/_4$ in. thick, such as used by the author, this is equivalent to about 1.76 fringes, the stress value of fringe No. 1 being 284 lb. per sq. in. Bakelite models with such large initial stresses could not be used for photoelastic research, and this may perhaps be the reason why Dr. Mesmer used celluloid in most of his investigations.

The author was very much interested in the remarks of Mr. Solakian and in the problem suggested by Dr. Everett.

Photoelastic Study of Shearing Stresses in Keys and Keyways

By ARSHAG G. SOLAKIAN[1] and GEORGE B. KARELITZ,[2] NEW YORK, N. Y.

A. G. Solakian

The technique of photoelastic determination of stresses in structural members using bakelite as the transparent medium is described. The mechanical properties of this material and the process of annealing it for the removal of the internal stresses are given. The shearing stresses in keys and keyways are investigated. It is shown that it is desirable to round the corners of the keyway, with a corresponding chamfering of the key. The use of color fringes called isochromatics for the determination of shearing stresses has been found very helpful and is highly recommended.

G. B. Karelitz

1 Introduction

The work described in this paper has been carried on as a research problem supported by the Ernest Kempton Adams Fellowship of Columbia University, New York. The laboratories and facilities of the Physics Department of this university were used. The problem assigned consisted of working out a simple technique for the photoelastic determination of stresses in a two-dimensional stressed state and of applying this method for the investigation of a practical case. A large variety of similar mechanical and structural problems might, however, be analyzed, giving quite interesting results.

The design of a key fitting into a keyway in order to transmit a given torque is more or less based on empirical formulas or "standard practice." St. Venant's classical formulas for the distribution of stresses in the different fibers of shafts of various cross-sections are hardly applicable to those ordinary cases where the introduction of a keyway causes discontinuity of the boundary lines. Very valuable tests were carried on in 1909 by Prof. Herbert F. Moore[3] in an investigation of the effects of keyways on the torsional strength of shafts, and some have tried to apply many ingenious methods for the measurement of stress intensities in shafts with keyways, such as the use of strain gages, Prandtl's membrane analogy, Luder's lines, etc. Yet these methods presume a torque applied to the shaft without due consideration to the rôle played by the key in transmitting the resulting stresses to its adjacent sides, producing heavy concentrations of stresses, an exact knowledge of which is of utmost importance for a balanced design of the elements and for the combined safety of the entire mechanism.

The photoelastic method is by far the most convenient and direct method of observation of stresses in this case. The magnitudes, as well as the directions of shearing and principal stresses, can be determined with sufficient accuracy. Meantime a colored or black and white photographic record of stress concentrations can be taken for future references, if so desired.

During the last 20 years a great many interesting problems have been handled by the photoelastic method. Practically most of these cases were of tension, compression, or bending, which could be analyzed mathematically with more or less difficulty and the results compared with those obtained by photoelasticity. The models used were of glass or xylonite (celluloid). Recently the possibilities of bakelite and phenolite were brought out.[4,5,6] Bakelite, known as C25 bakelite,[7] has been adopted for the work described in this paper, on account of its high optical sensitiveness, resulting in several orders of color fringes under moderate stresses.

The model tested is a compound piece consisting of three different parts—namely, the key, the shaft, and the hub or

pulley. The results of the tests are therefore dependent on the accuracy with which the parts are machined. Another peculiarity of the problem is the application of a constant torque to the shaft with the object of reproducing the actual conditions existing in practice. In order to eliminate the internal stresses caused during the machining process, the models were annealed after fitting the different pieces together. The establishment of a proper annealing process involved a large amount of experimentation.

2 THE PHOTOELASTIC METHOD

(*a*) *Historical.* The phenomena of double refraction of rays of light in Iceland spar was known to E. Bartholin in 1670. Due to the discoveries and further investigations of Seebeck, Brewster, Wertheim, Neumann, and others, it has been found that an isotropic material, such as glass, produces accidental double refraction of plane-polarized rays of light when stressed in tension or compression.

It was Prof. A. Mesnager[8] who first applied the double refracting property of glass under load into practical use in connection with the determination of stresses in the members of a glass model of an arch bridge. To Dr. E. G. Coker[9] is due the greatest credit of introducing celluloid as a material for models, the perfection of an optical set, and of the application of photoelasticity to the solution of a great many mechanical and structural problems. Recently Dr. H. Favre[10] developed a purely optical method of determination of principal stresses by measuring the absolute retardation of the refracted rays of light through a stressed piece of glass.

(*b*) *Principal Stresses and Maximum Shear.* A complete discussion of the details of a two-dimensional stressed state may be found in any standard book on the strength of materials. For the purpose of this paper it will only be mentioned that the principal stresses at a point being p and q, the maximum shearing stress will be $(p - q)/2$ and will act in a plane at 45 deg. with the planes of the principal stresses. Also it may be noted that when the two principal stresses are equal and of the same sign ($p = q$), the maximum shearing stress will be zero in any direction at this point.

The photoelastic method allows of observing directly the values of the maximum shearing stresses. Let a transparent stressed plate be illuminated by plane-polarized light and projected on a screen. When a ray of this light strikes the plate at a stressed point, the ray will be decomposed into two plane-polarized rays, vibrating in the planes of the principal stresses. These two rays travel through the plate with different velocities, proportional to the magnitude of the principal stresses, so that when they emerge out of the plate, the phase of one of the rays is retarded with respect to the other. The amount of retardation for a given wave length and thickness of material is proportional to the optical constant of the material and the difference of the two principal stresses, or to the intensity of the maximum shearing stress as given by $(p - q)/2$. An analyzer placed in the path of the two refracted rays unites the planes of vibrations of the two rays into one. However, on account of the existing phase difference between the two rays, interference takes place. If a monochromatic light be used—i.e., the green light of a mercury-vapor lamp of a wave length of 5460.7 angstroms, the field will be darkened for those points of the plate where the retardation is equal to $^1/_2$, $^3/_2$, $^5/_2$, etc., wave lengths. There will be in general a whole line of points producing the same retardation due to continuity of the stress function. The field will therefore be covered with dark fringes. Fringes of the first, second, third, etc., orders will correspond to retardations of $^1/_2$, $^3/_2$, $^5/_2$, etc., wave lengths. Since the retardation is proportional to the maximum shearing-stress intensity, each fringe line is a contour of equal shearing stress. The values of the shearing stresses corresponding to the different fringe lines can be determined easily by testing a calibrating beam in flexure, the material of the beam being the same as that of the model.

However, by using white light instead of the monochromatic light, a succession of colored fringes will appear in the order of yellow, red, and green. Indeed, whenever the green light is extinguished by interference, as described, the complementary reddish color will appear, and instead of the dark fringes, identical fringes of reddish color will come into appearance on the screen on which the plate model is projected. For each value of retardation another color will appear, and the field will have a multicolored appearance.

3 PHOTOELASTIC APPARATUS OF COLUMBIA UNIVERSITY

(*a*) *The Optical Set.* The authors were very fortunate in being provided with two large Iceland spar Nicols from the Physics Laboratories of Columbia University. This enabled them to design a very simple optical set with the addition of only three convex lenses. The loss of light therefore was small, and the introduction of optical troubles due to the presence of a great many lenses was avoided. A general assembly of the set is shown in Fig. 1. It is made up of a 500-watt and 110-volt alternating current point-source incandescent lamp operated through a switch and a rheostat, a condensing lens, a water cell, a large polarizing prism, a quarter-wave mica plate, the torsion or bending frame, two large convex lenses, another quarter-wave mica plate, an analyzing prism, and a screen with a photographic plate holder. The functions of each of these will be given later. The loading frame will now be described.

[9] E. G. Coker, *Philosophical Magazine*, vol. 20 (1910), p. 740. Numerous articles on photoelasticity and its applications, mostly in *Engineering*, 1911, 1912, 1914, 1921, 1922, 1925, etc.

[10] "Methode purement optique de determination des tensions intérieures, etc.," by H. Favre, *Schweizerische Bauzeitung*, December, 1927.

(*b*) *The Torsion Frame.* This part as a whole is attached to a large tension frame through a set of bolts, as shown in Figs. 2 and 3. The tension frame is built up of angles and plates, with a flat bottom provided with a set of leveling screws. The vertical uprights have holes of $^3/_8$ in. at regular intervals of 2 in., for the adjustment of the torsion frame to different heights. The center of the key is made to coincide approximately with the axis of the optical set, and by the proper adjustment of the lens system, the entire field of the key and the adjacent parts of the shaft and hub illuminated by the parallel rays of the polarized light will be projected on the screen. Torque is produced in the shaft by means of the handwheel *A* working around a screw *B* attached to a spring scale *C*. Any upward pull on the scale is divided equally in the two linkage systems *D* and *F* located at equal distances from the center line of the scale and connected to a horizontal lever *G* at its extremities through $^1/_4$-in. round steel pins. An upward force in *F* corresponds to an equal downward force in *I*,

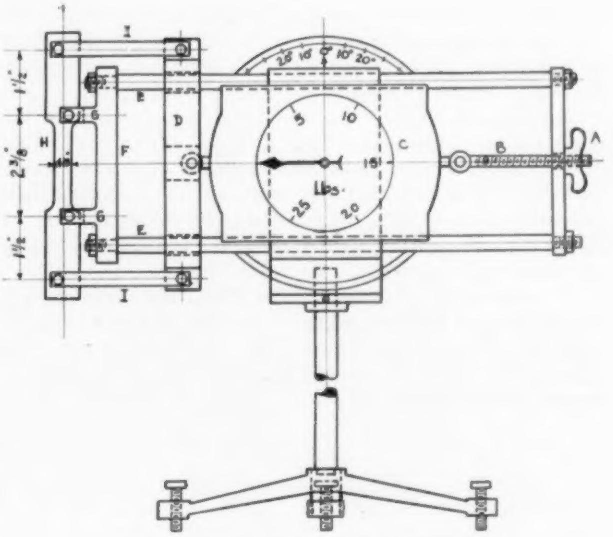

FIG. 4 DIAGRAM OF BENDING FRAME

which in combination with the equal and opposite force in *D*, produces a torque in the shaft around its central axis equal to one-half the scale reading multiplied by the distance between the bars *D* and *I*. The vertical links *D*, *F*, and *I* consist each of two strips of metal $^3/_{32}$ in. by $^1/_2$ in., one on each side of the model. The horizontal bars *G* and *H* are made of $^3/_{16}$-in. steel and are connected to the scale and to the linkage system as shown in the illustration. The model is held rigidly by means of a set of $^1/_8$-in. bolts in between two $^1/_8$-in. brass plates, which in their turn are bolted to the tension frame. The central portion of the brass plates is cut for a diameter of 6 in. in order to expose a corresponding surface of the transparent model to the rays of light for projection purposes.

(*c*) *The Calibration Frame.* The bending frame, a diagram of which is shown in Fig. 4, is used as a calibrating device to obtain a relation between color, order, and stress. It consists of a handwheel *A* working on a screw *B* to produce pull on the spring scale *C* and the bar *D* attached to the latter and sliding freely on the two rods *E*, which at their ends support a bar *F* with the two supports *G*, at a distance of $2^3/_8$ in. apart from center to center. The calibrating beam *H*, made of

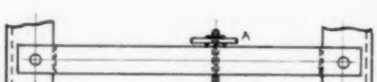

FIG. 2 DIAGRAM OF TORSION FRAME

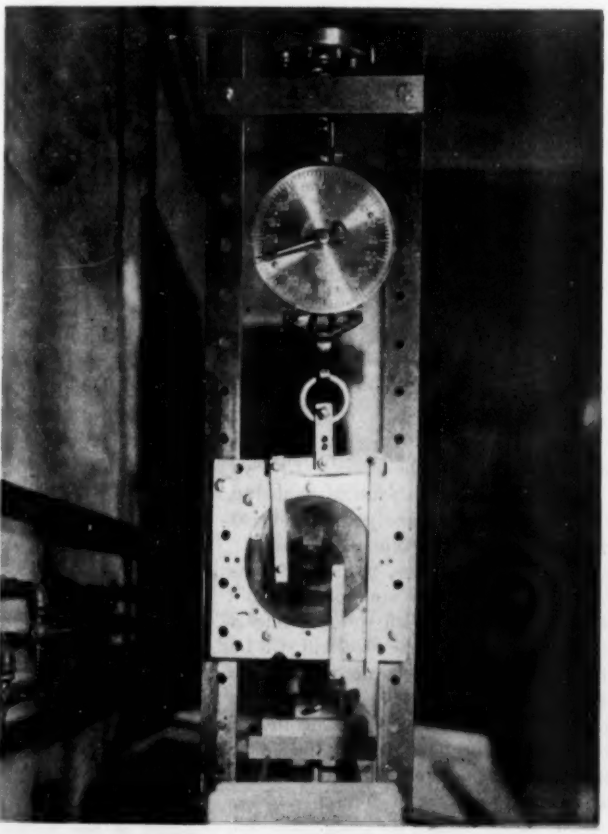

FIG. 3 TORSION FRAME

the same bakelite as that used for the models, is attached to the slots of the supports through $^1/_4$-in. round pins. At the two extremities of the bar *D*, $^1/_{16}$-in. by $^3/_{16}$-in. strips *I* are connected to the ends of the bakelite beam on both sides through similar pins, at distances of $1^1/_2$ in. from the supports outward. The load registered on the scale is equally divided in the strips *I* and acts at the ends of the beam, producing a uniform bending moment for all sections in between the two supports. The bending frame is supported by a $^3/_4$-in. round steel rod fixed on a tripod. It can be moved vertically up and down, as well as turned through any angle in a vertical plane.

(*d*) *Optics of the Apparatus.* The light from the lamp, after passing through the condensing lens, reaches the polarizer and is split into two rays, called ordinary and extraordinary rays. The first is reflected and absorbed by the sides of the prism, while the second passes through the prism and has its vibrations all in a plane perpendicular to the principal plane of the prism. The two large lenses are adjusted to obtain a parallel beam of light and sharp focusing. If the principal plane of the analyzer is set at 90 deg. with that of the polarizer—i.e., when the "Nicols are crossed"—the beam will not pass beyond the analyzer, producing complete extinction of light on the screen. Any rotation of one of the prisms will produce partial illumination. With the two Nicols crossed and the bakelite model not stressed, the field will still be dark. However, when the material is stressed, the rays of the polarized light, while passing through the model, will undergo a relative retardation during the process of the refraction in the material, and as the retardation is proportional to the shear intensity at a given point, color will appear on the screen with a succession of bands of yellow, red, and green of different orders, depending upon the intensity of the stresses in the plate. Should one principal stress at some point in the model be parallel to the plane of polarization of the parallel beam of light, the ray through that point will not be decomposed, and a dark spot will appear on the screen, marring the distinct appearance of the isochromatics. In order to avoid this, the plane-polarized light is changed to circular or elliptic polarized light by introducing two quarter-wave mica plates with their optical axes at 45 deg. with those of the Nicols.

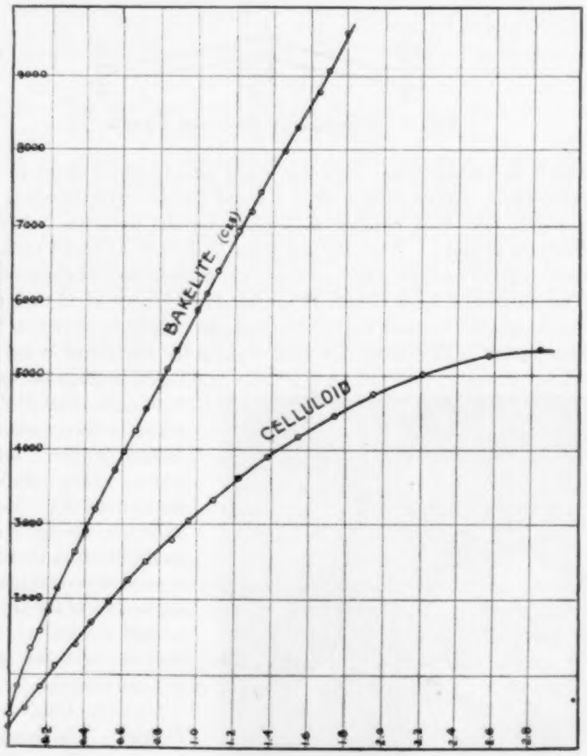

Fig. 5 Stress-Strain Curves

4 Materials

The materials commonly in use for models have been glass, xylonite (celluloid), phenolite, and bakelite. The last one was adopted by the authors on account of its comparatively high optical sensitivity in producing color fringes under moderate stresses. Glass has been used by the early experimenters, such as Brewster, Wertheim, Mesnager, etc. its chief advantages being perfect transparency and no residual stress-optical effect. On the other hand, glass is very difficult and expensive to machine, and must be very thick and highly stressed in order to produce multicolor effects. Xylonite is camphorated nitrocellulose, easily machined, but has considerable initial stresses, especially when not aged. It is not optically very sensitive and undergoes a large permanent set upon removal of stresses even far below its elastic limit, followed by a progressive creep. Phenolite is an organic compound made from phenol and formaline by the catalytic action of ammonia at ordinary pressure. In many respects it has the same qualities as bakelite.

Bakelite is a phenol resinoid, invented by Dr. L. H. Baekeland in 1907. The principal ingredients used in the manufacture of bakelite resinoid are phenol (commonly called carbolic acid) and formaldehyde. The transparent bakelite materials are produced directly from the initial resinoid by processing with heat at a temperature of about 300 deg. fahr. and a pressure of 50 to 100 lb. per sq. in., in a special type of autoclave. The material thus produced is a clear, amber-hued resin-like solid, having a specific gravity of 1.27. It will not melt at any temperature, but begins to char at about 570 deg. fahr It has a stress optical coefficient of about 500 brewsters, as determined by I. Arakawa, at least five times larger than that of celluloid, and therefore for a given thickness a greater number of isochromatics are brought into the field. The chief difficulty in using bakelite has been due to the presence of considerable initial stresses within the material as supplied or after machining it to a complicated shape with holes, corners, etc. After several trials the authors have found it possible to remove these unnecessary stresses by keeping the finished plate in an electrically controlled hot-air furnace at a temperature of 75 to 85 deg. cent. for at least one hour and then gradually cooling down to room temperature within 12 to 14 hours.[11] Under no circumstances should one try a temperature of 110 deg. cent. or above, as the transparency of the material will be affected. Both mechanical and optical tests run in the laboratories of Columbia University have indicated that the properties of bakelite are slightly affected as a result of annealing. Hence, the color-stress relations will no more be the same for the material in its initial and heat-treated conditions. However, by annealing the calibrating beam under the same temperature and time of cooling conditions as that used for the model, any discrepancy of this nature will be eliminated.

Bakelite models have a tendency to warp during the annealing process. It is necessary, therefore, to hold the plates in between two glass plates loaded on top.

---

[11] This method of annealing bakelite has been developed by the authors and used since December, 1930. Dr. Max M. Frocht's process of removing the internal stresses is in many respects similar, although developed independently. For details of Dr. Frocht's method, see his paper, "Recent Advances in Photoelasticity," presented at the National Applied Mechanics Meeting (A.S.M.E.), Purdue University, Lafayette, Ind., June, 1931.

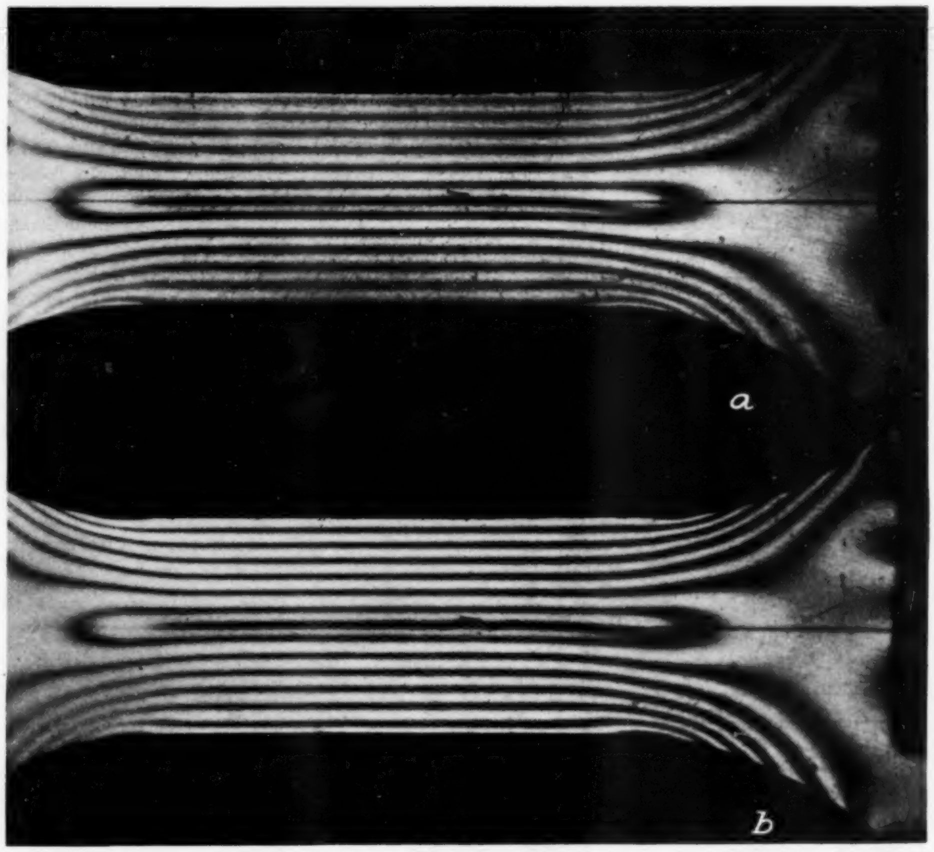

Fig. 7 Calibrating Beam in Flexure

(*a*, isochromatics in black and white obtained with white light; *b*, monochromatics in black and white obtained with mercury light.)

A stress-strain curve of C25 bakelite is given in Fig. 5. A similar curve for celluloid is added for comparison.

Although bakelite has a fairly high apparent elastic limit, yet time-creep tests of specimens of the material, both annealed and non-annealed, show that stresses within about 35 per cent of the maximum strength of the material do not produce permanent set. This corresponds to a working stress of 3200 lb. per sq. in. Bakelite has a considerable hysteresis for higher stresses, and a certain amount of permanent set will occur if the maximum intensity of the stresses is not kept within safe limits.

5 Keys

A key is used commonly to transmit a torque between a hub and a shaft. It will be assumed in this discussion that there is no press fit and that a good sliding fit exists between the hub and the shaft; i.e., that the total torque is transmitted through the key. The key works in shear. Several types of keys are used in machine building, such as the gib-head key, the woodruff key, the snub key, etc., but they differ from each other only in details. Therefore the analysis here is confined to a standard key and with the shearing stresses in and around it.

It will be recognized that with the existing practice of machining keyways, sharp edges bear against the surfaces of the key. This introduces great complexity in the analytical solution of the problem. High stress concentrations exist at certain critical points, far above the elastic limit of the material. Although the design of the key or the keyway is based upon the results of years of experience and experimental study, the frequent failures have shown the necessity of further research by an entirely different method than that used in the past.

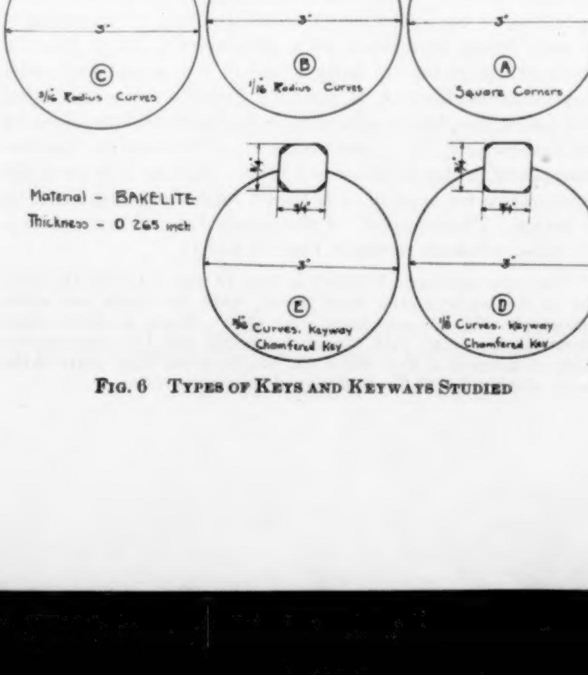

Fig. 6 Types of Keys and Keyways Studied

A $^3/_4$-in. square standard key corresponding to a shaft of 3 in. in diameter was adopted for investigation. Four modifications of the standard design were made by introducing $^1/_{16}$-in. and $^3/_{16}$-in. curves at the corners of the keyways and making the keys to fit these curves or chamfering the corners of the keys, as shown in Fig. 6.

6 Test Procedure

(*a*) *Method of Preparing Models.* The models were machined from bakelite of 0.265 in. thickness and were polished on large rotating disks provided with a layer of felt on their upper surfaces. Levigated alumina dust mixed with water was found to give a very high polish. A careful fitting of the three parts was obtained by a continuous examination of the models in the photoelastic apparatus. Any misfit, and therefore the appearance of local stresses, was easily detected and eliminated. After a satisfactory fit was obtained, the models were annealed as described. Subsequent to annealing, it was found necessary in many cases to fit the three parts again on account of the deformation of the plate as a whole during the process of freeing itself from the internal stresses, while cooling down to room temperature.

(*b*) *The Color-Stress Scale.* The material of the models was calibrated. A color-stress scale was prepared as follows: A beam made from bakelite, using the same material and of the same thickness as the models, was machined to proper shape and dimensions, as shown in Fig. 4. The beam was annealed as described. When stressed in flexure under a given load at the extremities of its cantilever arms, pure bending of a known intensity took place in the middle of the beam, corresponding to a certain extreme fiber stress. The middle portion of the beam was put in the path of the rays of polarized light and projected on the screen. Colored bands symmetrically placed on both sides of the neutral axis and in a direction parallel to the axis of the beam appeared on the screen. Fig. 7*a* is a photograph of the isochromatics in black and white. Fig. 7*b* is that of the monochromatics having replaced the white light used for the isochromatics by the green light of a mercury-vapor lamp.

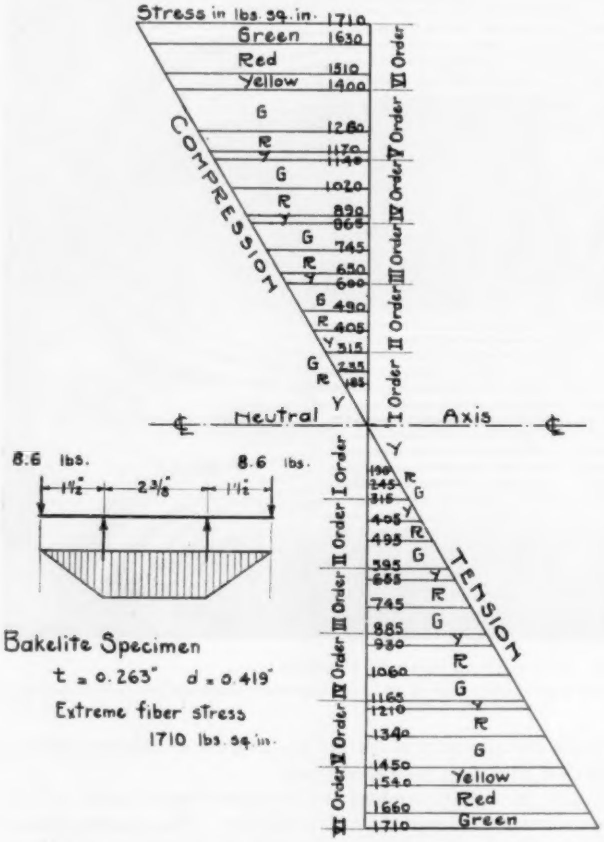

FIG. 8 COLOR-STRESS SCALE FOR C25 BAKELITE

Although the monochromatics give a more distinct picture, the use of isochromatics for the evaluation of stresses is preferred by the authors and is recommended for the following reasons:[12]

(*a*) Black and white photographs of the isochromatics are now obtained as easily as of the monochromatics.

(*b*) Isochromatics when projected or printed are more impressive and enable the observer to follow the changes of intensities of stresses in complicated structures.

(*c*) Black regions corresponding to $p - q = 0$ are easily detected in the isochromatics.

(*d*) With three-color bands in the isochromatics against two-color in the monochromatics, the optical sensitivity of bakelite is increased in the ratio of 3 to 2.

(*e*) The monochromatic fringe method in certain cases requires repeated loading and unloading of the material for the determination of the number and order of a fringe. This process produces permanent set in the material, and hence affects the results. With the isochromatics the first-order colors are easily recognized, and the higher ones are determined by counting from the first-order fringes toward the higher orders. A little practice will enable one to tell the correct order of fringes of orders below the fifth by a mere observation of the hues of the colors or by comparison with a standard color scale.

In order to obtain a color-stress relation for the evaluation of the stresses, the lines of divisions between the several isochromatics as well as the neutral axis were carefully marked. With fresh-cut specimens properly annealed, the neutral axis was in all cases coincident with the center line of the beam. Knowing the intensity of fiber stresses for a given uniform bending moment, and also the cross-section of the beam, a color-stress diagram was prepared, as shown in Fig. 8, where the stress equivalents of the different fringe lines are found from their relative distances from the neutral axis. The stresses given in Fig. 8 are the values of the principal tensile or compressive stresses p, the other principal stress being zero. The maximum shearing stresses are therefore $s = \frac{1}{2}(p - q) = \frac{1}{2}p$. The isochromatics represent also shearing stresses, and the values are given in Table 1.

TABLE 1 ISOCHROMATICS—COLOR-STRESS VALUES FOR BAKELITE C25

Color	Order	Symbol	—($p - q$) Stress, lb. per sq. in.— Tension	Compression	Average	Shear

Green		g_6				

The stress readings in Fig. 8 show that corresponding values of stress for a given color order are not the same for both sides of the neutral axis. This is due to irregularities in the material and to differences in thickness of the different fibers of the beam on both sides of the axis, inasmuch as tension and compression stresses will produce opposite changes of thickness. The average of the two values was taken in preparing the color-stress list, Table 1.

(*c*) *Magnitudes of Maximum Shearing Stresses.* The bakelite models shown in Fig. 6 were mounted in the loading frame. After the necessary adjustments, a constant torque of 166 in-lb. was applied to the round plate representing the shaft through the leverage mechanism, by introducing a total pull of 70 lb. in the spring scale. This was sufficient in all cases to produce a maximum stress corresponding to the green color of the sixth order. The color bands or isochromatics projected on a piece of white paper fixed to the screen were traced carefully. Photographs of the color bands were taken for a three-color print on Wratten Panchromatic plates, by using filters of red, green, and violet colors (Eastman filters A, B, and C). Later on it was found that black and white photographs of the color bands could be obtained very satisfactorily by a direct exposure of the rays on Eastman Ortho plates, without the use of a filter. Figs. 9*a* to 9*e* show the isochromatics for keys *A* to *E* traced from their projections on the screen. Photographs[13] of the square type of key and keyway under stress are shown in Figs. 10 and 11.

---

[12] For a detailed explanation of the reasons, see the discussions by the authors of Dr. Max Frocht's paper on "Recent Advances in Photoelasticity," Applied Mechanics Meeting (A.S.M.E.), Purdue University, Lafayette, Ind., June, 1931.

[13] The color photograph shown in Fig. 10 was taken at the same time as the isochromatics were traced, while the black and white photograph (Fig. 11) was taken long after. Hence it shows slight differences compared with the isochromatics and the color photograph, on account of time effect and reuniting the three parts of the model, which may not be absolutely of identical nature.

It will be observed that in nearly all cases the yellow color beyond the fourth order is not represented in the isochromatics on account of the fact that at high stresses it is very difficult to discriminate it from red and green colors.

7 Observations and Discussions

(*a*) *Shear Distribution in the Keys.* Curves showing the intensities of shearing stresses around the boundary lines and at various sections of the different types of keys are given in Figs. 12 to 16. These are all for a twisting moment of 166 in-lb. The ordinates to the curves representing the magnitudes of the unit shears are taken from the color-shear compilation, Table 1, corresponding to the proper isochromatic line of that point. Similar curves are drawn for the shear stresses in the shaft and hub around the keyway, as shown in Figs. 17 to 21. These are all for a twisting moment of 166 in-lb.

A comparative study of the shear intensities for the different types of keys and keyways allows us to make the following observations, true to all the different types:

(1) The maximum shear intensity on the surfaces of the keys is several times higher (in many cases from two to four) than the average at points where the edges of the shaft and the hub come into contact with the sides of the key. This is due to the pressure concentrations from the sharp corners of the keyway either in the shaft or in the hub, depending as to which one first comes into contact with the sides of the key.

(2) At one or two special corners of the key, depending upon the type of the key and the direction of the torque applied, the intensity of the maximum shear is as high as five times the average.

(3) The total shear carried by the middle horizontal section of the keys (proportional to the areas under the shear curves corresponding to these sections) is larger than that carried by any other section parallel to the middle ones.

(4) The material on the no-load side of the keys, both for the hub and the shaft, is practically free from stress (except in type *C*), which might be expected. Probably in the case of a long key this is true only for that part of the keyway adjacent to the free end of the shaft, while at the other end of the hub the material takes an active part in the transmission of the torque.

(5) Heavy stress concentration exists at the reentrant corners of the keyway. Contrary to expectations, introduction of a large-radius curve at the corners did not show a particular beneficial effect in this respect. Apparently the local stresses depend considerably on the proper fit of the key and on the location of the point where the pressure of the key against the keyway is concentrated.

(6) The effect of chamfering the keys has been found in some cases harmful on account of the introduction of high localized stresses due to sharp chamfered corners of the key. In the case of the key *C*, for example, the maximum shear in the key boundary at a point around the lower right corner is 455 lb. per sq. in. The introduction of a chamfer in the key increased this to 760 lb. per sq. in., without any appreciable reduction in intensity of shear on both sides of the corner of the key in either vertical or horizontal direction. However, the same is not true for the key *D*, where the largest value of the shear was increased only from 655 to 765 lb. per sq. in. at the upper left corner, while that at the lower left corner was decreased to a considerable amount, from 710 to 245 lb. per sq. in. On the other hand, the intensity of the shear on the

horizontal boundary faces was increased to some degree, due to the reduction of the bearing areas by the chamfering of the corners of the keys.

(7) The introduction of curves at the corners of the keys throws a certain amount of the torque to the corners of the keyway, especially in the case of the large-radius curved corners of the key *C*. This is largely due to the facility with which a key with larger curves at the corners will adapt itself easily to small displacement and adjustments of position during the transmission of a given torque to its adjacent sides in contact, resulting in compression stresses along diagonal planes.

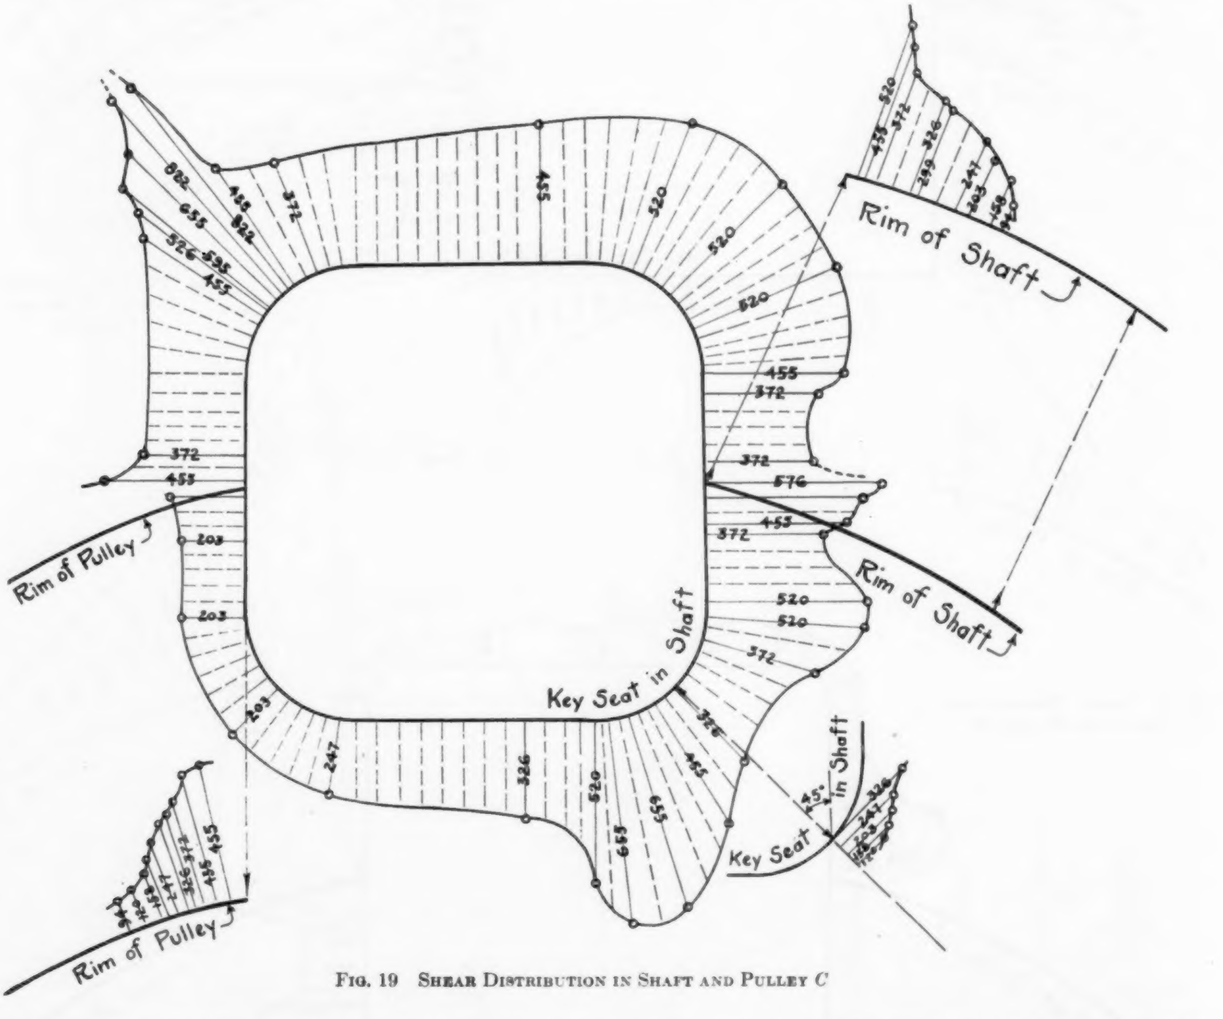

FIG. 19 SHEAR DISTRIBUTION IN SHAFT AND PULLEY *C*

(*b*) *Shear Distribution in Shaft and Pulley.*

(8) Results similar to those of the keys have been obtained concerning the intensity of shearing stress at points of contact of the line of joint between shaft and pulley against the faces of the key. The resulting maximum stresses are from three to five times larger than the averages in most cases, except in the keys *C* and *E*, which have resulted in more or less uniform distribution of shear stress all along the boundary of the keyhole, with a ratio of maximum to average of about two to one, except at one particular point in the key *E*.

(9) The curves showing the shear intensities on 45-deg. sections at the most stressed corners of the keyways illustrate to a striking degree the presence of high concentrated stresses at such points on account of the sharp or rounded corners of the keys, bearing against those of the keyways. This effect is more prominent in the case of the key with $^3/_{16}$-in.-radius curve, due to the reasons stated in the preceding paragraph (7). Chamfering of the keys has greatly reduced the intensity of stresses at the corners of the keyways.

(10) The key *A* with square corners seems to take the effect of the entire torque by the reaction of its sides against the adjacent boundary faces in the keyway, without transmitting a portion of it to the upper or lower horizontal faces on a large scale. This may be accounted for by the greater rigidity of position of this key on account of its relatively longer vertical faces in bearing.

(11) The values of the stresses along the rims of the shaft and the hub are largely dependent upon the existence and amount of the frictional forces at these surfaces, so that a direct comparison of their relative intensities cannot be of a conclusive character. However, it is interesting to observe the way of variation of shear intensities, always considerably larger near the boundary of the keyway and decreasing gradually for a short distance to a very small value, depending on frictional forces acting at these points.

CONCLUSION

The photoelastic method of measuring stresses in the case of a complicated two-dimensional stress state is very convenient. It is a powerful tool for designers, for quick and simple analysis of the stresses in the members they have designed. With bakelite as

FIG. 21 SHEAR DISTRIBUTION IN SHAFT AND PULLEY *E*

material for the models, the isochromatics give sufficient information as to the stress concentrations and general distribution of stresses in the loaded structure.

Further refinement of measurements, such as finding the directions of the principal stresses and shear lines, is of little practical value for designers. These measurements were therefore not touched upon in the paper, but are discussed in Appendix 1.

As to the construction of keys and keyways, there are very heavy stress concentrations of the order 4 to 1 and 5 to 1 at the corners of the keyways and at points where the edges of the shaft and the hub bear against the key. As a result, cutting in of a key may be expected, and is often observed. As to the concentration at the reentrant angle of the keyway, the increased stress is of no particular harm when the torque is steady, but it is dangerous with a variable load, as fatigue cracks may then occur.

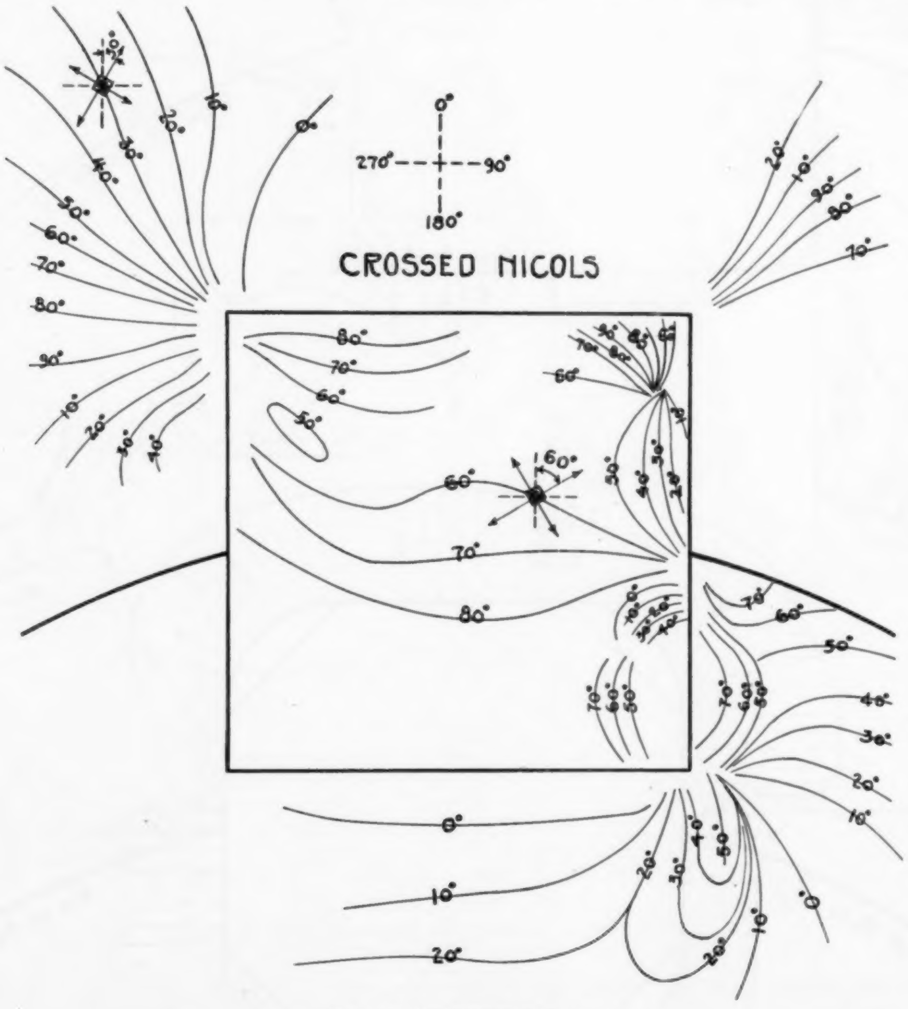

Fig. 22 Isoclinics for *A*

Appendix 1

DIRECTIONS OF PRINCIPAL STRESSES AND SHEAR LINES

With plane polarized light, when the directions of principal stresses at a point happen to be parallel and perpendicular to the direction of the plane of polarization of the analyzer, there will be extinction of light corresponding to this point as the vibrations of the ray emerging out of this point are at right angles to the principal plane of the prism. So there will be a series of black spots on the screen corresponding to similar points on the specimen, forming a set of black bands called "isoclinics." With the crossed nicols set at 0 deg., 10 deg., 20........90 deg., isoclinics of the corresponding numbers are obtained, and their center lines are traced on a paper attached to the screen. Fig. 22 shows the isoclinics for the square key and keyway.

However, there will be other black bands besides the isoclinics corresponding to points where $p - q = 0$, as is evident from the formula for the relative retardation of light during its passage through the stressed model, $\delta = c/\gamma\ (p - q)t$. These bands can be distinguished on account of their fixed position during the rotation of the crossed nicols, while the isoclinics shift their position during this process.

The directions of the principal stresses are now obtained graphically from the isoclinics. Starting with a certain isoclinic, i.e., the 20-deg. curve, crosses are marked at random all along this isoclinic, having one of the arms of the cross at an angle of 20 deg. with the direction of the principal plane of the crossed nicols, and in a direction corresponding to the direction of rotation of the nicols. The same process is repeated with all the other isoclinics. Lines drawn parallel to these crosses and spaced at

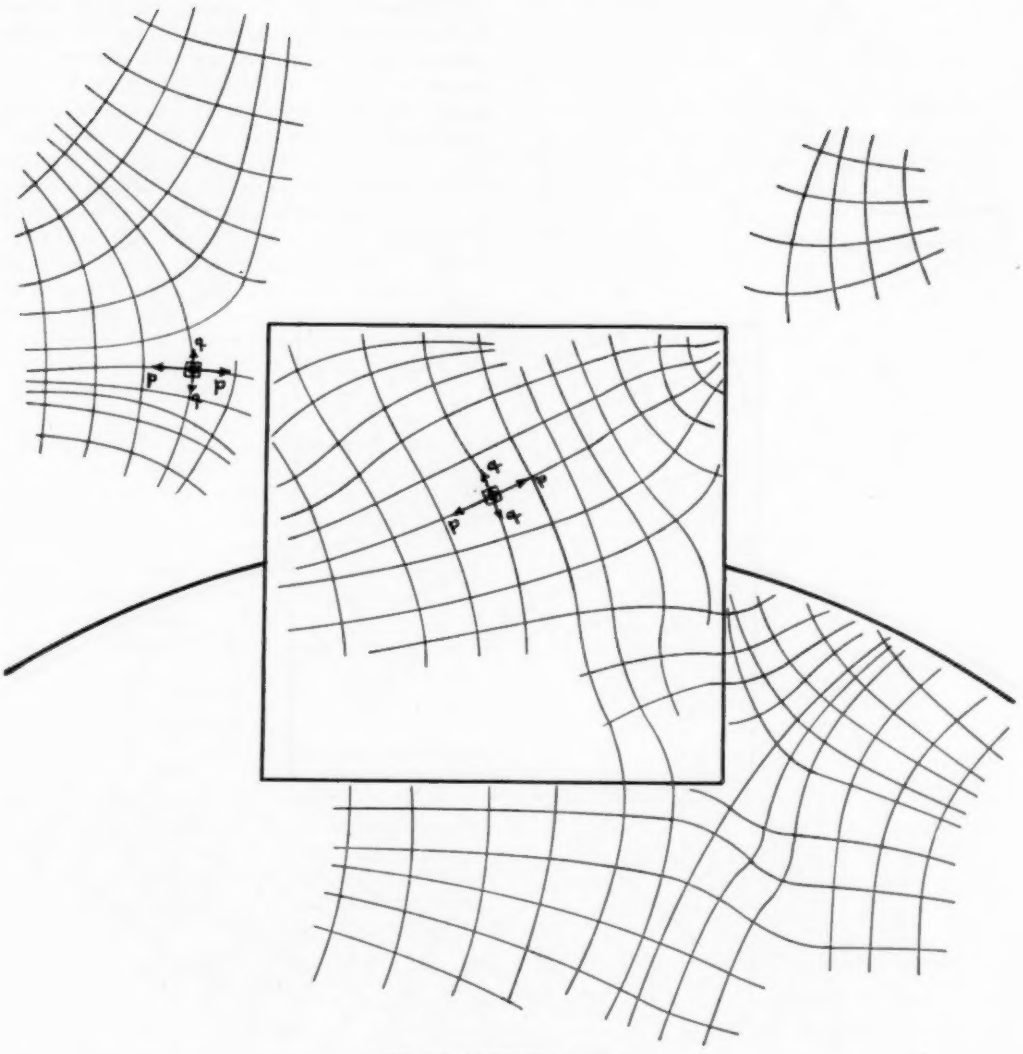

FIG. 23 ISOSTATICS FOR A

regular intervals with regard to a convenient reference line on the specimen are termed "isostatics," and they give the directions of the principal stresses p and q, at right-angles to each other. As to which one will be p or q, the identification will be very easy in many cases by the mere observation of the direction of application of the external load. Isostatics for the square key and keyway are shown in Fig. 23.

The general formula for shear $2\ \tau = (p_1 - q_1) \sin 2\varphi$ is maximum for $\varphi = 45$ deg. and becomes $s = \dfrac{p-q}{2}$, where s is the ultimate value of shear corresponding to a 45-deg. value of φ. Hence the directions of maximum shears are given by curves at 45 deg. with the isostatics, as shown in Fig. 24. As in general most of the failures in machine parts and structural members are due to the effect of maximum shearing stresses, a knowledge of their directions as well as their magnitudes is of great importance to the designer, for a predetermination of the most probable section of failure of the material due to overstressing.

ACKNOWLEDGMENT

The authors are greatly indebted to Dr. G. B. Pegram, head of the Physics Department of Columbia University, for continuous encouragement and helpful suggestions, as well as to Profs. A. H. Beyer, of the Civil Engineering Department, and W. D. Turner, of the Chemical Engineering Department, for their assistance in the work.

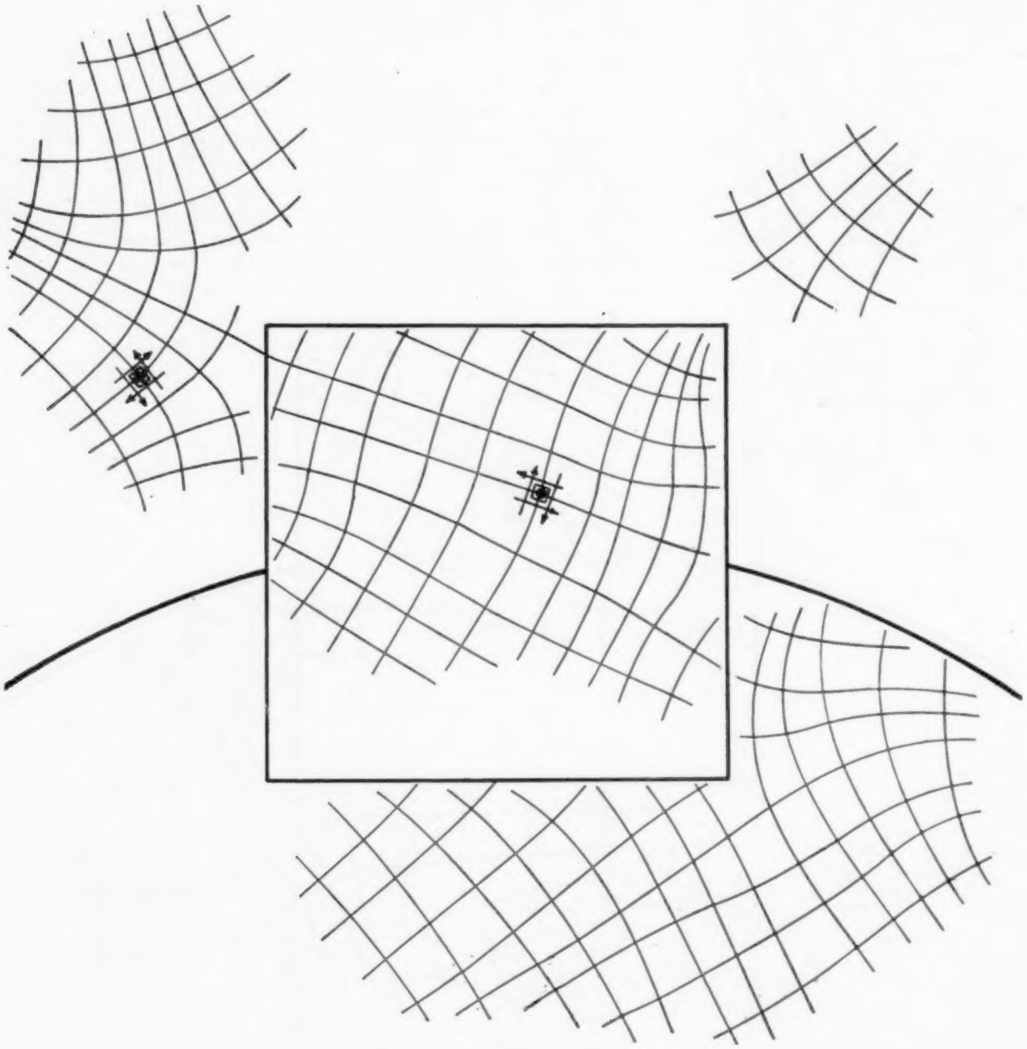

FIG. 24 SHEAR LINES FOR *A*

Discussion

J. P. DenHartog.[14] There is as yet no practical photoelastic method for measuring the stresses in three-dimensional cases. The distinction between two- and three-dimensional stress distributions should be very sharp, but in practical cases it is somewhat vague. In fact, there does not exist any practical stress distribution which can be termed two-dimensional with the exactness of a mathematician. But a rather large number of cases are so close to being two-dimensional that for the engineering accuracy required the photoelastic method is quite sufficient and very useful.

Among the numerous papers on the subject, now and then one appears discussing an application of a definite three-dimensional character, which is implicitly assumed to be two-dimensional. It seems that the present paper is an instance of this, for the following reason. A key has the object of transmitting a torque from a shaft to a disk or rotor of some kind, and it is well known that this transmitted torque is not distributed uniformly along the length of the shaft, but is much concentrated near the edge of the disk. This is illustrated in Fig. 25, where the ordinates indicate the torque transmitted through the key. The exact shape of this curve cannot, of course, be calculated, but an approximate consideration shows it to be something like an exponential curve, which has its steepest slope just at the point of maximum torque transmission. This steepness is of such a nature as to make the problem decidedly three-dimensional, especially at the point of maximum stress, which is of greatest interest.

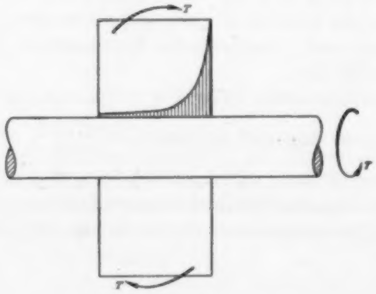

FIG. 25

---

[14] Research Laboratories, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

Another point in the test procedure which is not entirely satisfactory is the method of applying the torque, which gives a stress distribution quite different from the usual torque stress distribution in a shaft. The effect of this difference on the local stresses near the key due to the local key pressures will probably be small. But on the other hand, the stress in the corner of the keyway, due to the torque, will be very much affected. This may be a possible explanation for the unexpected result that rounding these corners did not improve the stress condition markedly.

The authors state that "most of the failures in machine parts are due to the effect of maximum shearing stresses." This is entirely correct as it relates to a first appearance of slip.

In a restricted area, like a fillet or groove, this is not serious. As the authors state, the real danger is caused by fatigue, and a fatigue failure is determined by the maximum tensile stress rather than by the maximum shear.

Adolph A. Moline.[15] Proper key design is an important factor in large apparatus, especially steel-mill motors, Diesel generator units, etc., in which the torque loads are not accurately known. The authors have contributed a paper which brings to light the somewhat unknown stress distribution in keys.

The authors state that a more favorable stress distribution results if fillets are placed in the corners of the keyways and if the keys are chamfered at the corners. This design, no doubt, reduces the stress concentration at the keyway corners. It is the writer's opinion, however, that the key would have a greater tendency to "roll," and thus fail by compression. Such a condition would also cause very high stresses in the rotor hub.

The writer uses a method of designing keys that may be of interest. It is based on the yield points of the materials involved and on the minimum torque-carrying diameter of the shaft. The shaft is assumed to fail in shear at one-half of its yield point in tension, and the key is assumed to fail in shear at 75 per cent of its yield point in tension. The maximum permissible compression stress in the key and rotor hub is taken as three times the average shear stress in the key. If the yield points are equal, the width of the key is found to be equal to $0.262 \dfrac{d^3}{LD}$, and the key height will be

$$2/3 \times 0.262 \times \frac{d^3}{LD} = 0.175 \times \frac{d^3}{LD}$$

where

d = minimum torque-carrying diameter of the shaft
L = length of the hub bearing against the key
D = diameter of the shaft at the key.

It sometimes is difficult with one key to arrive at a proper key-to-shaft-diameter proportion because of a limited hub length. In such cases, two keys are used, one of them being of the three-piece type in order to insure that both keys are effective.

M. Stone.[16] The discusser is interested in both major aspects of the paper, keys and photoelasticity. The type of investigation that the authors have undertaken—to obtain the stress-distribution and stress-concentration factors at the keyway with load applied through the key—is an advance over the more usual method when these influences are determined for a pure torque application. However, in any such investigation we are always confronted with the predicament of having to interpret the photoelastic findings practically. Photoelastic investigations, to mean anything scientifically, are made within the elastic limit of the model material. The actual concentrations found of 4 or 5 indicate that in the actual keys the yield point is exceeded in several points; i.e., the actual stress condition is part elastic and part plastic. This means that, practically, the plastic flow of the material results in much lower concentrations—which concentrations, even, must not be considered serious for static-stress application.

The discusser has for some time been engaged in the work of rationalizing key design. The limits set are: For a maximum allowable shear stress in the shaft S, the shear stress in the key is set at $1.5\,S$ and the bearing stress at $4.5\,S$. This results in key widths of approximately $^1/_4$ of the diameter or less, and key heights of $^2/_3$ the width—which are practical key dimensions. In application, the bearing stress is held at the yield point of the material used, which means that at several localized areas the stresses exceed the yield point, and without disastrous results.

FIG. 26

Regarding the point the authors make that a chamfered key causes high concentrated stress when the key turns slightly, it must be said that this concentration is highly local, and again is probably of no serious consequence. It is detrimental, however, to have keys with too large chamfers, for by far the most common type of key failure is by rolling out of place.

In the photoelastic section of the paper, the authors have discussed the question of stress separation. Although, in most cases, the photoelastic method's usefulness is to give a qualitative picture of the stress distribution, there are times when the actual distribution of normal stresses is necessary. When lateral extensometers are not available for measuring $(p + q)$ effects (the best method is that due to Favre, using the interferometer), this discusser has resorted to a graphical method, which he feels is simpler than that due to Filon or Mesnager.

[16] Development Section Engineer, Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Consider the general stress system, as shown in Fig. 26, and the element below it. From considerations of equilibrium, it can be shown that

$$\left.\begin{aligned}\frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau}{\partial x} = 0\\ \frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau}{\partial y} = 0\end{aligned}\right\}\ldots\ldots\ldots\ldots\ldots\ldots[1]$$

Integrating these equations partially, we get

$$\left.\begin{aligned}\sigma_{y1} = -\int_{y_0}^{y_1}\frac{\partial \tau}{\partial x}\,dy + \sigma_{y0}\\ \sigma_{x1} = -\int_{x_0}^{x_1}\frac{\partial \tau}{\partial y}\,dx + \sigma_{x0}\end{aligned}\right\}\ldots\ldots\ldots\ldots[2]$$

which, added, give

$$\sigma_{y1} + \sigma_{x1} = -\left[\int_{y_0}^{y_1}\frac{\partial \tau}{\partial x}\,dy + \int_{x_0}^{x_1}\frac{\partial \tau}{\partial y}\,dx\right] + \sigma_{y0} + \sigma_{x0} \ldots\ldots\ldots[3]$$

From a knowledge of stress conditions at a point in a plane, it is known that

$$\sigma_y + \sigma_x = \sigma_1 + \sigma_2 \ldots\ldots\ldots\ldots\ldots\ldots[4]$$

where σ_1 and σ_2 are the principal stresses at the same point.

Our method now has for its aim the determination of the $(\sigma_1 + \sigma_2)$ network, which, when superimposed on the $(\sigma_1 - \sigma_2)$ network that comes directly from the photoelastic measurements, will give us σ_1 and σ_2 separated at every point in the stress distribution. We thus wish to construct lines of constant $\sigma_1 + \sigma_2 = K$.

Let us introduce the new variable s into [3], where s is the distance along a $\sigma_1 + \sigma_2 = K$ line. Thus [3] reads

$$\sigma_{y1} + \sigma_{x1} = K = -\left[\int_{s_0}^{s_1}\left(\frac{\partial \tau}{\partial x}\frac{dy}{ds} + \frac{\partial \tau}{\partial y}\frac{dx}{ds}\right)ds\right] + K \ldots[5]$$

or

$$\int_{s_0}^{s_1}\left(\frac{\partial \tau}{\partial x}\frac{dy}{ds} + \frac{\partial \tau}{\partial y}\frac{dx}{ds}\right)ds = 0 \ldots\ldots\ldots\ldots[6]$$

defines a line of constant $\sigma_1 + \sigma_2$. Realizing that

$$\frac{dy}{ds} = \sin\alpha; \qquad \frac{dx}{ds} = \cos\alpha$$

then

$$\int_{s_0}^{s_1}\left(\frac{\partial \tau}{\partial x}\sin\alpha + \frac{\partial \tau}{\partial y}\cos\alpha\right)ds = 0 \ldots\ldots\ldots[7]$$

holds. The only way that [7] can hold is that the integrand itself is zero, and so we have

$$\frac{\partial \tau}{\partial x}\sin\alpha + \frac{\partial \tau}{\partial y}\cos\alpha = 0 \ldots\ldots\ldots\ldots\ldots[8]$$

or

$$\tan\alpha = -\frac{\partial \tau/\partial y}{\partial \tau/\partial x} \ldots\ldots\ldots\ldots\ldots\ldots[9]$$

Thus the slope of the $\sigma_1 + \sigma_2 = K$ line is at every point given by the ratio of the shear-stress gradients, and enables one to proceed from point to point very accurately and quickly. The shear-stress gradients $\partial\tau/\partial y$ and $\partial\tau/\partial x$ are obtained directly from the photoelastic results, so that the $(\sigma_1 + \sigma_2)$ network is as accurately obtained as the $(\sigma_1 \overset{-}{+} \sigma_2 = 2\tau)$ network is known.

R. E. Peterson.[17] In a number of failures of keyed shafting, the writer has noticed that the fatigue fracture occurred at the end of the keyway where a stress concentration additional to that treated by the authors is present. There are two general types of keyway end, as shown in Fig. 27—the profiled keyway, made with an end mill, and the sled-runner keyway, made with a slotting mill. Fatigue cracks originate at the places indicated in Fig. 27.

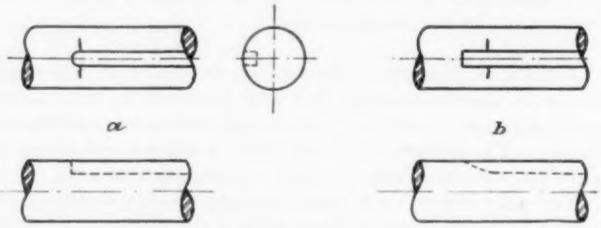

Fig. 27 Failure at Ends of Keyway
(a, profiled keyway; b, sled-runner keyway.)

Bending-fatigue tests now in progress indicate considerable advantage in the sled-runner keyway as compared with the profiled keyway. The point in making this statement is to indicate that the failure of keyed shafting is in general a three-dimensional problem.

Max M. Frocht.[18] Aside from the information which the paper furnishes for the problem of shear stresses in keys and keyways, it raises the fundamental issue of white light versus monochromatic light in photoelasticity. Before discussing this issue, however, the writer wishes to comment on the interpretation of stress patterns, equipment, and annealing process of bakelite.

On the second page the authors say: "If a monochromatic light be used,....the field will be darkened for those points of the plate where the retardation is equal to $^1/_2$, $^3/_2$, $^5/_2$, etc., wave lengths.....Fringes of the first, second, third, etc., orders will correspond to retardations of $^1/_2$, $^3/_2$, $^5/_2$, etc., wave lengths." These, in the writer's opinion, are erroneous statements. The numbers referring to the wave lengths should be replaced by 1, 2, and 3, respectively. The statement in the paper would be correct for the case of light vibrations in one plane in which vibrations of the same amplitude but having phase differences of odd-halves wave lengths annul each other. This is not the case here. The two rays traveling through any point in the stressed model lie in the principal planes—that is, in planes mutually perpendicular and not in one plane. For such conditions dark fringes appear for those points in the model which produce relative retardations or phase differences which in no way disturb the character of the entering ray. If, as is the case in photoelastic investigations, the ray entering the stressed model be circularly polarized, then dark fringes will appear for those stressed points for which the ray emerging from the model is also circularly polarized and of the same sign of rotation. It should be evident that this will be true only for additional phase differences of an integral number of wave lengths. For retardations of odd-halves wave lengths the emerging ray, it is true, remains circularly polarized, but its sign of rotation is reversed relative to the entering ray, and this results in a field of maximum illumination.

[18] Associate Professor of Mechanics, Carnegie Institute of Technology, Pittsburgh, Pa.

Quarter-Plates. On the fourth page, second column, the authors state that the function of the circularly polarized light is to remove the isoclinic from the stress pattern. This is undoubtedly an important function of the circular ray. There is, however, another important function which this ray performs and which the authors fail to mentoin. The use of circularly polarized light results in the removal of the directional effect of stress; that is, it is supposed to make the color at a point, or the fringe order, independent of the directions of the principal stresses. The writer will return to this point farther on in the discussion.

Equipment. It seems to the writer that the equipment used by the authors is unnecessarily complicated. This is especially true of the calibration frame, Fig. 4, the only function of which is to apply two couples to a beam. The main frame can be designed to produce bending as well as tension or compression. Nor is there a good reason for the rather intricate design of the calibration beam, shown in Fig. 4, necessitating careful and costly machining, when a simple, straight prismatic bar will suffice.

Annealing. It seems that the two authors do not agree on the exact nature of their claim regarding the annealing process. Thus Mr. Solakian implies essential differences[19] between the writer's process and the one described in the present paper, whereas Mr. Karelitz thinks that the two methods coincide. Mr. Karelitz[19] says: "Our observations regarding the ease of annealing, procedure, and temperature *coincide*[20] with those of the author,[21] which is gratifying." Two points of difference are mentioned by Mr. Solakian: one gives an annealing temperature of 75 to 85 deg. cent., against "about 70 deg. cent." as given by the writer; the second specifies that the models be kept at the annealing temperature for "at least one hour," contrasting it with 15 minutes' heating time given by the writer. In comparing the one hour against the 15 minutes, Mr. Solakian compares time intervals referring to different operations of the annealing process. The 15 minutes refers to the time taken by the writer to bring furnace and model to the required temperature; the time of "at least one hour" specified by the authors refers to the interval for which the models must be kept at the annealing temperature. These intervals represent totally different things. Again, in view of the small temperature gradient of the annealing furnace and the rather high tolerance of the annealing temperature, the writer fails to see the need for the specification of "at least one hour." To be more explicit, if the models be brought to the average annealing temperature of 80 deg. cent. and left alone in the furnace, the temperature at the end of one hour would be approximately 76 deg. cent., the average gradient being about 4 deg. cent.[22] In other words, the furnace will automatically keep the models within the range of the annealing temperature for at least one hour. The specification referred to is thus superfluous and tends only to unnecessarily complicate the process.

With regard to the higher annealing temperature which the authors propose, the writer wishes to observe, first, that their lower limit of 75 deg. cent. is not so very remote from "about 70 deg. cent.," as specified by the writer, and, second, that the scores of models successfully annealed by the writer, and shown photographically in his papers, prove that there is no need for such high temperatures.

Shear Stresses. It seems that this paper contains either too much material or not enough. If, as the authors believe, the principal stresses are of little practical value to the designer, then why go to the trouble of determining isoclinics and stress trajectories? The only practical value of these curves when not used to find the shear values is to facilitate the determination of the principal stresses, which the authors, as a matter of policy, do not determine. The writer cannot subscribe to the over-simplified theory that the principal stresses are of little practical value to the designer. Aside, however, from the importance or unimportance of the principal stresses by themselves, they are necessary in order to verify the correctness of the shear values. A complete solution would contain a static check and a continuity check. A static check is the minimum essential in a problem of stress analysis, and it is regretted that the authors have not made such a check.

Light. Referring to the more fundamental question of white light versus monochromatic light, the writer will discuss the alleged advantages of white light in the order in which they are summarized on the sixth page, the first column.

Paragraph (*a*) states, "Black and white photographs of the isochromatics are now obtained as easily as of the monochromatics." This seems vague and inconsistent with a preceding statement in which the authors concede that "monochromatics give more distinct pictures."

The writer is inclined to agree with the point made in (*b*) that isochromatics when projected or printed are more impressive, but would like to add that they are also less reliable. Compare, for example, Figs. 10 and 11. The two photographs are supposed to be of one and the same stress pattern, with the black fringes of Fig. 11 corresponding to the greens of Fig. 10. A casual inspection, however, reveals numerous differences. The differences between the two pictures are so great that they can hardly be attributed to the effect of creep and explained by the lapse of time between the taking of the pictures. If the effect of creep were pronounced enough to cause such differences, photoelastic research would hardly be possible.

Paragraph (*c*) states that black regions corresponding to $p - q = 0$ are easily detected in the isochromatics. This is true. It is equally true, however, that a little experience enables one to tell these points with relative ease when a mercury-vapor lamp is used. All one needs to do is to remove the color filter, and the dark spots come into relief. Also, due to the stationary character of these points, they are easily recognized with monochromatic light.

Paragraph (*d*) states, "With three-color bands in the isochromatics against two-color in the monochromatics, the optical sensitivity of bakelite is increased in the ratio of 3 to 2." On first thought this sounds plausible. Let us, however, examine this statement more carefully. Suppose we assume that a bakelite model $^{1}/_{4}$ in. thick is subjected to fairly high stresses within the elastic limit—say, stresses of the order of the 15th fringe. Let us further assume that the white-light stress pattern would distinctly reveal all the corresponding 15 greens.[23] To obtain the alleged increase in optical sensitivity all the 45 isochromatic bands of yellow, red, and green would have to be clearly identified. Let us see, however, what actually happens. Quoting as authority the authors of this paper, on the ninth page, the first column, they state: "It will be observed that in nearly all cases the yellow color beyond the fourth order is not represented in the isochromatics on account of the fact that at high stresses it is very difficult to discriminate it from red and green colors." In other words, according to their own experience it would only be possible to recognize 4 yellow bands out of the 15, and we should thus have a maximum of 34 bands[24] instead of 45, whereas with monochromatic light we should obtain 30. The ratio of the sensitivities would thus be 34 to 30 and not 45 to 30, as claimed in paragraph (*d*). The alleged ratio of 3 to 2 would have more weight if we deliberately restricted the stress range to the fourth green. It must be understood, however, that the important thing is not how many points can be obtained within an arbitrarily restricted range of low stress, *but how many points can be obtained for the maximum stress within the elastic limit.*

[20] Italics by the present discusser.

[21] The present discusser.

[22] If 80 deg. cent. be the average annealing temperature, 22 deg. cent., the approximate room temperature, and 14 hours, the average time for cooling, we have for the average temperature drop per hour $(80 - 22)/14 = 4.1$ deg. cent., approximately.

[23] This assumption is contrary to fact and it is made solely in order to show that under the most favorable conditions the contention of the authors is unwarranted.

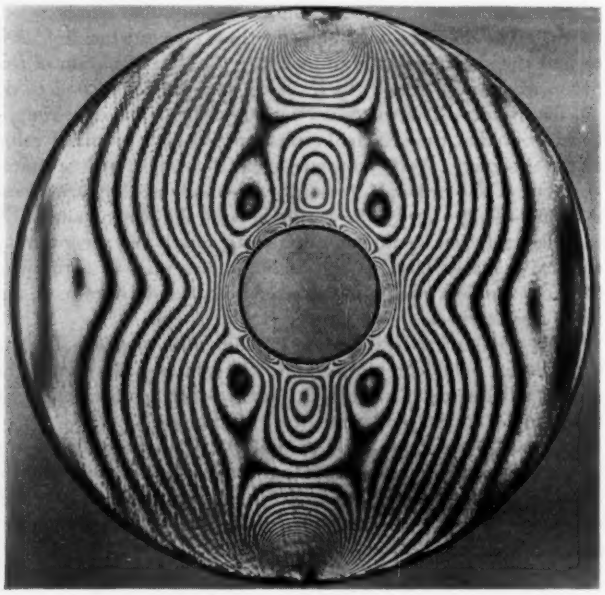

FIG. 28 DISK WITH HOLE UNDER VERTICAL CENTRAL LOADS (Annealed bakelite model. Monochromatic light.)

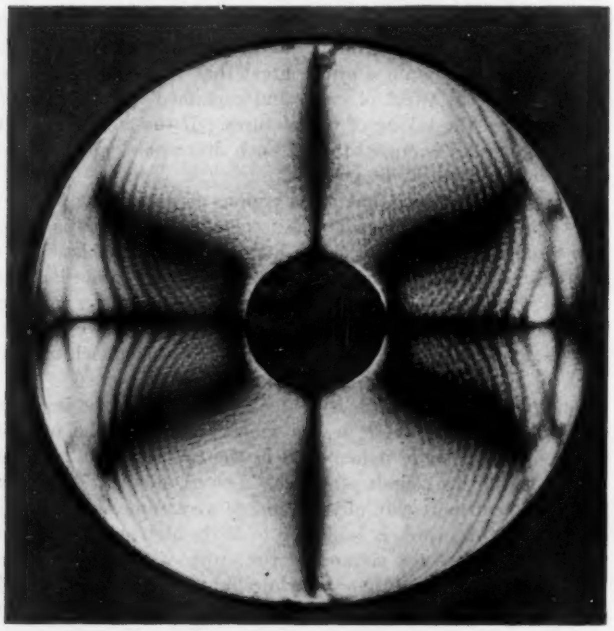

FIG. 29 DISK WITH HOLE UNDER VERTICAL CENTRAL LOADS (Annealed bakelite model. White light. Black curves represent the zero isoclinics. Note vagueness of isochromatics of higher order. Loads slightly greater than in Fig. 28.)

This, however, is not all. The 34 to 30 ratio, as already suggested, has been granted for the sake of discussion only. In reality the sensitivity with monochromatic light is greater than with white light. The authors have undoubtedly observed that isochromatics become narrower and fainter as their order increases. In fact, beyond the fifth green the colors become so crowded and washed out as to be of little value. Assuming that all isochromatics can be traced with accuracy (a task not always easy to perform, especially in the presence of creep) and taking as a practical limit the sixth green, we have a total of 18 isochromatic bands. With the fringe method the patterns are distinct even beyond the fifteenth fringe. We thus have within the elastic limit at least 30 bands with the fringe method, against 18 with white light, or an effect equivalent to an increase in the optical sensitivity of 5 to 3. This increase in sensitivity is clearly shown by Figs. 28 and 29. Attention is called to the absence from Fig. 29 of all the rich detail around the hole and about the vertical diameter of Fig. 28.

Paragraph (*e*) sets forth the imaginary difficulties of determining the fringe order with monochromatic light against the ease and simplicity of white light. Leaving for a moment the question of difficulty in determining the fringe order, the writer wishes to point out that even in the white-light method essentially the same difficulties exist. The process of counting is as necessary with white light as it is with monochromatic light, since the order of a color band must be known before a numerical value can be attached to it. The same is true about the need for slow loading. If the fringe pattern is of the escaping type, so is the color pattern, and to determine the number of escaping isochromatics one has to watch their formation during their slow loading just as in the case of fringes. As a matter of fact the determination of the fringe order presents no difficulties.

Effect of Creep. Mr. Solakian seems also to consider the effect of creep less detrimental with white light than with monochromatic light.[25] The existence of optical creep is, however, a strong point against the white-light method and in favor of the fringe or monochromatic method. It requires only a second or a fraction thereof to take an accurate fringe photograph of any stress pattern regardless of its complexity. The amount of time, however, necessary to sketch isochromatics is vastly larger and varies with the stress pattern. Consider, for example, Fig. 9, *a-e*. It would take at least 15 minutes to sketch any one of these, or approximately 900 seconds. The existence of creep is therefore bound to affect the drawing of the isochromatics at least 900 times more than it does the picture. The sharpness of the fringe photographs obtained by the monochromatic method is evidence of the absence of effect of creep. The fringe photographs should be taken immediately after the load is applied, and the determination of the fringe order should be carried out later. The presence of creep during the determination of the fringe order is of no importance.

Directional Effect. An inherent defect of the white-light method of paramount importance will now be pointed out—the directional effect of stress when white light is used. Consider two elements *A* and *B* in a body subjected to a two-dimensional-stress system, Fig. 30. Let us assume that the principal stresses on these elements are equal in magnitude, but differ in direction. If a ray of plane-polarized light be transmitted through this body, it will be resolved into rectilinear components in directions of the principal stresses whose magnitudes will depend on the direction of the plane of vibration of the impinging ray. If, for concreteness, the impinging plane-polarized ray has vibrations in a vertical plane, the components would be as shown in Fig. 30. In such cases the optical effect of a stress system acting upon an element would depend on the direction of their stresses as well as on their magnitudes. To obviate such a condition the plane-polarized ray is converted into a circularly polarized one, which breaks up into equal components regardless of the directions of the principal stresses. Such a condition is implied in the stress optic law $R = C\ (p - q)$, which does not contain the directions of the stress system. Now, the most effective way to produce circular polarization is by means of a quarter-plate. But a quarter-plate has meaning only when used with monochromatic light. There evidently can be no quarter-plate for white light. If white light be merely the combined effect of the fundamental colors having different wave lengths, then obviously a quarter-plate can be made to fit one but not all the colors simultaneously. Thus, white light gives elliptic polarization and not circular, with a consequent result that there is a directional effect of the stresses at a point. The writer has made some experiments to verify this theory. Strips of celluloid and bakelite were subjected to tension and placed in the path of the circular (?) ray of the polariscope, using white light. The strips were then rotated in the plane normal to the axis of propagation of the ray, and the changes of color were observed. The experiment showed that while the celluloid strip seemed to hold its color, the bakelite strip showed pronounced changes. Starting with a deep green in the vertical position, the color changed and showed a clear tinge of red in the horizontal position, indicating a possible error of approximately 20 per cent. What seemed to be evidence of circular polarization with celluloid thus proved to be evidence of its small optical sensitivity. There is therefore a directional effect when white light is used. Such, however, is not the case with monochromatic light. Here a quarter-plate can be made to produce true circular polarization, thereby eliminating directional effect and increasing the accuracy of the work.

---

[24] 4 yellows, 15 reds, and 15 greens.

[25] See paragraph (*a*) of Mr. Solakian's discussion of writer's paper, "On Recent Advances in Photoelasticity," loc. cit.

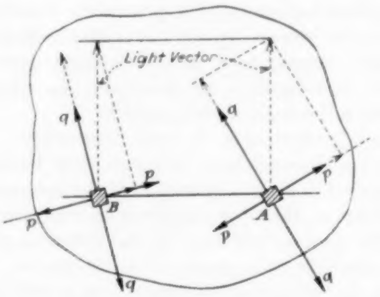

FIG. 30 DIAGRAM SHOWING THAT COMPONENTS OF LIGHT VECTOR DEPEND ON DIRECTIONS OF PRINCIPAL STRESSES

The fringe or monochromatic method has also the advantage that it makes practicable the taking of clear moving pictures and thereby contributes an effective tool for many fields of investigation, especially for the study of impact stresses.

The writer advocates the use of the fringe or monochromatic method because he believes that it has genuine merits and superiorities over the white-light method. This, however, does not mean that he bans white light from his laboratory. There are two occasions on which he uses white light: one is when sketching isoclinics, the other when investigating the sign of stress—two uses of white light which seem to have escaped the attention of the authors.

The paper will undoubtedly stimulate further interest in photoelasticity. It is gratifying that this useful and interesting field of investigation is beginning to receive the attention that it merits.

ALPHONSE A. ADLER.[26] As a member of the Committee on the Standardization of Shafting, Keys, and Keyways, the writer is much interested in the results given in this paper. Requests continually come before this committee to standardize square and rectangular keys for large sizes of shafting. It is the writer's belief that because of the importance of fit of key and keyway and the crudeness of the theory underlying their design, it would be unwise to standardize the larger sizes, since this might convey the impression that such keys represent good machine design.

It is the writer's opinion that the tangent type of key shown in Fig. 1 is much better adapted to heavy work than the rectangular key, since it can be removed and reinstalled with a reasonable degree of certainty of complying with assumptions made in its original design. This is not usually true in the ordinary rectangular key unless it is generous in its proportions.

The tangent type of key is installed in pairs, as shown in Fig. 31, each key having two tapered wedges, which must be driven with an initial compression sufficiently great so that any torque applied in the direction of driving will not release the trailing key of its entire initial compression. Tangent keys are not commonly used, perhaps because their merits for heavy duty are not fully appreciated.

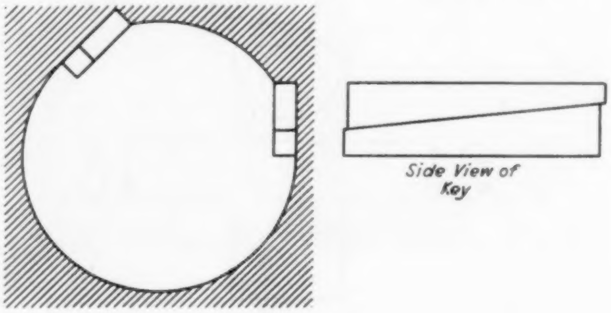

FIG. 31

Moreover, tangent keys might have their taper so adjusted that any reasonable predetermined compression pressure could be obtained along the length of the key to insure proper division of torque along this dimension. This is almost a hopeless task for the ordinary rectangular key, and if it were possible, the dismantling and reassembling would disturb the initial stress distribution.

In view of this, perhaps the authors would like to continue their experiments to test out the merits of the tangent keys. The writer will be pleased to assist by giving the formulas for their design which he used while engaged in teaching machine design.

H. F. MOORE.[27] In this interesting paper reference has been made to tests of the effect of keyways on the strength of shafts made some 23 years ago at the University of Illinois.[28] These tests were all *static* tests and an arbitrarily determined elastic limit[29] was used as a criterion of strength. This gives a fairly reliable index for *static* strength, but should not be relied on as an index of the weakening effect of a keyway under repeated stress.

[NOTE: Discussion of this paper jointly with that of Max M. Frocht by Prof. Raymond J. Roark will be found following the latter paper.]

AUTHORS' CLOSURE

The authors are much gratified by the interest the various discussers have taken in the paper.

Mr. Den Hartog's remarks are correct in so far that a key problem is to a certain extent a three-dimensional case. This is also emphasized in Mr. Peterson's discussion. As a matter of fact there are few stress problems of an absolutely two-dimensional nature. However, the general stress distribution in a cross-section of the keyed shaft is probably not very different from that given in the paper, particularly for regions of the key not including the very first tenth division close to the highest-stressed end. Considering the fact that the width of the model used for stress analysis is a very small fraction of the length of the key and assuming that Mr. Den Hartog's stress representation along the length (l) of the key under a torque from both ends is correct quantitatively, the rate of stress variation over a length (δl) equal to the thickness of the model (Fig. 32) is so small as to have a negligible effect on the general stress distribution in the cross-section of the mechanism at that section.

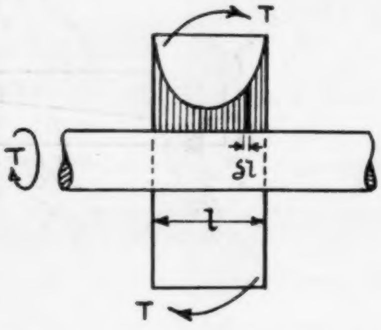

FIG. 32 TORQUE TRANSMITTED THROUGH THE KEY

Several other methods of producing torque in the model were tried, but the one described in the paper was finally adopted because it did not appreciably affect, even with the maximum torque, the stresses developed in the neighborhood of the keyway.

Mr. Stone's proposition of determining a $p + q$ stress network from the $p - q$ stress network by the application of a formula giving the slope of the $p + q$ line in terms of the shear-stress gradient has its definite merits, and seems to be much simpler than the Maxwell-Filon method of graphical integration commonly used for such cases. Mr. Z. Tuzi tried a similar method about five years ago with good results.

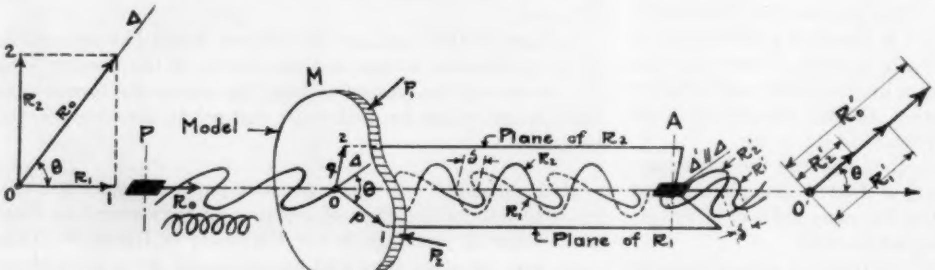

FIG. 33 OPTICS OF POLARIZED LIGHT IN A PHOTOELASTIC APPARATUS

Professor Roark's remarks are to a certain degree true with regard to the limitations of the photoelastic investigations to the range of stresses within the elastic limit of the material. However, the authors believe that it is possible to investigate problems even though the stresses exceed the elastic limit of the bakelite.

Mr. Adler's tangent type of key certainly deserves a special photoelastic investigation to determine its characteristics as compared with the types already tested.

Dr. Frocht's discussion is very interesting. The authors appreciate his thoroughness, although they hardly agree with him with regard to his interpretation of the contents of the paper and especially to the way employed in representing it to the public. The authors will take up the different points about in the same order that they appear in the discussion.

It is not an "erroneous statement" to ascribe the successive appearance of stress fringes to retardations of $^1/_2$, $^3/_2$, $^5/_2$, ... etc. wave lengths of monochromatic light, instead of 1, 2, 3,... etc. The difference between the two, as a matter of fact, is a question of origin of reference. However, it is interesting to note that the discusser himself proves the validity of the authors' statement. According to the discusser's conception, "the statement in the paper would be correct for the case of light vibrations in one plane....... The two rays traveling through any point in the stressed model lie in the principal planes, that is, in planes mutually perpendicular and not in one plane....." Let us refer to Fig. 33, in which R_0 represents (approximately) a ray of circularly polarized monochromatic light emerging from the polarizing prism P and vibrating in any plane Δ at the instant of striking the plate. The ray after its passage through the stressed transparent model M refracts into two rays R_1 and R_2, each vibrating in the planes of the two principal stresses p and q mutually perpendicular to each other. The discusser's observations of light vibrations refer to this section of the optical set, which is a wrong section of reference as the stress fringes are formed due to interference of the two refracted rays taking place after these rays pass through the analyzing prism A, which brings the vibrations of the two rays into *one plane* Δ' parallel to Δ, as shown in the above-mentioned figure—a condition imposed by the discusser for the validity of the authors' statement.

Quarter-Plates. This part is considered under "Directional Effect."

Equipment. The authors do not consider the equipment "unnecessarily complicated." The optical set is the simplest of its kind ever designed, having the smallest number of lenses and other component parts. The calibrating-beam apparatus serves also as a Coker compensator. The suggestion of replacing this with a "simple, prismatic beam" in a research laboratory is a little hard to accept for accurate results.

Annealing. The discusser is much worried about the discrepancies in the methods of annealing of bakelite and the "discovery" of the process. Regarding "the priority" in making public an annealing process for bakelite as claimed by the discusser in his oral discussion, the authors merely wish to remark that their method was informally disclosed to a group of members of the A.S.M.E. Applied Mechanics Division, as part of an exhibit of the photoelastic equipment of Columbia University, on April 21, 1931, about two months before the discusser's paper was presented. The discusser's insistence on lower temperature in annealing and a shorter time of heating than that specified by the authors does not stand a scientific test. In addition, it has not been efficient in certain cases, as is evident from his remark that "in cases of stubborn stresses a second annealing will be found effective."

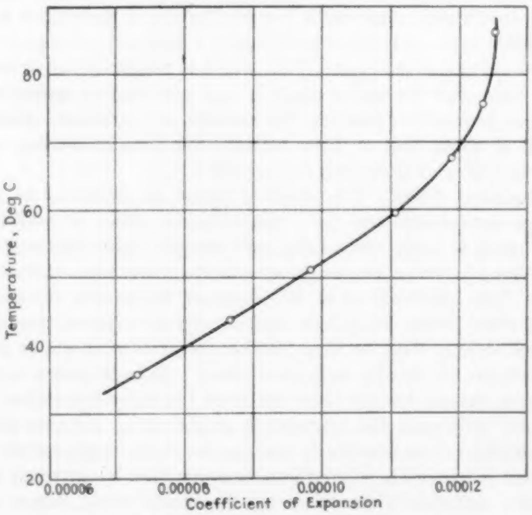

Fig. 34 Relation Between Temperature and Coefficient of Expansion of Bakelite

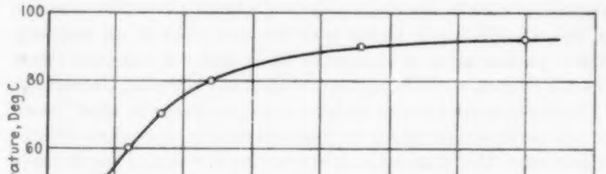

Fig. 35 Relation Between Temperature and Time of Conduction of Bakelite

Fig. 34, showing the relation between temperature and the coefficient of expansion of bakelite, demonstrates that expansion is continuous up to about 80 deg. cent. At this point the material enters a plastic stage, in which cohesive strength is a minimum, so that internal equilibrium is most easily attained. Remembering that bakelite is one of the best-known insulators of heat, one would hardly expect ten minutes' heating to produce a uniform temperature throughout its thickness, even when in the form of a $^{1}/_{4}$-in. plate. This is borne out by Fig. 35, showing temperature differences between interior and exterior plotted against time. It will be seen that after only ten minutes a large difference exists; the interior temperature continues to rise for slightly more than an hour (the minimum limit specified by the authors and for a constant heat value). Without thermal equilibrium, stress equilibrium cannot be expected.

Shear Stress. The authors have already stated that the principal stresses are not necessary to a practical designer, who is mostly interested in the concentration of the stresses in general and the failure phenomenon present in the mechanism. Isoclinics and stress trajectories are given in the Appendix only for one type of key, with a short description, as frequent reference was made in the paper to them. A knowledge of the directions of the maximum shear stresses is an asset to the designer, and the curves representing these could not have been obtained without the help of the isoclinics or stress trajectories. It is a vague statement to say that the principal stresses are necessary in order to verify the correctness of the shear values, as the first can be computed only when the shear values are already known.

Light. The authors are now in a position to state that with the addition of a pair of filters to their optical set, the white light—still keeping the three predominant colors on the screen—gives as distinct a photographic print of the object as that obtained with mercury monochromatic light, as will be seen in Fig. 36, which shows the stress fringes in a Dardelet self-locking bolt and nut connection.

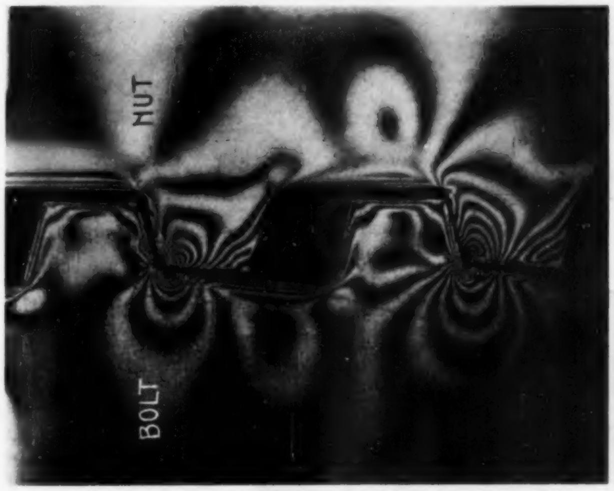

Fig. 36 Stress Fringes in a Dardelet Self-Locking Bolt and Nut

(Taken with white light.)

The authors regret that the discusser compares Figs. 10 and 11 to prove that "the isochromatics are less reliable," as during the presentation of the paper it was mentioned that the color photograph in Fig. 10 was not identical with that given in Fig. 11 for reasons of non-originality in loading conditions for both cases and the difficulties encountered in obtaining a good color print of the image. Besides, footnote No. 13 should have been a sufficient safeguard against comparing the two figures.

The optical sensitivity of bakelite cannot be measured by the total number of fringes produced under a very high stress, and it does not depend upon the quality of light, as it is a characteristic of the material itself, such as is the case in comparing glass, celluloid, phenolite, bakelite, etc. Moreover, it is a prohibitive practice to try to produce a large number of stress fringes, on account of plastic deformation and creep in the material, which is a prevailing phenomenon in nearly all the stress patterns of the discusser. Although attractive to the eye, it renders the pictures worthless from the point of view of stress analysis.

The authors' statement in paragraph (*e*) concerning the ease of determining the order of an isochromatic fringe with white light is found to be "imaginary." Let us refer back to Fig. 36. As will be seen, there are possibly six to eight regions in the picture where the stresses originate or fringes constantly change under a continuously changing tension in the bolt. With monochromatic light there should be about an equal number of observers each counting the number of fringes passing a certain reference mark, or 6 to 8 repeated loadings and unloadings of the model, which being composed of three separate parts (the figure shows only one-half of the model) there will be no originality of stress condition corresponding to each stage, besides the introduction of permanent set in the material as a result of repeated fluctuations of stress. A second case is that shown in Fig. 37, in which the fringes represent the $p-q$ stresses in a portion of a shrink-fit connection, where the diameter of the disk is slightly larger than the hole in the ring. As these fringes are formed during the gradual cooling down of the preheated ring during a long period of time in an annealing oven, the question of counting the fringes during their formation is not practicable. Further cases in which the use of monochromatic light is still more prohibitive have come to the attention of the authors in connection with recent studies of the stresses in reinforced-concrete structures and shrinkage stresses in composite materials, of which a case is that given in Fig. 38, representing the initial stresses in a bakelite specimen developed during the cooling of the material with a bar of metal inserted in the mold. Unless one knows the exact order of one or more of these fringes, the solution of the problem is an impossible one with monochromatic light. As the authors have already stated, for such cases, even in the absence of the neutral line, or one or two fringes, the orders of the other ones can be determined quite easily with white light from the hues of their respective colors of the lower-order isochromatics.

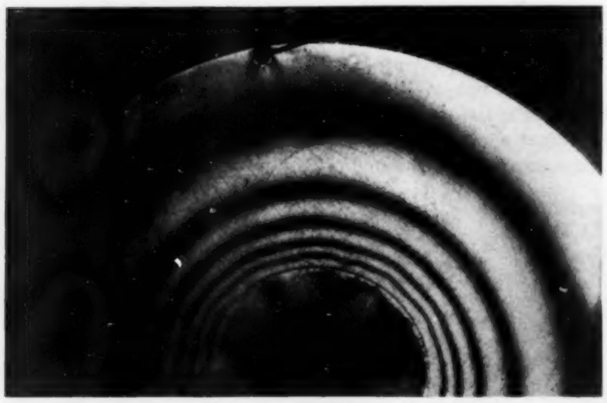

FIG. 37 SHRINK-FIT STRESS FRINGES IN A RING
(Taken with white light.)

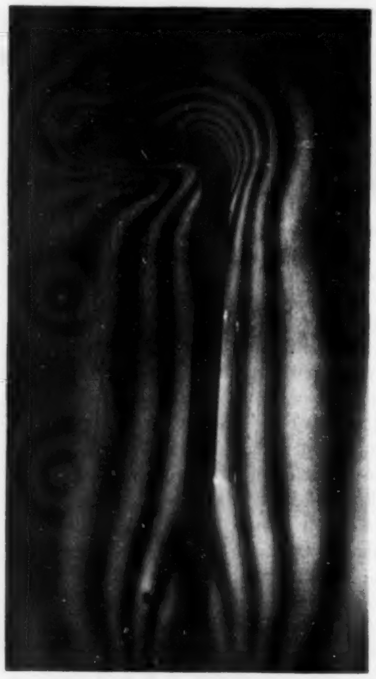

FIG. 38 STRESS FRINGES DUE TO SHRINKAGE AND PULL IN THE ROD
(Taken with white light.)

Effect of Creep. This is practically null for the maximum stress limits adopted by the authors in their tests—about 8 fringe orders. Such an effect can be observed in the experiments of the discusser where more than 25 fringes possibly exist at a point. The sharpness of a fringe photograph is not a sign of absence of creep, on account of the very short time allowed for exposure, amounting to one or two seconds only. But if it does not affect the plate, it certainly has a constantly changing effect on the deformations produced in the model, as a result of which pictures taken at different times after the application of a constant load will differ from each other to a degree which depends upon the rate of change of the creep effect, which is relatively larger for a short time after the load is applied. As a precaution against the slightest creep effect possible, the authors, as a principle, allow a period of about half an hour between the time of loading and photographing or sketching the isoclinics.

Directional Effect. The physical principles involved in this section are correct only for a quarter-wave plate; in addition, they apply to both white light and mercury light—although in less degree to the latter—as there is no absolutely monochromatic light. The observations of the discusser concerning the directional effect of the white light and quarter-wave plate, however, are not strictly true, as there are two quarter-wave plates in a photoelastic set, one for each nicol prism. As both plates are of identical nature, having been cut from the same mica sheet of constant thickness, the retardation produced by the first plate (which may not be necessarily one-quarter wave length for all the different colors of the white light) is neutralized by an equal and opposite retardation produced by the second plate, hence the directional effect of the white light does not exist with a well-designed optical set. An explanation of the change of color obtained by the discusser in his experiments of rotating a piece of stressed bakelite in circularly polarized white light is that possibly the two quarter-wave plates used are not alike in all respects. Such a phenomenon of change of color under a constant stress does not happen with the optical set used at Columbia University.

The authors are pleased to hear from the discusser that "there are two occasions on which he uses white light, one when sketching isoclinics, the other when investigating the sign of the stress—two uses which seem to have escaped the attention of the authors." Unfortunately there is no mention of such a use in either publications of the discusser; on the other hand, one reads the contrary in the expression that: "The sodium lamp (highly monochromatic) which was used for isoclinics was replaced by the mercury-vapor lamp....etc." As the authors' work throughout has been done with white light for isoclinics as well as for the stress fringes, it was not necessary to mention that fact repeatedly. Concerning "the sign of the stress," as stress fringes obtained with either light are lines of constant shear stress or $(p-q)/2$, and not of p or q separately, there is no specific sign for shear stress, whether it is due to tension, or compression, or any possible combination of the two. If the discusser refers to a beam under constant bending moment, the neutral black fringe only serves to separate the tension region from that of compression, but does not tell whether a certain fringe corresponds to tensile stress or compression, unless the conditions of bending are known beforehand. Even then in this case, the distinction is only for a limited field of the beam as the neutral axis is not a continuous line from one end of the beam to the other, and besides, in this specific case, the stresses in the beam are only the p stresses, as the q stresses are zero.

Before concluding, the authors would call attention to another interesting fact in connection with Figs. 28 and 29 which the discusser has inserted to prove the "increased optical sensitivity of bakelite by the use of monochromatic light." At first glance this may seem to be true for one who has not had much experience with photoelasticity. However, it is not very difficult to detect that Fig. 28, corresponding to monochromatic light, is taken with *circular polarized light,* giving very sharp fringes, while Fig. 29, corresponding to white light, is taken with *plane polarized light,* as is evident from the absence of the isoclinics from Fig. 28 and their appearance in Fig. 29; as a result of the presence of these black fringes with a slightly dark hue in the field of the plane polarized light, the color fringes in Fig. 29 do not appear in a way as they should. In addition, the time of exposure for both cases is different, which is why the black isoclinic is much clearer than the color fringe in the print. For such a comparison of the two lights, Fig. 7 in the paper would give the discusser all the information necessary.

The authors thank Professor Moore for his correction of footnote 3.

APM-54-11

The Center of Torsion for Angle and Channel Sections

By W. L. SCHWALBE,[1] URBANA, ILL.

The author presents a method of determining the position of the center of torsion in a channel section when the bar, held at one end, is subjected to a torsional couple. The case of the angle section is first investigated and an expression for the distance from the center line of leg to the center of torsion is determined. The case of the channel section is then analyzed by the same method.

FOR THE determination of longitudinal tensile and compressive stresses that exist in an I-beam or channel when the bar is subjected to a torsional couple only, with one cross-section of the bar remaining plane, that is, free from any torsional warping, it is necessary to know the location of the axis about which the bar twists. For sections such as the I-section with rectangular axes of symmetry, the axis of torsion coincides with the centroidal axis of the bar, but for sections with only one or no axis of symmetry this is not the case.

The terms "shear center"[2] and "center of twist"[3] have been used to denote the point in the plane of the cross-section of a beam through which the plane of the transverse bending loads must pass in order that no torsional effect be present. If the plane of the loads does not pass through this point, then the cross-section rotates with respect to this point and the bar is in combined bending and twist. A. Eggenschwyler[4] has given the formula $x_B = \frac{I_{xy}'h}{I_x}$ for the location of the shear center (Fig. 1); where I_{xy}' is the product of inertia of the half-section with respect to the x and y axes and I_x is the moment of inertia of the whole cross-section with respect to the x-axis. Similar formulas have been obtained by R. Maillart[5] and by C. Weber.[6]

A series of tests was made at the University of Illinois (reported in Bulletin 211 of the Experiment Station) in order to locate the shear center for channel-beam sections ranging in depth from 4 to 15 in. The arrangement of the beam is shown in Fig. 2. The method of locating the shear center is illustrated in Fig. 3.

A comparison of values for x_B, as obtained by different methods, is given in Table 1. The method for determining the distance $x_B = \frac{h}{2}\frac{x_c}{y_c}$ (from the web center to the center of torsion) for the channel section when the bar is subjected to torsion only, is given in the following analysis.

ANGLE SECTIONS

The determination of the axis of torsion for channel shapes depends on the location of the axis of torsion for angle shapes, the channel-shaped cross-section being regarded as made up of angle elements. An angle bar, fixed at one end, is subjected at the free end to a torsional couple M (Fig. 4). The moment of the couple M is such as to rotate any cross-section of the bar at distance z from the fixed end, through a small angle θ about a center B (Fig. 5), without appreciably changing the shape of the cross-section. The whole angle section is considered to be made up of two rectangular elements L_1 and L_2, of lengths h and widths w. The rotation of the section as a whole with respect to center B may then be resolved into translations of the legs L_1 and L_2 and rotations of the legs about their respective centroidal centers c_1, c_2 (Fig. 6). In Fig. 6 the center lines only of the sections are shown. Now the translational displacement $\overline{c_1c_1}'$ of the leg L_1 from position I to position I', may be regarded as a bending deflection of the element since one end of the member remains fixed. Similarly, $\overline{c_2c_2}'$ is the bending deflection for L_2. After the bending deflections of the legs L_1 and L_2 have taken place, then the two elements are twisted with respect to centroidal centers c through angles θ until continuity is established at O and the final position of the section, as a whole, results. Longitudinal stresses due to torsion are negligible compared to the bending stresses. This picture of the action furnishes a basis for locating the center of torsion B for the section as a whole in the following way. For a small angle θ the deflection, arc $\widehat{c_1c_1}'$ (see Fig. 7), may be regarded as a straight line, hence the deflection curve of the leg L_1 lies in a plane. This plane may be taken as tangent to the deflection, arc $\widehat{c_1c_1}'$, at the point c_1. The neutral plane N_1 for the bending action of the rectangular section L_1 is perpendicular to the plane of the deflection curve and passes through the centroid c_1. Since the center of rotation B_1 for the arc $\widehat{c_1c}'$ lies on a line which is per-

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

pendicular to the tangent of the arc at the point c_1 it follows that the point B lies on the neutral axis N_1. Similar considerations for the leg L_2 lead to the conclusion that B lies on N_2, the neutral axis for L_2. Hence B is determined by the intersection of N_1 and N_2 (Fig. 6).

In order to determine the neutral axis N_1 let the x and y components of the deflection $\overline{c_1c_1}'$ be ξ_1 and η_1, respectively. Then the bending stress in the section L_1 is

$$S_1 = \frac{M_{y1}x_1}{I_{y1}} + \frac{M_{x1}y_1}{I_{x1}} \dots\dots\dots\dots\dots [1]$$

where M_{x1} and M_{y1} are the x and y components of the bending moment in L_1 and I_{x1}, I_{y1} are the moments of inertia of the cross-sectional area with respect to the axes x_1 and y_1, respectively (Fig. 5).

FIG. 2 ARRANGEMENT OF CHANNEL BEAM FOR TESTING

For the leg L_2 the bending stress is

$$S_2 = \frac{M_{y2}x_2}{I_{y2}} + \frac{M_{x2}y_2}{I_{x2}} \dots\dots\dots\dots\dots [2]$$

The equations of the neutral axes N_1 and N_2 are obtained from the stress Equations [1] and [2] by putting $S_1 = S_2 = 0$.

$$S_1 = \frac{M_{y1}x_1}{I_{y1}} + \frac{M_{x1}y_1}{I_{x1}} = 0 \dots\dots\dots\dots [3]$$

$$S_2 = \frac{M_{y2}x_2}{I_{y2}} + \frac{M_{x2}y_2}{I_{x2}} = 0 \dots\dots\dots\dots [4]$$

Subjecting Equation [3] to the transformation of coordinates $x_1 = x$, $y_1 = y - h_1/2$, then

$$\frac{M_{x1}}{I_{x1}}\left(y - \frac{h_1}{2}\right) + \frac{M_{y1}}{I_{y1}}\,x = 0 \dots\dots\dots\dots [5]$$

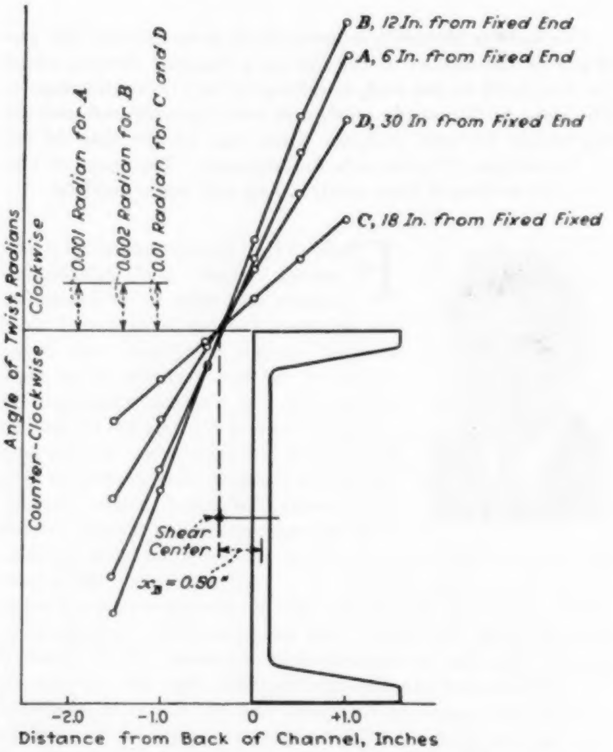

FIG. 3 SHEAR CENTER FOR 4-IN. 5.4-LB. CHANNEL TESTED AS A CANTILEVER WITH LENGTH OF 55 IN. AND LOAD OF 270 LB. AT END

Also, letting $x = x_2 + h_2/2$ and $y = y_2$, Equation [4] becomes, with reference to the origin of coordinates at O,

$$\frac{M_{x2}y}{I_{x2}} + \frac{M_{y2}}{I_{y2}}\left(x - \frac{h_2}{2}\right) = 0 \dots\dots\dots\dots [6]$$

The coordinates of the intersection of Equations [5] and [6] are then given by

$$\left.\begin{aligned} x_B &= \frac{\dfrac{h_1}{2} - \dfrac{h_2}{2}\,\dfrac{I_{x2}M_{y2}}{I_{y2}M_{x2}}}{\dfrac{I_{x1}}{I_{y1}}\,\dfrac{M_{y1}}{M_{x1}} - \dfrac{I_{x2}}{I_{y2}}\,\dfrac{M_{y2}}{M_{x2}}} \\ y_B &= \frac{h_1}{2} - \frac{I_{x1}}{I_{y1}}\,\frac{M_{y1}}{M_{x1}} \cdot x_B \end{aligned}\right\} \dots\dots\dots\dots [7]$$

The ratios of the bending moments in the expressions for x_B and y_B in terms of known quantities may be determined as follows. Since the two legs L_1 and L_2 are continuous at the point O, the bending stress in L_1 at O is equal to the bending stress in L_2 at the point O. This condition may be formulated as $S_{1,o} = S_{2\,o}$ or

$$\frac{M_x h_1}{I_{x1}} - \frac{M_{y2}h_2}{I_{y2}} = 0 \dots\dots\dots\dots\dots [8]$$

FIG. 5

Again, from the geometric continuity of the section at O, it follows that for a small angle θ (see Fig. 6),

$$\eta_0 = \eta_1 \text{ and } \xi_0 = \xi_2$$

also

$$\xi_1 = \frac{h_1}{2}\theta - \xi_2 \qquad \text{and} \qquad \eta_2 = \frac{h_2}{2}\theta - \eta_0$$

Combining the above expressions and eliminating θ, there results

$$\xi_1 + \xi_2 - \frac{h_1}{h_2}(\eta_1 + \eta_2) = 0 \ldots\ldots\ldots\ldots\ldots [9]$$

Since the deflections ξ and η are continuous functions of the distance z, measured along the axis of the bar, Equation [9] may be differentiated twice with respect to z. Then

$$\frac{d^2\xi_1}{dz^2} + \frac{d^2\xi_2}{dz^2} - \frac{h_1}{h_2}\left(\frac{d^2\eta_1}{dz^2} + \frac{d^2\eta_2}{dz^2}\right) = 0 \ldots\ldots\ldots [10]$$

Multiplying [10] by E, the modulus of elasticity of the material (assuming a homogeneous, isotropic material) and by making use of the bending-moment-curvature relation

$$E\frac{d^2(\;)}{dz^2} = \frac{M}{I}$$

there results

$$\frac{M_{y2}}{I_{y2}} + \frac{M_{y1}}{I_{y1}} - \frac{h_1}{h_2}\left(\frac{M_{y1}}{I_{x1}} + \frac{M_{x2}}{I_{x2}}\right) = 0 \ldots\ldots\ldots [11]$$

Since the whole member is under the action of torsional couples only, it is clear that the summation of the bending moments on legs L_1 and L_2 must equal zero. Hence

$$M_{x1} - M_{x2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

$$M_{y1} - M_{y2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

Equations [8], [11], [12], and [13] are compatible if

$$I_{y2}I_{x2} = I_{y1}I_{x1} \quad\ldots\ldots\ldots\ldots\ldots\ldots [14]$$

From Equations [8], [11], [12], and [13]

$$\frac{M_{y2}}{M_{x2}} = \frac{M_{y1}}{M_{x1}} = \frac{h_1}{h_2}\frac{I_{y2}}{I_{x2}}$$

Substituting in [7] and making use of [14] there results

$$\left.\begin{aligned} x_B &= \frac{h_2}{2}\frac{I_{y1}}{I_{y1}+I_{y2}} \\ y_B &= \frac{h_1}{2}\frac{I_{y1}}{I_{y1}+I_{y2}} \end{aligned}\right\} \quad\ldots\ldots\ldots\ldots\ldots [15]$$

CHANNEL SECTIONS

When a straight channel bar of cross-section as shown in Fig. 8 is subjected to a twisting couple M, one section in the bar remaining plane, the method for determining the center of torsion is similar to that given for the angle. The rotation of the channel section about some center B is resolved into a translation or bending deflection of the angle A_1 (Fig. 9) from position I to position I' and a rotation of this angle about its center of torsion B_1, to the final position; a translation of the angle A_2 from position II to position II′ and a rotation of A_2 about its center of torsion B_2 to the final position, continuity being established at O.

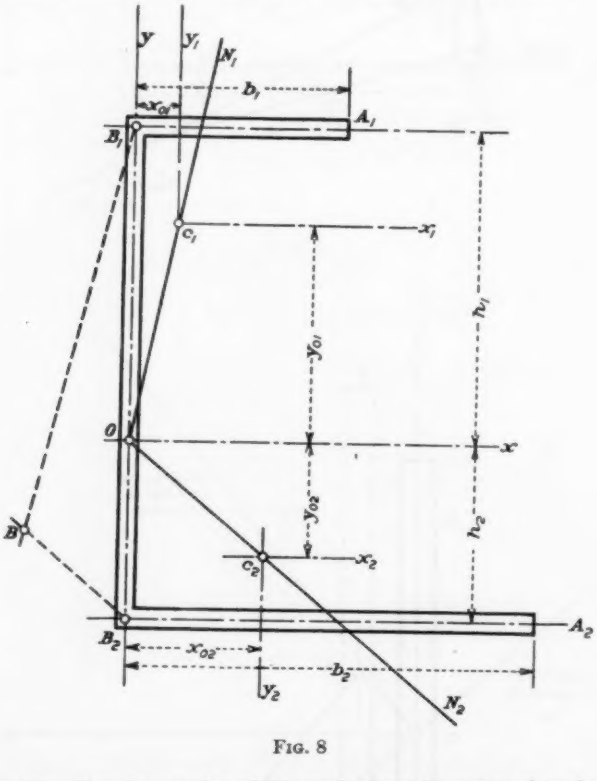

FIG. 8

Since the bending deflections are perpendicular to the neutral bending axes, it is only necessary to determine the intersection of lines drawn through B_1 and B_2, parallel to the neutral axes N_1 and N_2, in order to locate the center B.

The neutral axes N_1 and N_2 are determined if the point O is known, where O is that point on the center line of the web of the channel which has no longitudinal or bending stress; hence it is a point on both neutral axes. If O is known, then the angles A_1 and A_2 with the centroids c_1 and c_2 are determined.

The point O may be determined approximately by satisfying similar conditions as those given in the discussion for the angle alone. That is,

1 Bending stress $S_{1,o} = S_{2,o} = 0$
2 Continuity at O
3 Equilibrium.

The stress conditions may be written thus

$$S_{1.o} = \frac{M_1{}^h x_{o1}}{R_1{}^h} - \frac{M_1{}^v y_{o1}}{R_1{}^v} = 0 \quad\ldots\ldots\ldots\ldots [16]$$

$$S_{2.o} = -\frac{M_2{}^h x_{o2}}{R_2{}^h} + \frac{M_2{}^v y_{o2}}{R_2{}^v} = 0 \quad\ldots\ldots\ldots\ldots [17]$$

$$\frac{M_1{}^h x_{o1}}{R_1{}^h} - \frac{M_1{}^v y_{o1}}{R_1{}^v} + \frac{M_2{}^h x_{o2}}{R_2{}^h} - \frac{M_2{}^v y_{o2}}{R_2{}^v} = 0 \quad\ldots\ldots [18]$$

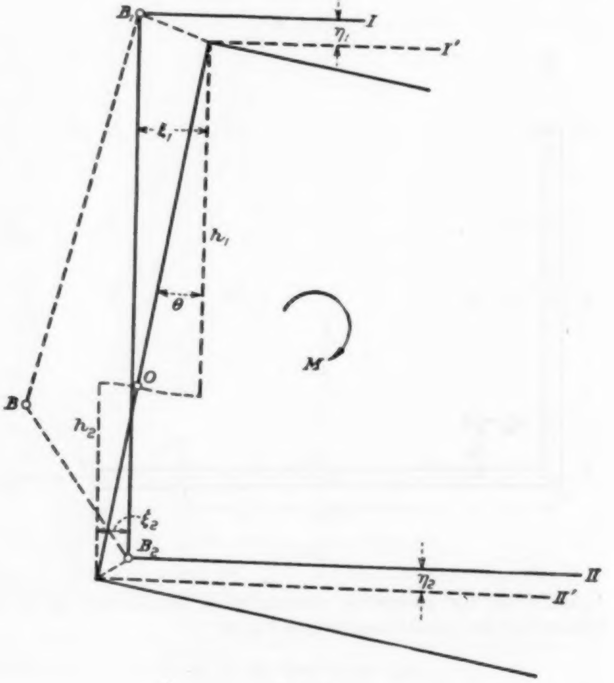

FIG. 9

where M^h is the bending moment for which the horizontal deflection ξ is the effect, and M^v is the bending moment for which the vertical deflection η is the effect.

$$R^h = \sqrt{I_y{}^2 + I_{xy}{}^2} \quad \text{and} \quad R^v = \sqrt{I_x{}^2 + I_{xy}{}^2}$$

where I_x, I_y and I_{xy} are the moments and product of inertia of the angle section with respect to x-y-axes with the origin of coordinates at the centroid c of the angle section. The subscripts 1 and 2 refer to the angles A_1 and A_2 with origins at c_1 and c_2, respectively.

The continuity equations are obtained from the following conditions which are evident from Fig. 9:

$$\eta_1 = \eta_2$$

$$\frac{h_1}{h_2}\xi_2 - \xi_1 = \left(\frac{h_2}{h_1} + 1\right)\xi_o$$

ξ_o is the horizontal displacement of the point O. For a small angle of rotation θ, ξ_o may be neglected, hence

$$\frac{h_1}{h_2}\xi_2 - \xi_1 = 0$$

The equations which express continuity then are

$$\frac{M_1^v}{R_1^v} - \frac{M_2^v}{R_2^v} = 0 \qquad [19]$$

$$-\frac{M_1^h}{R_1^h} + \frac{h_1}{h_2}\frac{M_2^h}{R_2^h} = 0 \qquad [20]$$

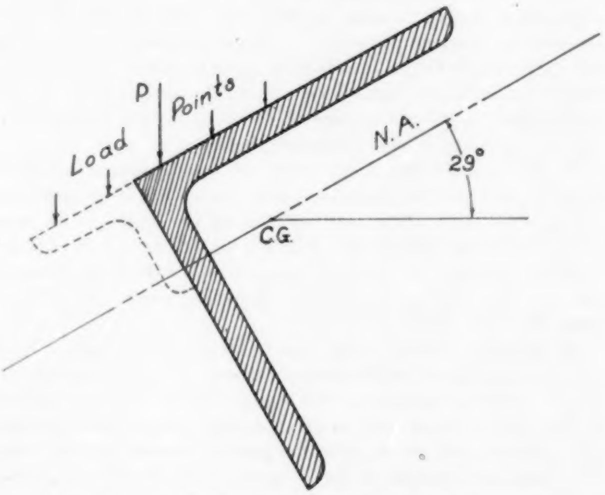

FIG. 10 ARRANGEMENT OF ANGLE BEAM FOR TESTING

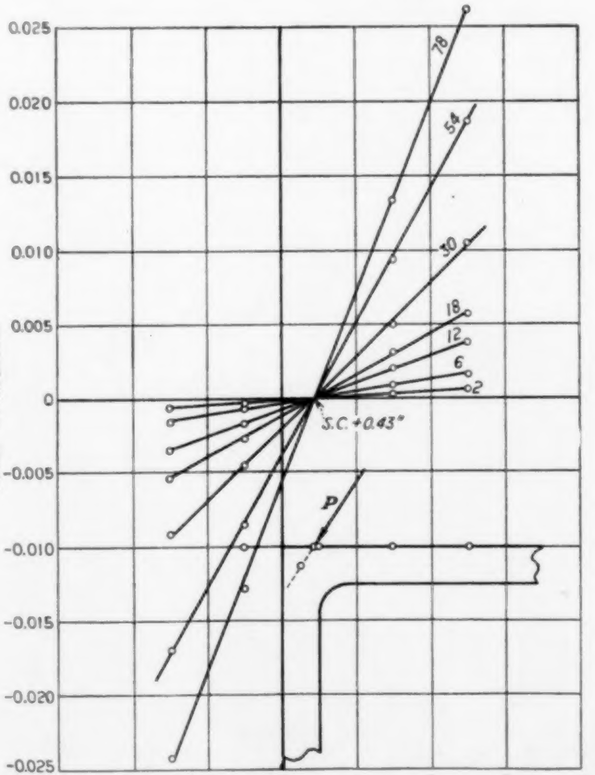

FIG. 11 LOCATION OF SHEAR CENTER OF 6-IN. BY 6-IN. BY $^1/_2$-IN. ANGLE BEAM SET AT 29 DEG.

The condition of equilibrium for the section as a whole is: $M_1 + M_2 = 0$. In terms of the x and y components of M_1 and M_2 the equations of equilibrium become

$$-\frac{I_{(xy)1}}{R_1^h} M_1^h + \frac{I_{x1}}{R_1^v} M_1^v - \frac{I_{(xy)2}}{R_2^h} M_2^h + \frac{I_{x2}}{R_2^v} M_2^v = 0 \qquad [21]$$

$$\frac{I_{y1}}{R_1^h} M_1^h - \frac{I_{(xy)1}}{R_1^v} M_1^v - \frac{I_{y2}}{R_2^h} M_2^h + \frac{I_{(xy)2}}{R_2^v} M_2^v = 0 \qquad [22]$$

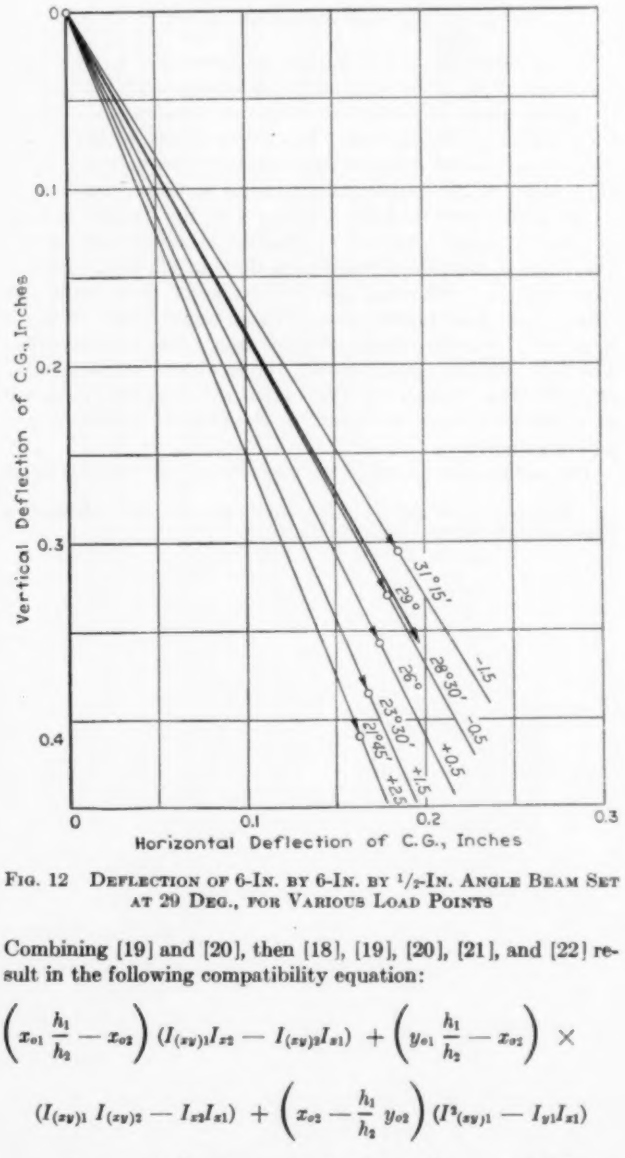

FIG. 12 DEFLECTION OF 6-IN. BY 6-IN. BY $^1/_2$-IN. ANGLE BEAM SET AT 29 DEG., FOR VARIOUS LOAD POINTS

Combining [19] and [20], then [18], [19], [20], [21], and [22] result in the following compatibility equation:

$$\left(x_{o1}\frac{h_1}{h_2} - x_{o2}\right)(I_{(xy)1}I_{x2} - I_{(xy)2}I_{x1}) + \left(y_{o1}\frac{h_1}{h_2} - x_{o2}\right) \times$$

$$(I_{(xy)1}\,I_{(xy)2} - I_{x2}I_{x1}) + \left(x_{o2} - \frac{h_1}{h_2}\,y_{o2}\right)(I^2_{(xy)1} - I_{y1}I_{x1})$$

$$= (y_{o1} - y_{o2})\,(I_{(xy)1}I_{y2} - I_{y1}I_{(xy)2}) - (x_{o1} - y_{o1})\,(I^2_{(xy)2}$$

$$- I_{x2}I_{y2}) - (y_{o1} - y_{o2})\,(I_{x1}I_{y2} - I_{(yx)1}I_{(xy)2}) \qquad [23]$$

Equation [23] is then solved for h_1/h_2 in order to locate O. For any special case the solution is easily found by successive approximations.

Where the cross-section has an axis of symmetry as in the usual rolled-steel channel, Equation [23] results in $h_1/h_2 = 1$. The center of torsion B then lies on the axis of symmetry and at a distance x_B from the web center (Fig. 1). Making use of Equation [15] the value of x_B is found to be

$$x_B = \frac{h}{2}\frac{x_c}{y_c} - \left(x_{B1} + y_{B1}\frac{x_c}{y_c}\right) \qquad [24]$$

For sections of small width w, x_{B_1} and y_{B_1} for the angle section may be put equal to zero, hence

$$x_B = \frac{h}{2}\frac{x_c}{y_c} \qquad [25]$$

Discussion

Wm. J. Putnam.[7] The author has presented a very clear derivation of a usable equation for determining the location of the shear center or center of torsion for unsymmetrical structural shapes of thin section. The writer simply wishes to add some corroborative evidence as to the correctness of the equations given in their application to angle sections.

The author cites in Table 1 values of x_B for channel sections of various weights and sizes, obtained experimentally at the University of Illinois and reported in Bulletin 211 of the Experiment Station. Following the publication of those data, the writer made some further tests using an angle section, 6 in. × 6 in. × $^1/_2$ in., 8 ft. long, embedded in a 12-in. concrete cube. The cube was then held between the head and weighing table of a 200,000-lb. testing machine so that the angle iron projected as a cantilever beam as shown for the channel sections in the author's Fig. 2.

The section was placed in the concrete so that the legs made an angle of 29 deg. to the horizontal and vertical, as shown in Fig. 10, in order that the neutral axis, which is perpendicular to the plane of the deflection, would be parallel to one leg. The load consisted of a weight hung on the free end of the beam in various positions across the top flange or that plane extended.

The angle of twist for each position of the load was measured at seven sections along the beam by means of a level bar on a 20-in. gage length reading to 0.001 in. The results of these readings are shown in Fig. 11, by which the position of the load for no twist is found to be at 0.43 in. from the corner of the angle. Since the angle has equal legs, the shear center will be at the intersection of the action line of the load in this position and the bisector of the angle between the legs.

In this manner the shear center is found experimentally to be at a point 0.27 in. from the back of each leg. Applying the author's Equation [15] and considering the angle to be composed of two rectangles each 5.75 in. by 0.5 in., x_B and y_B are found to be 0.022 in. from the intersection of the center lines of the two legs, which means that the shear center is 0.272 in. from the back of each leg.

Incidentally, while taking the observations on twist, readings were also taken of the horizontal and vertical displacements of the center of gravity of the angle. These data are plotted in Fig. 12 and show that when the load was applied through shear center with the angle in the position stated, the deflection was practically normal to the computed direction of the neutral axis.

A New Type of Dynamic-Balancing Machine

By ERNEST L. THEARLE,[1] SCHENECTADY, N. Y.

In this paper is described a novel type of dynamic-balancing machine developed for production balancing. The machine employs an automatic compensating device, making it possible for an unskilled operator to obtain accurate readings of amount and position of unbalance correction with great rapidity. The theory underlying the action of the machine is given and the characteristics of the automatic balancing head are investigated. The method of operating the machine is explained and data on the accuracy of balance obtainable are included.

During the past few years the manufacturers and users of many kinds of machinery have become greatly concerned with the problem of vibration elimination. In general the solution of this problem lies in (1) proportioning the parts of the machine to avoid any conditions of resonance, and (2) reducing to a minimum the forces tending to excite vibration. We are here concerned with the practical accomplishment of this latter task by means of the dynamic balancing of rotating parts.

The modern tendency toward more complete motorization, where a number of electric motors may be mounted on and directly connected to a machine, has led the manufacturer of that machine to pass at least a part of the responsibility for the smooth running of his product to the motor manufacturer. Consequently, the motor manufacturer is demanding dynamic-balancing equipment with which unskilled operators can quickly and accurately balance motor rotors. An effort to satisfy this demand has resulted in the dynamic-balancing machine described in this paper.

The Rotor-Suspension System

It may readily be shown, both analytically and experimentally, that any substantially rigid rotating body can be correctly and completely balanced by the addition (or removal) of two weights, one in each of two arbitrarily chosen transverse planes of the body. In general, two weights are both necessary and sufficient to obtain a correct dynamic balance. The two transverse planes in which the balancing weights are applied (or removed) will be known as the "planes of correction." These planes of correction and the radii at which the balance corrections are applied may be chosen arbitrarily, or to suit the convenience of attachment or removal of weight. The function of the balancing machine is thus to determine four quantities which are the amounts of the two correction weights and their angular positions relative to the rotor to be balanced.

Consider a rotor mounted as shown diagrammatically in Fig. 1, where z is the axis of rotation, S an elastic supporting member such as a spring, and P a pivot permitting angular oscillation of the rotor in a vertical plane about the horizontal axis O. B and C are the chosen balance-correction planes. When rotating about the axis z, such a rotor in a general state of unbalance will oscillate in a vertical plane about the axis O of the pivot.

It will now be possible, by any one of a number of known methods, to determine a balance-correction weight W_1 which, when applied to the rotor in the correction plane C and in the proper angular position, will suppress the previously observed oscillations. When this balance correction is accomplished, the rotor will run smoothly in the support shown in Fig. 1. This complete absence of oscillation indicates that the application of weight W_1 has so altered the distribution of rotating mass that the resultant of all remaining unbalanced forces has no moment about the pivotal axis O and is therefore a single force lying in the transverse plane A containing the pivotal axis.

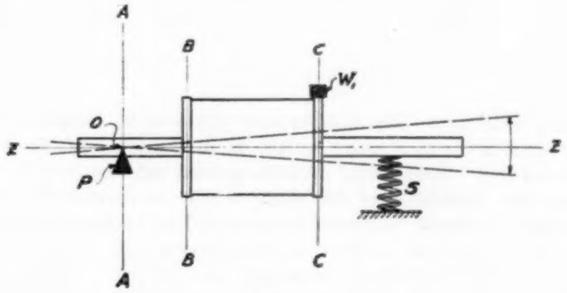

Fig. 1

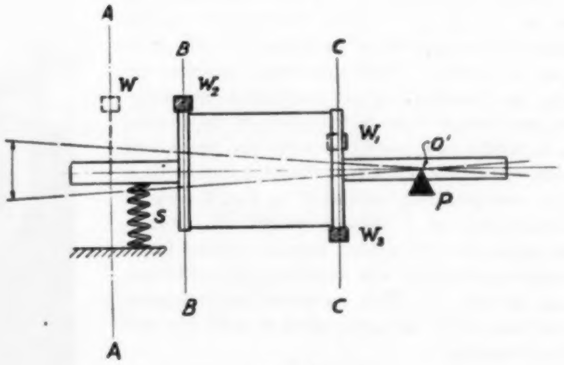

Fig. 2

If the rotor is now mounted as shown in Fig. 2 with the pivotal axis displaced to a new position O', a single weight W can be found which will complete the balance if applied to the rotor at the correct angular position in the first pivotal plane A. Since, as shown, in Figs. 1 and 2, it is impracticable to attach a permanent correction weight to the rotor in the plane A, this hypothetical weight W must be replaced by its equivalent, composed of the two weights W_2 and W_3 in the chosen correction planes B and C, respectively. This method is frequently undesirable, since it requires an application to the rotor of a total of three balancing weights where only two are necessary for a correct balance.

As shown in the process just described, after applying the first balance-correction weight W_1 in the correction plane C, the remaining unbalance is a single force lying in the plane of the

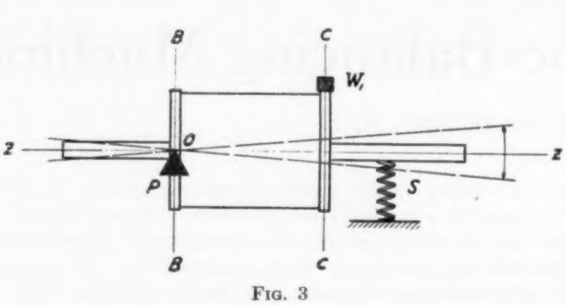

FIG. 3

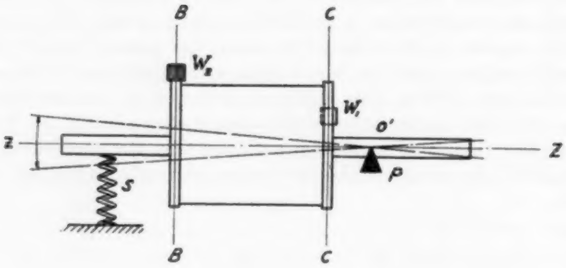

FIG. 4

first pivotal axis. The balance may therefore be completed by the application of a single weight W in the plane of the first pivotal axis. Lawaczeck,[3] in 1908, pointed out that in order to make the application of this single weight convenient, the first pivotal axis should be placed in the second correction plane B.

The rotor to be balanced is now supported as shown in Fig. 3 with the pivot or fulcrum P placed at O, in the second correction plane B. A weight W_1 can be determined which, when applied to the rotor in the plane C and in the correct angular position, will suppress all oscillation of the rotor about the axis O. When this weight has been applied, the resultant of all remaining unbalance must be a single force in the plane of the pivotal axis O, which now coincides with the previously chosen correction plane B. Moving the pivot P to any new position, such as O' in Fig. 4, permits determination of a second weight W_2, which, when applied at the proper angular position in the correction plane B, will suppress all oscillations about the axis O'. This completes the balancing of the rotor with the application of only two correction weights.

The structure supporting the rotor while carrying out the above-described balancing process is shown in Fig. 5. The journals of the rotor rest in half-bearings D mounted in a light but rigid cradle consisting of two longitudinal tubes E clamped in the two cross-members F. The size and spacing of bearings may readily be changed to suit various rotor sizes.

The cradle (with rotor) is carried by four vertical springs and four horizontal springs shown at G and H, respectively, in Fig. 5. Two pairs of flat fulcrum springs, shown at J and K, are clamped to the cradle tubes and project downward between the jaws of fulcrum vises shown at L and M, the latter being rigidly fixed to the frame of the machine. Either pair of fulcrum springs, with their corresponding vises, can be adjusted into any desired transverse plane of the rotor to be balanced. The pivotal axis of the cradle and rotor may be shifted quickly from one transverse plane of the rotor to another by opening the first pair of vises and closing the second pair, thus causing the first pair of fulcrum springs to become inactive and the second pair active. The rotor is driven at constant speed by means of a light and uniform belt from a driving motor.

Consider now the form of restraint imposed upon the cradle and object to be balanced when either pair of fulcrum springs is clamped in its corresponding pair of vises, the other vises being open. Assuming the vises shown at M, Fig. 5, to be open, the fulcrum springs K are inactive and play no part in restraining the cradle. With vises L closed, the lower ends of the fulcrum springs J are rigidly clamped to the frame of the machine. The point O, at the center of the rotor shaft and in the plane of fulcrum springs J, is thus held in a fixed position. Flexure of the fulcrum springs J permits a horizontal oscillation of the cradle and rotor about the vertical axis y and a vertical oscillation about the horizontal axis x. The stiffness of the horizontal cradle springs H is adjusted so that the natural frequency of horizontal oscillation of the cradle and rotor is equal to its natural frequency of vertical oscillation.

For the purpose of analysis, the rotor to be balanced and its supporting cradle, mounted thus, may be replaced by the approximately equivalent system shown in Fig. 6. Since any general state of unbalance can be corrected by the application of two weights, that unbalance may be represented by the same two weights applied in the chosen correction planes, as at u and w in Fig. 6. Here the pivot point O is placed in the plane of un-

[3] See German Patent No. 201,787.

balance u. The unbalance weights u and w are not considered as being a part of the rotor; their respective actions on the rotor are shown, instead, as external forces. The rotor in Fig. 6 is shown in a general position, displaced from its mean or rest position by rotation through an angle α horizontally about the y-axis and an angle β vertically about the x-axis. Its speed of rotation is assumed constant. Our interest lies in the motion of the point S at the center of the shaft, the position of which is described by the coordinates $x = L\alpha$ and $y = L\beta$.

Let

b = a damping factor
g = acceleration due to gravity
I = moment of inertia of rotor and cradle about the axis x or the axis y, assumed to have the same value about any diametral axis through the point O
J = moment of inertia of the rotor about its axis of rotation or shaft center line
k = stiffness factor or spring constant of the equivalent horizontal and vertical cradle-supporting springs, which are assumed adjusted to equal stiffness
u, w = unbalance weights as shown in Fig. 6
ω = rotative speed of rotor, in radians per second

All external forces exerted on the cradle and rotor, except that of gravity, are represented by the vectors appearing in Fig. 6(a). The force of gravity is omitted, as a simplification, since it can be shown to have no influence on the motion of the rotor. Vectors $ur\omega^2/g$ and $wr\omega^2/g$ represent the forces exerted on the rotor by the unbalance weights u and w. This latter expression $wr\omega^2/g$ is approximate; the additional components of this force due to oscillation of the rotor about the point O may be neglected. The reaction at the pivot point O is indicated by vectors Q_x and Q_y. Vectors P_x and P_y represent the resultant of all spring reactions and include all damping or friction forces. The magnitudes of these vectors may therefore be expressed by

$$P_x = kl\alpha + bl\frac{d\alpha}{dt} \qquad [1]$$

and

$$P_y = kl\beta + bl\frac{d\beta}{dt} \qquad [2]$$

Referring now to Fig. 7, the vectors $Id\alpha/dt$, $Id\beta/dt$, and $J\omega$ represent the three components of angular momentum of the rotor and cradle, with respect to their corresponding axes, when the rotative axis of the rotor lies along the line O-n, displaced from the z-axis by the angles α and β. As motion of the rotor continues to any new position such as O-m, with the angular displacement $\alpha + \Delta\alpha$ and $\beta + \Delta\beta$, changes in its angular momentum take place which are represented by the vectors $J\omega\Delta\alpha$, $J\omega\Delta\beta$, $I\Delta(d\alpha/dt)$, and $I\Delta(d\beta/dt)$. The *rates of change* of angular momentum, in the same directions as the *changes*, are shown in Fig. 8 by the vectors $J\omega d\alpha/dt$, $J\omega d\beta/dt$, $Id^2\alpha/dt^2$, and $Id^2\beta/dt^2$.

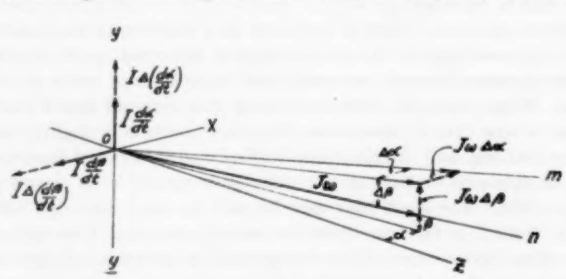

FIG. 7

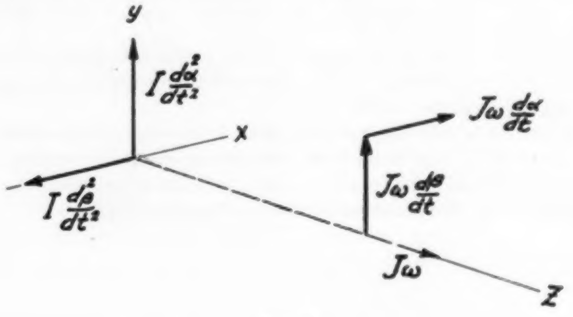
The sum of the moments of all external forces acting on the rotor, as shown in Fig. 6, about either of the axes, x or y, may be equated to the rate of change of angular momentum with respect to that axis as shown in Fig. 8.[3] It must here be borne in mind that the vectors shown in Fig. 6 are *force* vectors, while those in Fig. 8 are *couple* vectors. Thus



y
$I\frac{d^2\alpha}{dt^2}$
X
$J\omega\frac{d\alpha}{dt}$
$I\frac{d^2\beta}{dt^2}$
$J\omega\frac{d\beta}{dt}$
$J\omega$
Z

FIG. 8

$$I\frac{d^2\beta}{dt^2} - J\omega\frac{d\alpha}{dt} = \frac{awr\omega^2}{g}\sin\omega t - lP_y \qquad [3]$$

and

$$I\frac{d^2\alpha}{dt^2} + J\omega\frac{d\beta}{dt} = \frac{awr\omega^2}{g}\cos\omega t - lP_x \qquad [4]$$

Substituting [1] and [2] for P_x and P_y in [3] and [4] and rearranging,

$$\frac{d^2\beta}{dt^2} + \frac{bl^2}{I}\frac{d\beta}{dt} + \frac{kl^2}{I}\beta - \frac{J\omega}{I}\frac{d\alpha}{dt} = \frac{awr\omega^2}{gI}\sin\omega t \qquad [5]$$

$$\frac{d^2\alpha}{dt^2} + \frac{bl^2}{I}\frac{d\alpha}{dt} + \frac{kl^2}{I}\alpha + \frac{J\omega}{I}\frac{d\beta}{dt} = \frac{awr\omega^2}{gI}\cos\omega t \qquad [6]$$

Considering only forced oscillations of the system, the solution of this pair of simultaneous equations is

$$\alpha = A\cos\omega t + B\sin\omega t \qquad [7]$$

$$\beta = A\sin\omega t - B\cos\omega t \qquad [8]$$

where

$$A = \frac{awr[kl^2 - (I - J)\omega^2]\omega^2}{g([kl^2 - (I - J)\omega^2]^2 + l^4b^2\omega^2)} \qquad [9]$$

and

$$B = \frac{awrl^2b\omega^3}{g([kl^2 - (I - J)\omega^2]^2 + l^4b^2\omega^2)} \qquad [10]$$

The resultant angular displacement γ of the rotor shaft from its rest position, at any instant of time, is given by

$$\gamma = \sqrt{\alpha^2 + \beta^2} = \sqrt{A^2 + B^2} \qquad [11]$$

Substituting [9] and [10] in [11],

$$\gamma = \frac{awr\omega^2}{g\sqrt{[kl^2 - (I - J)\omega^2]^2 + l^4b^2\omega^2}} \qquad [12]$$

Since γ is constant with respect to time, the axis of the rotor shaft describes a right circular cone, and any point at the center of the rotor shaft moves in a circular path. The point S thus moves in a circular path of radius ρ, as shown in Fig. 6, where

---

[3] See "Textbook of Mechanics," by E. H. Wood, 1926 ed., sec. 226.

$$\rho = L\gamma \qquad [13]$$

or

$$\rho = \frac{awrL\omega^2}{g\sqrt{[kl^2 - (I - J)\omega^2]^2 + l^4b^2\omega^2}} \qquad [14]$$

This radius ρ will be used here as the amplitude of vibration, since it is proportional to the observed amplitude of vibration of any point on the cradle.

As shown in Fig. 6(*b*), an end view of the rotor, displacement of the point S lags behind the disturbing unbalance weight w by the angle ϕ. Also, $\sin \omega t = \sin \phi$ and $\cos \omega t = \cos \phi$ when γ and $\beta = 0$. Substitution of these in Equation [8] gives

$$\tan \phi = \frac{B}{A} \qquad [15]$$

$$\tan \phi = \frac{l^2b\omega}{[kl^2 - (I - J)\omega^2]} \qquad [16]$$

The resonant speed of the system is here defined as the rotor speed at which the amplitude of cradle vibration is a maximum, with no damping present. When the damping constant b is zero, expression [14] for amplitude obviously becomes a maximum when its denominator vanishes. Imposing this condition gives the resonant speed

$$\omega_r = \sqrt{\frac{kl^2}{(I - J)}} \qquad [17]$$

It may here be pointed out that, since the pivot point O was chosen to lie in the transverse plane containing the unbalance weight u, the above expressions describing the rotor motion are independent of this weight and may therefore serve as a measure of the unbalance weight w alone.

Using data taken from a small balancing machine, carrying a rotor weighing about 34 lb., values of the phase angle ϕ and amplitude ρ were calculated from Equations [16] and [14] and plotted against rotor speed.

The resulting curves, Fig. 9, show the familiar amplitude vs. speed and phase angle vs. speed relations for a system such as this. The amplitude ρ practically reaches its maximum value at the resonant speed of about 1055 r.p.m. and, for the same number of r.p.m. away from this speed, is greater when above the resonant speed than when below.

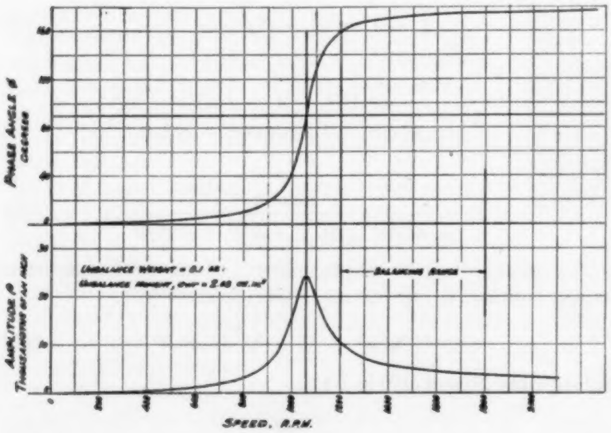


FIG. 9

What is most important to us here is the relation between the phase angle ϕ and speed, as shown by the upper curve of Fig. 9. Since, at constant speed, both the radial displacement ρ of the point S and the phase angle ϕ are constant with respect to time, the motion of the rotor is pure rotation about the axis z. When the speed of rotation of the rotor is somewhat below the resonant speed, the phase angle ϕ is small, hence the displacement of the shaft is in the general direction of the unbalance w. An instantaneous end view of the rotor would appear as shown in Fig. 10(*a*) where its motion is pure rotation about the axis z. The shaft may be said to whirl with its "heavy side" farthest from the axis of rotation.

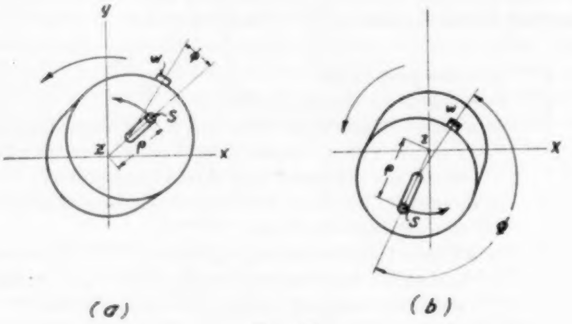

FIG. 10

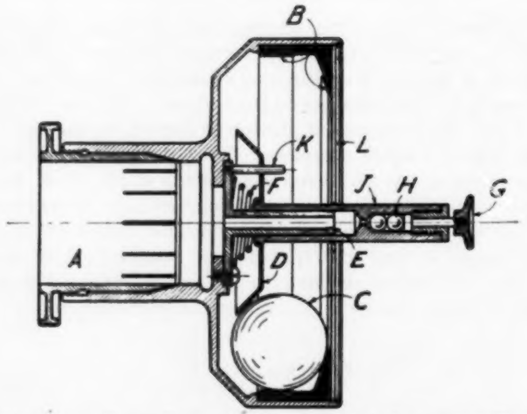

FIG. 11 AXIAL CROSS-SECTION OF ONE TYPE OF AUTOMATIC BALANCING HEAD SUITED TO THE BALANCING OF ELECTRIC-MOTOR ROTORS

When the rotor speed is increased to a value somewhat above the resonant speed, the phase angle ϕ increases quite rapidly when passing through resonance and approaches a value of 180 deg. Thus, when the rotor is running at a constant speed somewhat above that of resonance, the phase angle ϕ is slightly less than 180 deg. and the shaft end is displaced in a radial direction about opposite to that of the unbalance weight w as shown in Fig. 10(*b*). The shaft may now be said to whirl with its "light side" "out," or farthest from the axis of rotation. This motion provides forces which serve to operate an automatic balancing device now to be described.

THE AUTOMATIC BALANCING HEAD

Fig. 11 shows an axial cross-section of one type of automatic balancing head suited to the balancing of electric-motor rotors. This type of head is carried on the end of the rotor shaft, where it is clamped and centered by means of the split-collet chuck A. Pressed into the face of the head is a carefully hardened and ground race B, in which are placed two steel balls C of equal size. These balls are clamped in any position in their race by the conical clutch D, carried by the central staff E, and held against them by the spring F. The clutch is actuated by finger

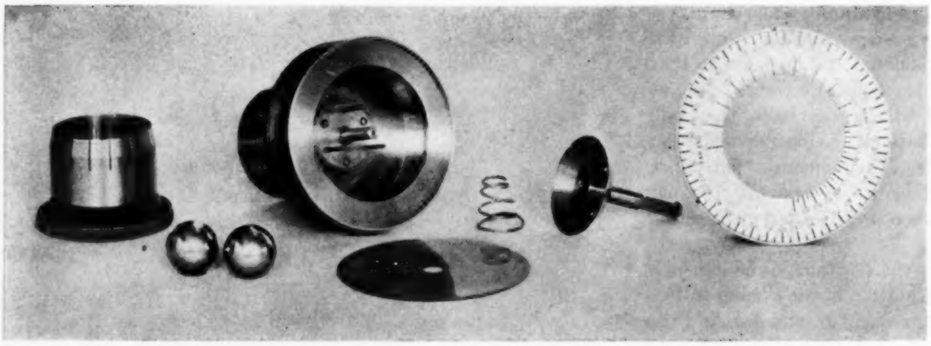

FIG. 12 DISASSEMBLED AUTOMATIC BALANCING HEAD AND SCALE FOR A 1.875-IN. SHAFT

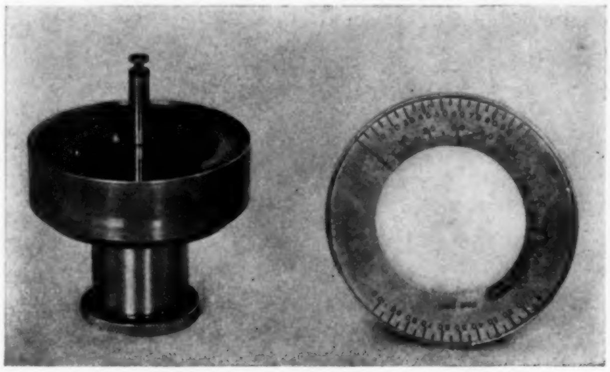

FIG. 13 AUTOMATIC BALANCING HEAD AND SCALE FOR A 1-IN. SHAFT

pressure on the button G, bearing against a ball thrust bearing H in the outer end of clutch sleeve J. Three pins K prevent relative rotation of clutch to ball race. A transparent window L serves to exclude foreign matter.

Fig. 12 shows a balancing head disassembled; a smaller head is shown assembled in Fig. 13. The dials shown, for measuring and bisecting the angle between the balls, are cupped to slip over the outer periphery of the head when needed.

The two steel balls in the balancing head provide the two variables necessary and sufficient to satisfy any condition of unbalance required of the head, within its capacity, when used in conjunction with a pivoted rotor. Thus the head, at any one speed of rotation, may introduce to the rotating system a force, in its plane, in any radial direction, and of any amount varying from zero when the balls are diametrically opposite each other to the full capacity of the head when they are in contact.

Consider this balancing head to be rigidly fixed to the end of the rotor shaft shown in Fig. 6, concentric with the shaft and in the radial plane of the point S. Since we are dealing here with a system pivoted at a point O, the effect of any unbalance weight such as w (Fig. 6) on the system will be proportional to the product of the "unbalance" (wr) and its moment arm (a). In the text following, such a product (wra) will be referred to as a "moment of unbalance."

An axial view of the rotor and head will appear as shown in Fig. 14 where the balls C are shown in any general positions within their race B. The moment of unbalance in the rotor, combined with that introduced by the balls C, is represented by the resultant unbalance vector U. If the speed of rotation of the rotor is somewhat above that of resonance, the phase angle ϕ will be slightly less than 180 deg., and the axis of rotation of the system shown in Fig. 14 will be at Q, with the point S, at the end of the rotor shaft and center of the race, moving in a circle of radius ρ.

Considering its motion and equilibrium to be *relative to the race*, each ball must be treated as existing within a centrifugal force field evidenced by the force $F = Wr'\omega^2/g$ exerted on it in a direction determined by the axis of rotation Q of the system and the center of the ball. At sufficiently high speeds of rotation the influence of gravity becomes negligible.

Assuming the surface of the race to offer negligible rolling resistance, the reaction of the race on a ball will be normal to the race surface and therefore toward its center S, as shown by the vectors N. It is apparent from Fig. 14 that, since the forces F have components tangent to the race, each ball experiences an urge in such a direction e that its displacement in that direction will *decrease* the resultant moment of unbalance of the system. Also, the only condition of rotation of the system under which the balls will be in stable equilibrium relative to the race is that of

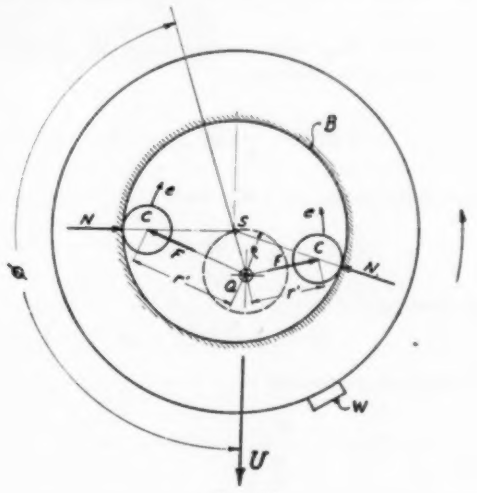

FIG. 14

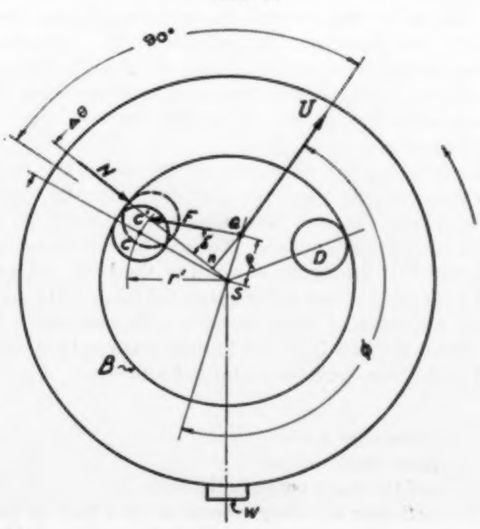

FIG. 15

rotation about the axis S. This condition obtains when the axis Q coincides with axis S, the amplitude ρ is zero, and the moment of unbalance introduced by the balls is equal and opposite to that in the rotor. Thus, when the rotor is running above its resonant speed and the clutch is depressed to free the balls, they will automatically assume the correct positions to suppress oscillation of the rotor and its supporting cradle. The moment of unbalance introduced by the balls must then be equal and opposite to that of the rotor, of which the angle between the balls and its bisecting line serve as a measure.

Let C and D in Fig. 15 represent the positions of equilibrium of the balls relative to their race. Rotation of the system is then about the axis S, and the resultant moment of unbalance of the system is zero. Now assume that the ball C is caused to move through an angle $\Delta\theta$ to a new position C'. This displacement of ball C introduces an unbalance U displaced approximately 90 deg. from position C or C'. The axis of rotation of the system shifts a distance ρ, from S to Q, in a direction determined by the phase angle ϕ. Since equilibrium of the balls is considered as relative to their race, the ball at C', of weight W, must be considered to experience, from the centrifugal force field in which it exists, a force

$$F = \frac{W}{g}(\overline{QC'})\omega^2 \qquad [18]$$

The component of this force tending to return the ball to its equilibrium position is therefore

$$F \sin\delta = \frac{W}{g}(\overline{QC'})\omega^2 \sin\delta \qquad [19]$$

Since, from the geometry of Fig. 15,

$$\sin\delta = \frac{(\overline{Qn})}{(\overline{QC'})} \qquad [20]$$

and, approximately,

$$\overline{Qn} = \rho\cos(180^\circ - \phi) \qquad [21]$$

the restoring force on the ball is

$$F\sin\delta = \frac{W}{g}\rho\omega^2\cos(180^\circ - \phi) \qquad [22]$$

Since comparatively large variations of phase angle ϕ, when near a value of 180 deg., cause only slight variations of the factor $\cos(180^\circ - \phi)$, Equation [22] indicates that a not too great departure of the phase angle ϕ from a value of 180 deg. will have a negligible influence on the stability of the head, and will in no way affect the accuracy of its indications. This has been found to be the case.

In investigating the sensitivity of the balancing head it is necessary to consider the resistance offered by the race to the rolling of a ball. In Fig. 16 is shown a ball C, in its race B, in a state of impending rolling. The axis of rotation of the head is at Q, and that amplitude of whirl of the head just sufficient to start rolling of the ball C is represented by ρ_0. The coefficient of rolling resistance, a linear distance μ, is assumed to be constant. Since the ball is in equilibrium relative to its race, the forces F and N are equal, opposite, and collinear.

Let

d = diameter of a ball
D = diameter of the race
ϵ = half the angle between the balls
μ = coefficient of rolling resistance for a ball on its race
R = ratio of race diameter to ball diameter = D/d

From the geometry of Fig. 16,

$$\sin\delta = \frac{\overline{Sn}}{r'} \qquad [23]$$

also

$$\sin\delta = \frac{2\mu}{d} \qquad [24]$$

hence

$$\frac{\overline{Sn}}{r'} = \frac{2\mu}{d} \qquad [25]$$

But

$$\overline{Sn} = \rho_0 \sin(\epsilon - \delta) \qquad [26]$$

and since ρ_0 is very small compared to the radius r', the angle δ is small compared to the angle ϵ and may be neglected. Thus substituting $\overline{Sn} = \rho_0 \sin\epsilon$ in Equation [25],

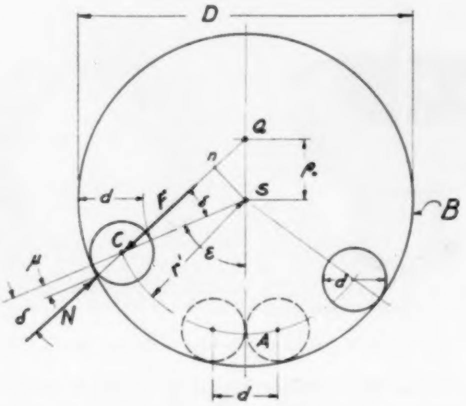

Fig. 16

$$\frac{\rho_0 \sin\epsilon}{r'} = \frac{2\mu}{d} \qquad [27]$$

$$\rho_0 = \frac{2r'\mu}{d\sin\epsilon} \qquad [28]$$

or

$$\rho_0 = \frac{\mu}{\sin\epsilon}\,\frac{D-d}{d} = \frac{\mu}{\sin\epsilon}(R-1) \qquad [29]$$

The sensitivity of the balancing head may be defined as the reciprocal of the amplitude ρ_0 of impending ball motion. Thus

$$\text{Sensitivity} = \frac{1}{\rho_0} \qquad [30]$$

Equation [29] shows that the head sensitivity depends upon the angle 2ϵ between the balls, or upon that fraction of the capacity of the head being utilized. Maximum sensitivity is realized when the head is being used to measure the smallest unbalance moments, the balls taking up positions almost diametrically opposite each other. Then very nearly,

$$\sin\epsilon = 1 \qquad [31]$$

and

$$\text{Maximum head sensitivity} = \frac{1}{\mu(R-1)} \qquad [32]$$

Minimum sensitivity is realized when the head is used at maximum capacity, or when the balls are in contact as at A. Then

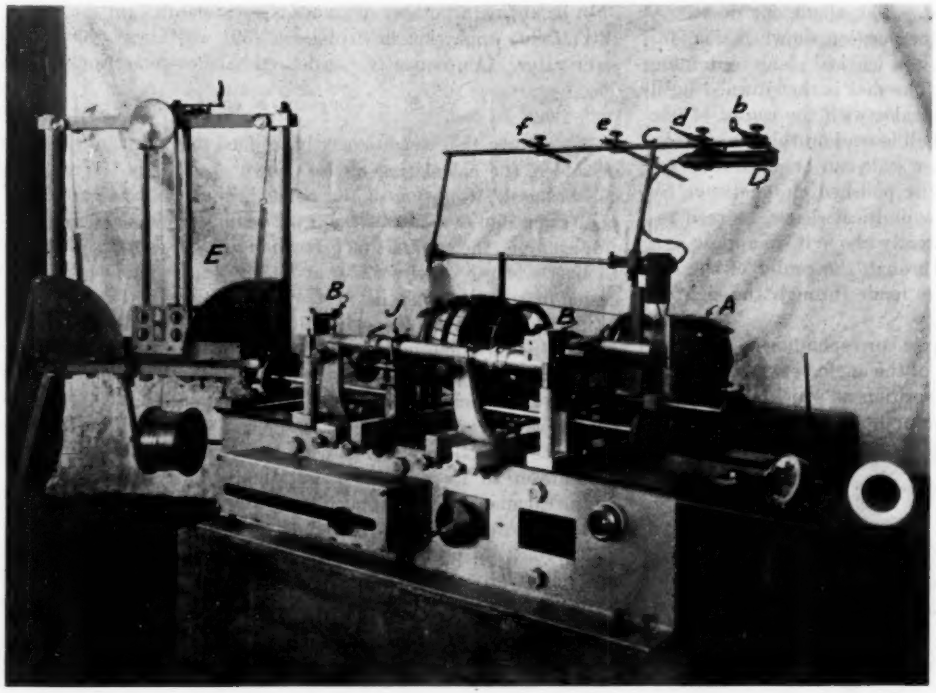

Fig. 17 10- to 50-Lb. Dynamic-Balancing Machine

$$\sin \epsilon = \frac{d}{2r'} = \frac{d}{D-d} = \frac{1}{R-1} \qquad [33]$$

and

$$\text{Minimum head sensitivity} = \frac{1}{\mu(R-1)^2} \qquad [34]$$

Expressions [32] and [34] for head sensitivity indicate that the ratio R of race diameter to ball diameter should be made as small as possible. However, an attempt to carry these proportions too far results in a serious loss in head capacity which becomes zero when $R = 2$. Of course the coefficient of rolling resistance μ should be made as small as possible by careful hardening and finishing of the race and by the use of high-grade steel balls. The actual effective resistance to rolling may be minimized by tapering the apparently cylindrical surface of the race very slightly, so that the balls may be rolled in an axial direction by depressing the clutch.

Operation of the Balancing Machine

Fig. 17 shows a small machine suitable for balancing motor rotors weighing from about 10 lb. to 50 lb. The rotor to be balanced is placed in the machine with its longest shaft extension, upon which the balancing head is clamped, projecting to the right. The fulcrum springs J at the left, which are adjusted to lie in the second correction plane, are clamped; those at the right are left free. The rotor and head are brought to a speed 30 or 40 per cent above that of resonance by means of the driving motor A, controlled by a foot-operated switch. When the clutch of the balancing head is depressed, thus releasing the two balls in their race, they automatically assume such positions as suppress oscillation of the rotor and its supporting cradle. When this condition exists, as shown by the hands of the dial indicators B coming to rest, removing pressure from the clutch button causes the balls to be clamped in their respective positions. The dial indicators B are driven from points at the end of a cradle tube, and show the amplitudes of vibration of these points in thousandths of an inch. These indicators are usually used only to show the absence of vibration, no measurements of amplitude being necessary.

The rotor is now brought to rest and the dial shown in Fig. 13

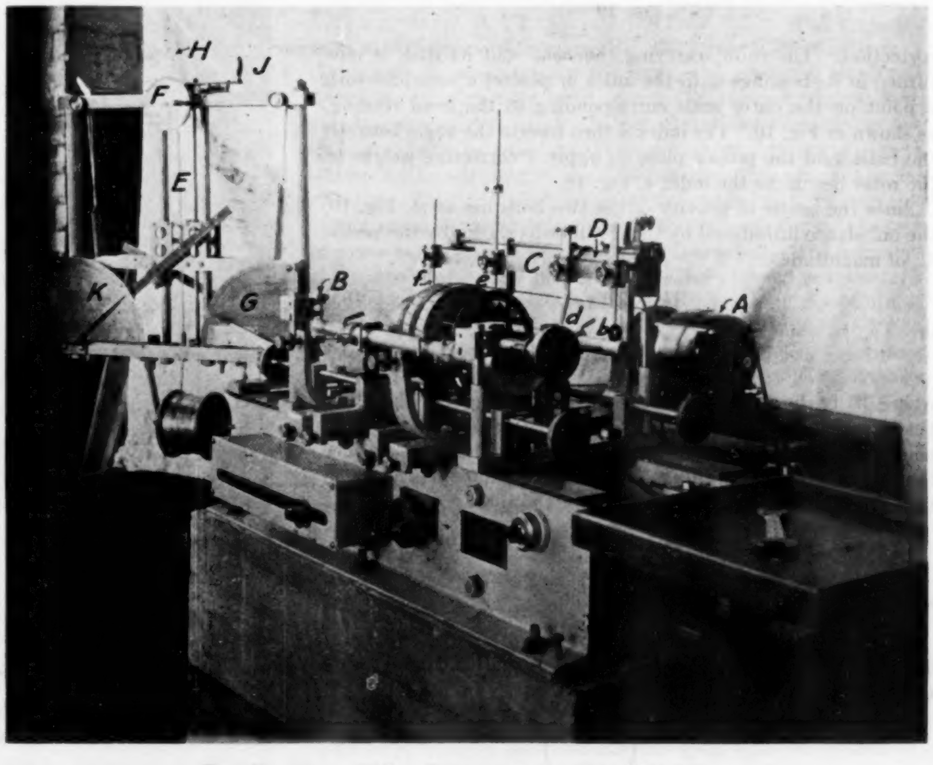

Fig. 18 10- to 50-Lb. Dynamic-Balancing Machine is placed over the face of the head. The alignment device *C*, carrying a lamp *D*, is brought to the position shown in Fig. 18, where its three indices *d*, *e*, and *f* lie in a vertical plane containing the axis of rotation of the rotor. The dial is then turned until the zero line on its inner scale coincides with the center of one ball, and the position of the other ball is read on this inner scale. The setting and reading of the inner scale can be accurately accomplished, since illumination of the polished clutch sleeve by lamp *D* causes the image of this cylindrical sleeve, as seen reflected from the surface of a ball directly above it, to appear as a sharp, bright, radial line passing through the center of the observed ball. These observations are made through the sight *b*, Figs. 17 and 18.

The number read on the inner scale corresponding to the position of the second ball is a measure of the angle between the balls and serves to determine both the position at which a corrective weight should be applied to the rotor and the amount of this correction. The rotor, carrying the head and its dial, is now turned in its bearings until the index or pointer *d* coincides with a point on the outer scale corresponding to the head reading, as shown in Fig. 19. The index *d* then bisects the angle between the balls, and the proper place to apply a corrective weight to the rotor lies under the index *e*, Fig. 18.

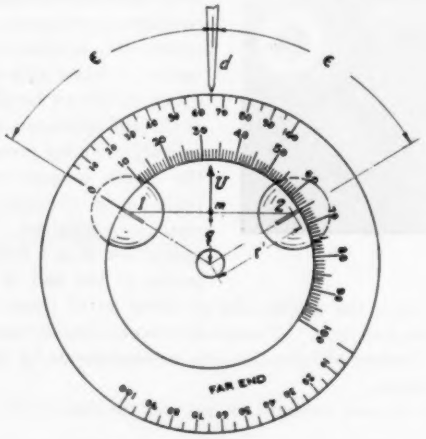

FIG. 19

Since the center of gravity of the two balls lies at *m*, Fig. 19, the unbalance introduced by them will be as shown by the vector *U*, of magnitude

$$U = 2Wq \qquad [35]$$

or

$$U = 2Wr'\cos\epsilon \qquad [36]$$

where *W* is the weight of each ball and ϵ is half of the angle between them. If Fig. 6(*a*) is considered to represent the rotor being balanced, with the center of the head at the point *S*, since the unbalance introduced by the head in its plane has annulled the effect of the unbalance weight *w* of the rotor,

$$\frac{(2Wr'\omega^2\cos\epsilon)}{g}L = \frac{(wr\omega^2)a}{g} \qquad [37]$$

or

$$2Wr'L\cos\epsilon = wra \qquad [38]$$

This determines the unbalance weight *w* equal in magnitude to the correction to be applied. Thus the correction weight

$$w' = w = \left(\frac{2Wr'L}{ra}\right)\cos\epsilon \qquad [39]$$

In balancing a number of rotors of identical design, the factor $(2Wr'L/ra)$ appearing in expression [39] will always have the same value. Consequently, the desired balance-correction weight

$$w' = \text{Constant} \times \cos\epsilon \qquad [40]$$

When correction weights may be applied to a rotor in the form of solder, the calculating device shown at *E*, Figs. 17 and 18, can be used. Rotation of the handwheel *F* (Fig. 18) until the pointer on dial *G* indicates the head reading previously obtained (for example, the reading "65" shown in Fig. 19) causes the device to eject a length of wire solder at *H*, Fig. 18, proportional to the cosine of half the angle between the balancing-head balls. The proper "constant of proportionality" setting for the calculator may be readily determined and fixed by a simple adjustment of the mechanism. If this adjustment is correctly made when setting up the machine, the length of solder ejected will be of the desired weight *w'*. A stroke of the lever *J* cuts off this measured piece of wire solder, and causes the return of the calculator mechanism to its initial configuration. The solder delivered by the calculator is then applied to the rotor at the point indicated by the index *e*, in the first, or right-hand, correction plane.

The fulcrum springs *J*, Fig. 17, at the left end of the rotor are now released by opening their vises. Those at the right, which are adjusted to lie in any convenient transverse plane of the rotor, are clamped by closing their vises. The magnitude and position of the corresponding correction weight to be applied in the second correction plane, at the left end of the rotor, are now determined in a manner similar to that described above. The balancing head remains on the right-hand extremity of the rotor shaft. Since the pivotal point of the system is now *between* the balancing head and the correction plane of the rotor, the outer scale marked "far end" on the dial shown in Figs. 13 and 19 is used in determining the position at which the correction shall be applied. The dial *K* (Fig. 18) of the calculating device, which is subject to a different

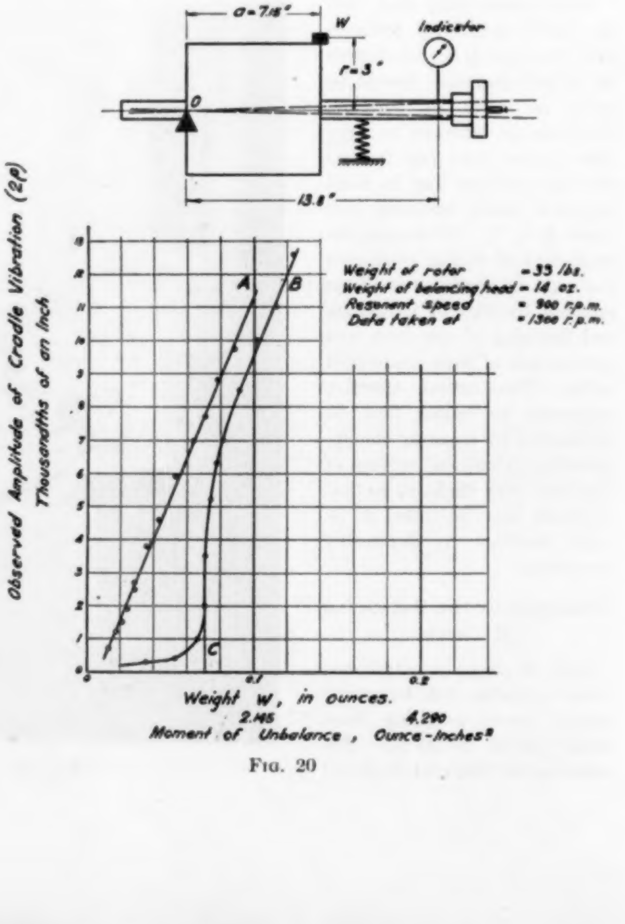

FIG. 20

constant of proportionality, is used in cutting the proper correction weight. The application of this weight, in the second correction plane of the rotor and at a point indicated by the index *f*, completes the balancing process. The balancing head is now removed from the rotor shaft and, if desired, the rotor may be subjected to a check run with both sets of fulcrum springs released.

If the rotor unbalance should in any case happen to be greater than the balancing-head capacity, it will be found impossible to bring the indicator hands to rest by depressing the balancing-head clutch. This indicates that the head capacity is exceeded, and, upon stopping the machine, the two balls in the head will be found in contact. Their positions specify a point on the rotor at which a correction should be applied, of amount at least equivalent to the full capacity of the balancing head. If the application of this correction reduces the rotor unbalance to a value within the head capacity, performance of the machine will again be normal.

Performance of the Balancing Machine

In determining the accuracy of balance obtainable with this machine, a 34-lb. motor rotor carrying a balancing head weighing 14 oz. was placed in the cradle. This rotor, with head, was very accurately balanced. The resonant speed of the system was found to be about 900 r.p.m. Various known weights were then applied to the rotor, and the corresponding amplitudes of cradle vibration were observed at a rotor speed of 1300 r.p.m., about 45 per cent above that of resonance. The values of observed amplitude of cradle vibration, as plotted versus unbalance weight (w) and moment of unbalance (wra) in Fig. 20, correspond closely to *twice* the amplitude ρ used in the above analysis, since they were obtained from observations of the total displacement of the hand of a dial indicator placed approximately in the transverse plane of the balancing head.

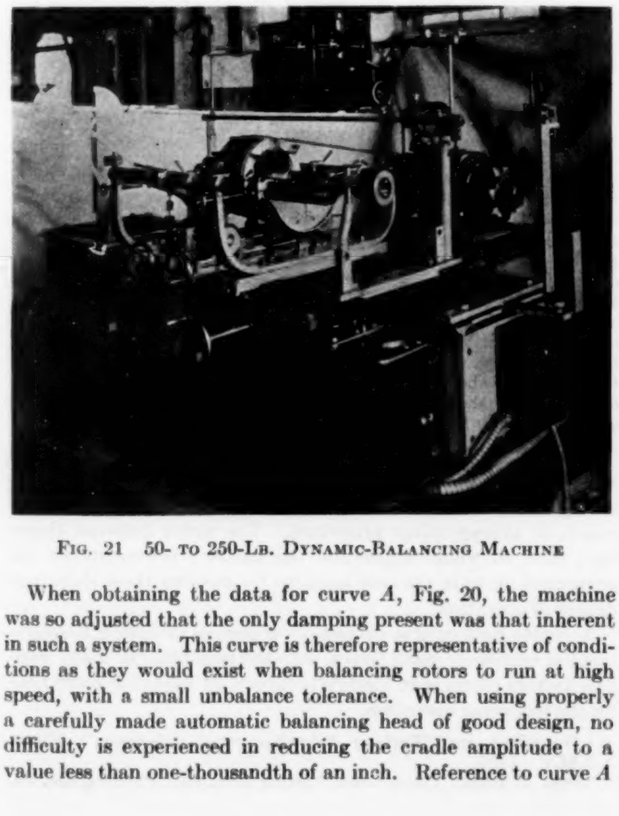

Fig. 21 50- to 250-Lb. Dynamic-Balancing Machine

When obtaining the data for curve *A*, Fig. 20, the machine was so adjusted that the only damping present was that inherent in such a system. This curve is therefore representative of conditions as they would exist when balancing rotors to run at high speed, with a small unbalance tolerance. When using properly a carefully made automatic balancing head of good design, no difficulty is experienced in reducing the cradle amplitude to a value less than one-thousandth of an inch. Reference to curve *A* shows that the balancing head will then indicate the amount and position of a correction to be applied to a rotor of this size within a tolerance of 0.34 oz-in.,[2] which, in this particular case,[4] amounts to less than 0.016 oz.

When the machine is used for the production balancing of standard motor rotors, to be run at a comparatively low speed, the unbalance tolerance may be considerably greater than the machine is capable of meeting. In this case the introduction of some damping, in the form of Coulomb friction resisting motion of the cradle, is found to make the machine more stable and therefore more easily handled by an unskilled operator. The effect of this damping on the behavior of the machine is shown by curve *B*, Fig. 20. As the balls in the head approach their equilibrium positions, causing the moment of unbalance of the system to approach its tolerance, the observed amplitude decreases quite rapidly until, when the tolerance is reached, the damping devices seize. In order that the "cut-off" of the indicators will be absolute, they are driven through devices which may be adjusted to fix an amplitude below which they are inactive. This, in effect, extends the vertical part of curve *B* downward as shown at *C*, and the indicator hands come definitely to rest when the unbalance tolerance is reached. The accuracy of balance obtained is thus less dependent upon the operator's judgment, which may vary from day to day, than it would otherwise be.

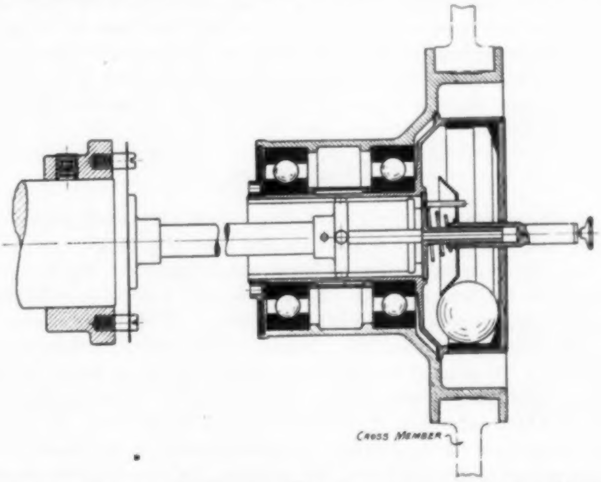

Fig. 22 Automatic Balancing Head Carried in Its Own Ball Bearings, Mounted in a Separate Cradle Cross-Member, and Attachable to a Rotor Shaft Through a Universal-Coupling Device

Since the balancing head functions very quickly the total time required to balance a rotor depends mainly upon that necessary for loading and unloading the machine, stopping and starting the rotor, and applying the corrective weights. As only two runs are necessary, the starting and stopping time is a minimum.

Rotors small enough to be lifted to and from the machine by hand can easily be completely balanced, by an unskilled operator, in less than four minutes. This time includes that required for the application of the corrective weights, and for loading and unloading the machine.

To place this figure on a basis comparable with claims made by some of the more conservative balancing-machine manufacturers, the time required for the application of the corrective weights must not be included. Repeated tests have shown that an operator can easily load the machine, determine and mark the positions of the corrections, cut the corrective weights to size, and unload the machine in a total time of two minutes.

---

[4] Wire solder $^1/_8$ in. in diameter weighs about 0.058 oz. per inch of length.

Fig. 21 shows a larger size of machine capable of balancing rotors weighing from 50 to 250 lb.

In many cases, mounting the balancing head directly on the rotor-shaft extension is undesirable. The head is then carried in its own ball bearings within a stationary outer shell which is mounted in a third cradle cross-member, and is driven by a light universal-coupling device which may be attached to either end of the rotor shaft. This arrangement has a number of obvious advantages. Such a balancing head is shown, in section, in Fig. 22.

Discussion

J. Ormondroyd.[5] Several attempts have been made to make automatic balancing machines on the general principles as outlined by the author. One of these was proposed by the French engineer LeBlanc in 1913. A discussion of LeBlanc's attempt will be found in Loewenstein's translation of Stodola's "Dampfturbinen," pages 1134–1135. Hardly a year passes by that some one does not suggest the use of a suitable balancing groove with some solidifying liquids such as solder or babbitt being applied to them which automatically finds its place in the grooves. In spite of all this talk on the subject, the author seems to have made the first practical application of the process. He has done the job so well that one can find nothing about it to criticize, and the writer wishes to express heartiest congratulations for the results which he has obtained.

T. C. Rathbone.[6] The author has described a very clever application of the principle of automatic balancing above the critical speed. Although this principle has been known for some time, the author deserves the greatest credit for putting it into practical use. So far as the writer knows, the attempts to provide automatic balancing by means of mercury or by loose washers on the shaft have never been entirely satisfactory. The author's system employing the two balls which can be fixed in position when they have adjusted themselves to balance, appears to be the practical answer to the problem.

The author describes the necessity for making the natural frequency in the vertical and horizontal direction the same. In the analysis, this is accomplished by making the moment of inertia of rotor and cradle the same for both directions, and at the same time providing equal stiffness in the two directions.

The writer is interested in knowing whether any practical difficulty is encountered in obtaining these conditions when the machine may be called on to handle rotors of various dimensions. It would also be of interest to know whether practical differences in the damping factor b, in the vertical and lateral dimension, would cause appreciable departure from a circular motion. Both the amplitude and the lag angle are affected by the damping, so that theoretically, at least, the motion of the ball-race center could take the form of any ellipse bounded by the rectangle formed by the vertical and lateral amplitude. For an extreme case, the motion could become linear (on a diagonal of the rectangle). If small deviations from the circular motion do occur, particularly where Coulomb damping is deliberately introduced, are the ball positions materially affected?

It appears to be necessary to insure that the center of the ball race coincides precisely with the axis of rotation rather than the axis of the shaft. If the shaft is eccentric at the plane of the ball race, the motivating forces on the balls, as shown in Fig. 16, would be affected in such a way as to cause them to assume false positions. It would be of interest to know if the author has encountered any difficulty on this score.

The writer's experience with vibratory motion on complex structures, where the most curious transitions of ellipses[7] from one shape and inclination to another are produced by changes in speed or in the inertia and elastic characteristics, have perhaps made him unduly concerned over the possibility of compounding to maintain purely circular motion.

T. Y. Olsen.[8] The author has presented in a very clear and interesting manner the mathematical basis for general elements of design in balancing machines. He has also brought into use through the ball-type automatic-balancing head a principle which has long been recognized.

Of historic interest and possible offering a thought for further development is an article discussing this principle on page 184 in the issue of December, 1904, of *Railway Machinery* describing a method using three eccentric disks mounted on a shaft in such a manner that they could adjust themselves and automatically balance the rotor.

The following is an extract from the article, involving tests some time previous to 1904:

> Some years ago William Sellers & Co., Inc., Philadelphia, conducted a series of tests upon an experimental steam turbine, similar in principle to the present Curtis turbine. As the disks rotated at very high speed, some convenient method of balancing was sought, and the plan illustrated [see Fig. 23] was originated. In the figure, *A* is the disk to be balanced, and *a*, *b*, and *c* are three thin disks turned up in the form of eccentrics and mounted on the shaft with the main disk. The bore of the eccentric was a close fit on the shaft, so there will be some frictional resistance between the eccentrics and the shaft; yet they were not so tight that it was necessary to drive them in place. The eccentrics were spaced 120 deg. apart, and as the main disk attained its speed *the eccentrics gradually shifted automatically*, until they reached such position that apparently brought themselves, together with the disk and shaft, into perfect running balance. Just why the vibrations of the shaft were such as to cause this behavior of the eccentrics is a problem for the mathematicians to handle, but such is the fact, and we will leave it for others to explain.

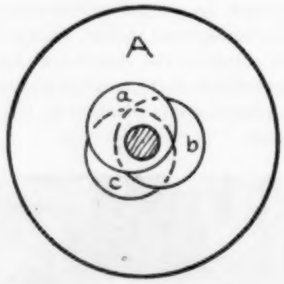

Fig. 23

Balancing is having careful thought wherever rotating parts are manufactured, thereby emphasizing the development of balancing machines for the most convenient and practical application to average plant procedure. The writer believes, therefore, that all would appreciate the author's comments on the provisions made in the new machine for meeting these shop conditions of operation.

Accurate balancing is necessarily a process involving measurement of extremely small forces, with the possibility of many variable factors entering to disturb accuracy, or requiring more time for the balancing operation.

[7] Described in "Turbine Vibration and Balancing," Trans. A.S.M.E., 1929.

[8] Pres. & Treas., Tinius Olsen Testing Mch. Co., Philadelphia, Pa.

The automatic balancing head in Fig. 11 is secured to the end of the shaft by a contracting chuck gripping the shaft near the end in a comparatively restricted area. The ball balancing weights are overhung outside this support area in the chuck. How much looseness is permissible between the shaft and the sleeve *A* without seriously affecting results? How much error is likely to be created by a looseness of, say, 0.001 or 0.002 in. at this point? If a shaft has a tapered or threaded end, can the automatic balancing head be conveniently applied?

In connection with Fig. 20, reference is made to reading unbalance of 0.016 oz. 3 in. from center of shaft or 0.34 oz-in.[2] With this degree of sensitivity of this machine, what is the range or minimum and maximum amount of unbalance which the machine will actually measure to the same degree of accuracy? What is the minimum included angle between the balls, at which the aforestated accuracy can be obtained? In previous text is mentioned that if the amount of unbalance is beyond the capacity of machine, the two balls will come together, and a tentative correction is made, and if necessary repeated until the frame becomes quiet with the balls slightly separated. If unbalance is beyond the capacity of the balls, is there any way of estimating approximately the amount of unbalance for the purpose of making tentative correction?

Are the balls in the balancing head sensitive to the presence of dirt or wear to a degree which might require frequent attention? As an average about how long will the balls run without requiring replacement?

When different weights of rotors are to be balanced, what adjustments are required in the balancing machine?

The armature to be balanced is rotated by a drive belt running around and pulling against its outer surface. What limitations on irregularity of the surface of the part being tested will produce detrimental effects in taking fine readings of unbalance? How would a part to be balanced be driven with the outer surface very irregular or tapered, such as a gasoline-engine crankshaft, steam-turbine rotor, or some electrical armatures? Is it necessary to carefully control variation in the action of the belt which might cause vibration such as to interfere with accurate check on final balance?

Is the motor mounted on the stationary base or on the vibrating unit? Which construction is the better as affecting accurate indications of unbalance?

Has the friction in the indicator dial any noticeable dampening effects when measuring small amounts of unbalance?

The part mentioned to be balanced is rotated at 1300 r.p.m. What benefits are derived from running at this high balancing speed?

Readings for the amount and angular position of unbalance are taken from the automatic balancing head which is located on the end of the shaft or some other position not in the axial plane where corrections are to be made to the part being balanced. If some other material than solder is to be used for making the balancing correction, can the soldering instrument be used to transfer the readings so as to indicate the angular position and ounce-inches correction which is to be made in some other manner?

AUTHOR'S CLOSURE

The automatic balancing device proposed by LeBlanc consists of a hollow drum or cylinder containing a liquid or its equivalent such as mercury, and mounted on a flexibly supported shaft.

When rotating above its critical speed, the shaft is displaced in such a way that the drum containing the liquid is whirling with its "light side" out. The liquid is then supposed to flow to the light side of its container, and thus correct for the initial unbalance.

It is readily seen that this action cannot take place completely, for if the mercury distributes itself in such a way as to balance the drum, then the drum will run true, the mercury will be uniformly distributed, and can introduce no unbalance correction. The LeBlanc automatic balancing device is thus imperative.

The author's experience with devices such as loose rings or disks mounted on the shaft has been that it is very difficult to make them operate. Due to excessive friction, several sharp blows with a hammer were necessary to cause three rings to assume their desired positions even approximately.

Some variation from true circular motion of the cradle, caused either by non-uniform springs or irregular damping, has been found to have no appreciable effect on the action of the balancing head. Eccentricity of the ball race, however, causes the balls to assume false positions. This difficulty is avoided by proper set-up, not mounting a head on a long overhanging shaft, or by using the type of head shown in Fig. 22.

APM-54-13

The Propeller-Type Fan

BY O. G. TIETJENS,[1] EAST PITTSBURGH, PA.

In this paper a method is given showing how it is possible to present the complete characteristics of fans in a very concise manner. This is usually done by giving pressure-volume curves for different sizes and speeds. Here this relationship for all sizes and speeds is shown by three curves.

Theory is developed according to which all data for designing a fan can be determined if the volume per minute and the pressure rise, i.e., the power output of the fan, are given. In addition, it is shown how the efficiency due to air friction can be calculated, and in what way the loss due to the rotational velocity of the air behind the fan is determined by the pressure increase produced by the fan.

The limitation of the theory is then dealt with, and various restrictions regarding the validity of the assumptions made are discussed. Finally a short description of a test equipment for fans is given.

THE propeller-type fan has many advantages compared with the centrifugal type. Generally speaking, we may say that for a given power output the propeller-type fan with its housing is smaller in size and simpler in construction and therefore cheaper than a centrifugal fan. In addition, the speed of rotation is higher for propeller-type fans than for those of the centrifugal type, particularly for fans of large power output, which means a smaller and cheaper motor. Finally, the efficiency of a propeller-type fan, if properly designed, is higher than that of a centrifugal fan, particularly for large volume output, whereas for a comparably small volume and high pressure, the centrifugal type may be considered superior with respect to efficiency.

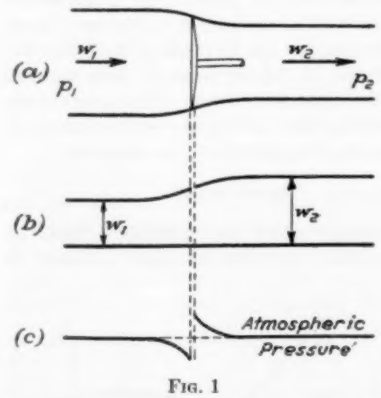

FIG. 1

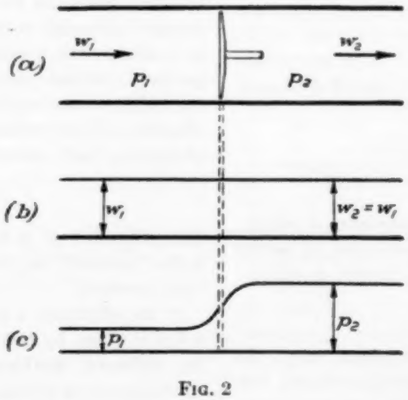

FIG. 2

The highest pressure obtainable is about the same for both types of fans, and for air of atmospheric pressure is approximately 20 in. of water.

For higher pressures a special type of centrifugal blower, the so-called compressor, is developed.

Despite the importance of the propeller-type fan, there is, as contrasted with the airplane propeller, no theory for it, and but few data are available concerning its performance. However, the conditions of operation of an airplane propeller are quite different from those of a propeller-type fan, therefore making it impossible to apply without any modification the well-developed propeller theory to fan design. In brief, this difference consists in the fact that a propeller accelerates a certain amount of air in the axial direction, the reaction force of which represents the thrust, while a fan operating in a housing increases the pressure of the air flowing through the fan area.

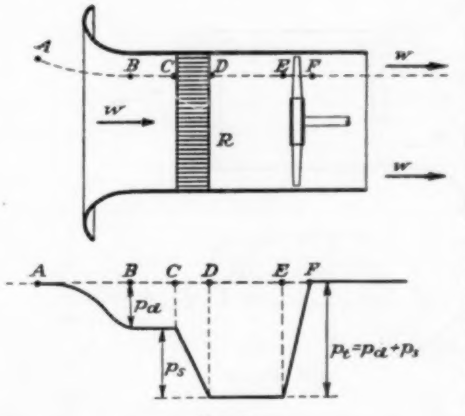

FIG. 3

Figs. 1 and 2 illustrate better the difference between the performances of a propeller and a fan. Instead of considering a propeller moving with a certain velocity through the quiet air, we assume the propeller to be at rest and the air flowing toward it with the same velocity, say, w_1, in the opposite direction. The air acted on by the propeller is accelerated in the axial direction to the velocity w_2, this being done partly ahead of the propeller and partly beyond it, as shown at (*a*) and (*b*), Fig. 1. In the plane of the propeller there is a discontinuity in pressure. As shown in Fig. 1(*c*), the pressure ahead of the propeller decreases from the atmospheric pressure p_1 to a lower pressure corresponding to an increase of velocity at this point. In the propeller plane a sudden increase of pressure takes place above the atmospheric pressure. Beyond the propeller the pressure again decreases, with a corresponding increase in velocity, until the atmospheric pressure is again reached.

The operating conditions under which a fan works are quite different, as shown in Fig. 2. Due to the fact that a fan operates inside a housing, usually having the shape of a pipe, there can be no increase in axial velocity [Fig. 2, (*a*) and (*b*)]. The pressure rise in the plane of the fan must therefore be connected with a certain rotational velocity, which relation will be dealt with later.

I—POWER OUTPUT OF A FAN

Let us consider the performance of a fan in a special case. The task of the fan may be to cool the radiator *R* in Fig. 3 by

drawing air through from left to right. Considering the pressure variation along a line from A to F we notice first a drop from A to B corresponding to a velocity increase from zero at point A to a certain velocity, say, w, at point B. The pressure drop, usually called dynamic pressure (p_d), is, according to Bernoulli's equation, equal to $^1/_2\rho w^2$, where ρ is the density of the air. From B to C the pressure is practically constant, whereas the static pressure p_s decreases from C to D according to the restriction to the air flow caused by the radiator. From D to E the pressure is again constant. Due to the fact that the static pressure of the air leaving the pipe like a jet is equal to the atmospheric pressure, the fan has to create a total pressure rise equal to the sum of the dynamic and static pressures, or $p_t = p_d + p_s$.

In this case the fan is drawing the air through the radiator. The static pressure varies somewhat differently where the fan is forcing air through the radiator as shown in Fig. 4. In both cases it is seen that the work to be done by the fan is to increase the pressure of a certain volume of air. Therefore, denoting the volume flowing per unit time through the fan area by V, and the total pressure rise by p_t, the product $V \times p_t$ represents the power output of the fan. Considering the physical dimensions of V and p_t,

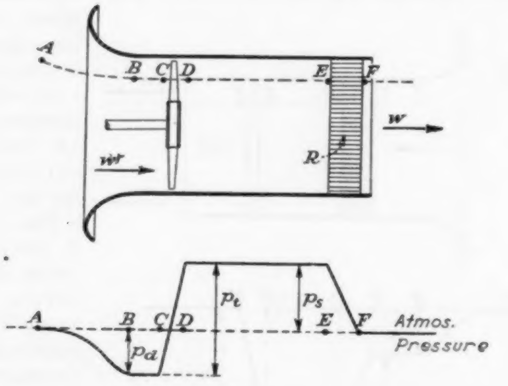

FIG. 4

$$V \times p_t = \frac{\text{length}^3 \times \text{force}}{\text{time} \times \text{length}^2} = \frac{\text{length} \times \text{force}}{\text{time}} = \text{power}$$

we see that the product of V and p_t has the dimension of power. The efficiency η of a fan, being defined as the ratio of power output to power input, is therefore determined by the equation

$$V \times p_t = \eta \times \text{power input.}$$

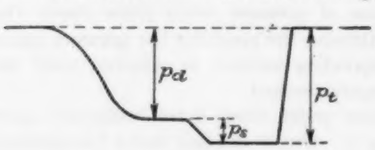

FIG. 5

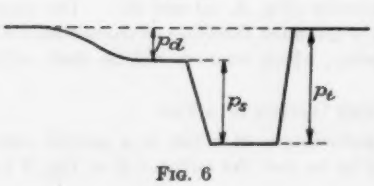

FIG. 6

The conditions under which a fan has to operate vary. In some cases the fan has to deliver a large volume per minute, but has to overcome only a small static-pressure drop; in other cases only a small volume per minute is wanted, but a large pressure rise. In the first case the dynamic pressure forms a large part of the total pressure (as shown schematically in Fig. 5), while in the second case (Fig. 6) the static pressure predominates. The working conditions of a fan are thus characterized by the ratio:

$$\frac{p_d}{p_d + p_s} = \frac{p_d}{p_t}$$

This ratio varies from zero to unity, being close to zero for a compressor and equal to unity for a desk fan.

As an example let this ratio be determined for the particular case of a cooling arrangement on top of a Diesel locomotive as shown in Fig. 7. Assume the volume required to be 16,000 cu. ft. per min., the diameter of the fan 32 in., the diameter of the hub 12 in., and the pressure drop through the radiator 1 in. for the required amount of air. The velocity of the air discharged by the fan is then

$$\frac{16{,}000 \times 144 \times 4}{(32^2 - 12^2)\pi}$$

$$= 3330 \text{ ft. per min.}$$

and the dynamic pressure height therefore 0.68 in. of water.

We then have the ratio

$$\frac{p_d}{p_t} = \frac{p_d}{p_d + p_s} = \frac{0.68}{0.68 + 1} = 0.405$$

By multiplying the numerator and the denominator of p_d/p_t by the volume, it is seen that this ratio shows how much of the total power output is used to impart to the air a certain amount of kinetic energy. In the particular case under consideration about 40 per cent of the total power output of the fan is represented by the kinetic energy of the air discharged by the fan. In some cases, as for instance in the present one, this kinetic energy—although a part of the power output of the fan—must be considered as a loss since no use can be made of it. Only the product (volume per minute) × (static pressure drop through the radiator) can be considered as useful work. The aerodynamic efficiency of the cooling arrangement in Fig. 6—not the efficiency of the fan itself—is therefore determined by the equation

$$V \times p_s = \eta_s \times \text{power input}$$

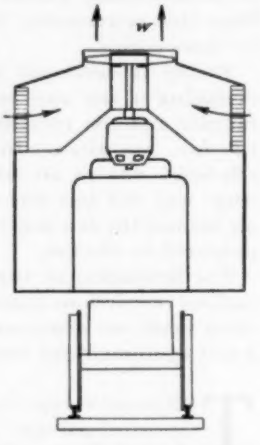

FIG. 7 COOLING ARRANGEMENT FOR DIESEL LOCOMOTIVE

The efficiency η_s is sometimes called the "efficiency based on static pressure" as contrasted with the efficiency η based on total pressure.

If the efficiency η of a fan is given by tests for different working conditions or as a function of p_d/p_t as shown in Fig. 8, it is a very simple matter to calculate the efficiency based on static pressure, all that is necessary being to multiply the efficiency η for a given value of p_d/p_t by the factor $[1 - (p_d/p_t)]$. The broken line represents the limit for the efficiency based on static pressure,

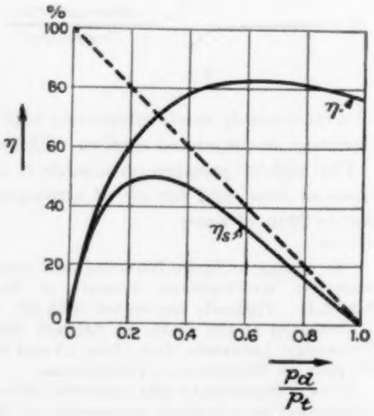

FIG. 8

which line would be reached if the fan itself had an efficiency of 100 per cent. Due to the fact that for $p_d/p_t = 0$ the volume delivered by the fan is zero, the pressure, however, being of finite magnitude, we have no power output for this value of p_d/p_t. Therefore the curve of η as a function of p_d/p_t has to start from zero. This efficiency curve can be obtained by using an experimental set-up such as that shown in Fig. 19. By changing the position of the baffle in this figure the volume of air per unit time and the difference between the pressure inside of the box and the atmospheric pressure can be varied, and therefore also the ratio p_d/p_t.

II—Characteristics of a Fan

The volume delivered by a fan per unit time can be expressed by the equation

$$V = \varphi A u \quad [1]$$

where A represents the fan area and u the peripheral speed. φ being a non-dimensional factor does not depend on the size of the fan or on the speed but only on the design of the fan—as, for instance, on the number of blades—and in addition on the working condition, i.e., on p_d/p_t.

The total pressure produced by the fan can be expressed by the equation

$$p_t = \psi \frac{\rho}{2} u^2 \quad [2]$$

where ρ denotes the density of air, i.e., mass per unit volume. ψ likewise does not depend on the size of fan or on its speed, but only on type of fan, and for a given fan on the ratio p_d/p_t. Fig. 9 shows the typical shape of the φ and ψ curves as functions of p_d/p_t. These curves differ for each design of fan, and may together with the efficiency curve be considered as the characteristics of the fan. As mentioned in the two preceding paragraphs, the curves do not depend on the size of the fan or on its speed.

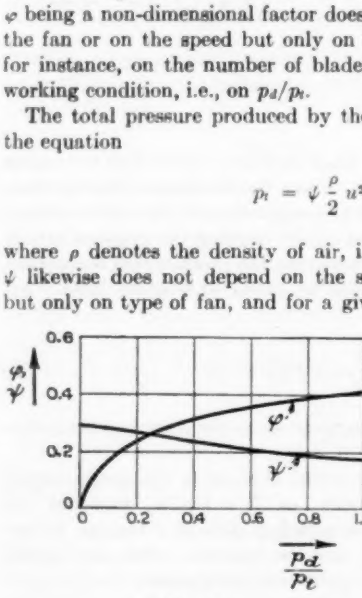

FIG. 9

Another expression for the value p_d/p_t can now be easily developed by using Equations [1] and [2]. Knowing that p_d is equal to $^1/_2\rho w^2$, where w is the axial velocity through the fan area A, we have in connection with [2]

$$\frac{p_d}{p_t} = \frac{\frac{\rho}{2} w^2}{\psi \frac{\rho}{2} u^2} = \frac{1}{\psi}\left(\frac{w}{u}\right)^2$$

Since $V = Aw$, [1] may be written

$$\frac{w}{u} = \varphi$$

and we have

$$\frac{p_d}{p_t} = \frac{\varphi^2}{\psi} \quad [3]$$

In order to obtain the characteristics φ, ψ, and η of a fan with respect to $p_d/p_t = \varphi^2/\psi$, it is necessary to measure the volume delivered per unit time, the difference of static pressure produced by the fan, and the power input to the shaft of the fan. These measurements have to be made for different working conditions or different positions of the baffle in Fig. 19. By measuring the volume we obtain, according to [1], the value φ after having determined the area A and the r.p.m. In addition, the ratio V/A gives the axial velocity at the fan area, and therefore the dynamic pressure $p_d = {}^1/_2\rho w^2$. By measuring the static pressure p_s and adding to this value that of the dynamic pressure just calculated, we obtain the total pressure and can therefore, according to [2], determine ψ. The ratio of the power output Vp_t to the measured power input then gives the efficiency η. In this way we obtain for each position of the baffle a value of φ, of ψ, and of η, and we are thus able to plot these variables as functions of $p_d/p_t = \varphi^2/\psi$.

Fig. 10 shows the φ, ψ, and η curves obtained in this way for a particular fan. It is seen that this fan works with the highest efficiency for high value of the ratio p_d/p_t. Another fan will have a different efficiency curve with its maximum at another value of φ^2/ψ. For each working condition of the fan, i.e., for each value of φ^2/ψ, it is possible, according to [1] and [2], to determine two of the four values p, V, A, and u if the other two are given. The fact that these performance curves for all kinds of fans run from $\varphi^2/\psi = 0$ to $\varphi^2/\psi = 1$ makes it very convenient to compare different fans with each other and to select in a particular case the one giving the best performance.

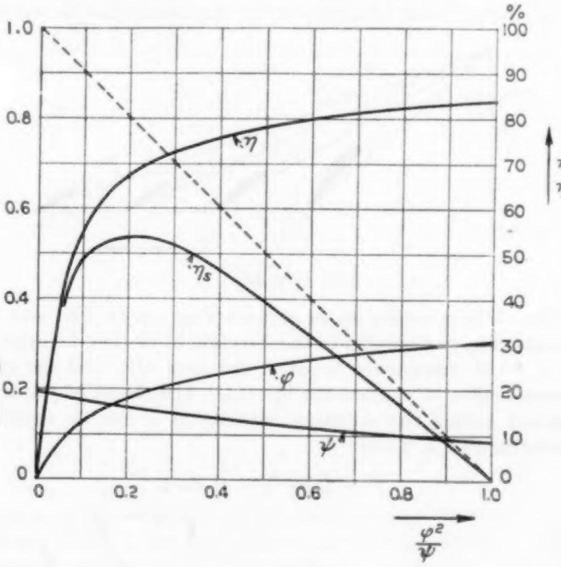

FIG. 10

III—Blade-Element Theory

The power output of a fan, i.e., volume times total pressure, can also be expressed in another way. The volume per unit time being equal to the fan area A times the axial velocity w, we can write

$$Vp_t = Ap_t w = Tw \quad [4]$$

where T is the force acting on the fan area. This force usually is called the thrust. The thrust times the axial velocity is thus equal to the power output of the fan.

If n is the number of blades, a thrust of T/n will be produced by each blade. Dividing the blade in Fig. 11 in elements $b \times dr$, where b is the width of the blade and generally varying with the distance from the hub, the thrust of such an element will

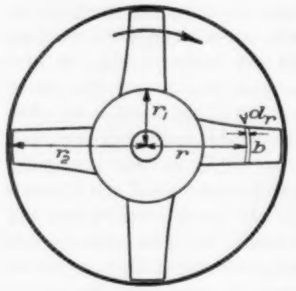

FIG. 11

be dT/n, wherein the general case dT varies with the distance from the hub or with the radius r.

Let us now replace dT by another term. The relative velocity v of a blade element with respect to the air is equal to the geometrical sum of the axial velocity w, which is assumed as uniform over the area A, and the tangential speed $u = \omega r$, where ω is the angular velocity. Dividing the velocities v, w, and $u = \omega r$ by the angular velocity and turning each element through 90 deg., we obtain Fig. 12.

Let us now assume that the performance of a blade element is like that of an element of an airplane wing moving with the speed v through quiet air, and having an angle of attack equal to α. Later it will be seen how far this assumption is justified.

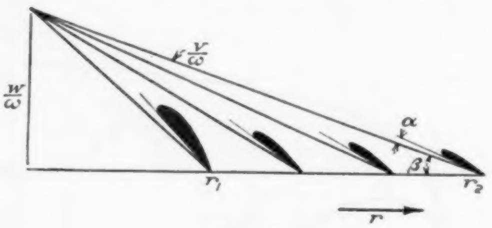

FIG. 12

The air force acting on an airplane wing can be split into two components, one parallel to the direction of motion, i.e., parallel to v, which component is called the drag (D), and the other perpendicular to v called the lift (L). The thrust of the blade element having the direction opposite to w can be expressed according to Fig. 13 by

$$T = L \cos \beta - D \sin \beta \quad [5]$$

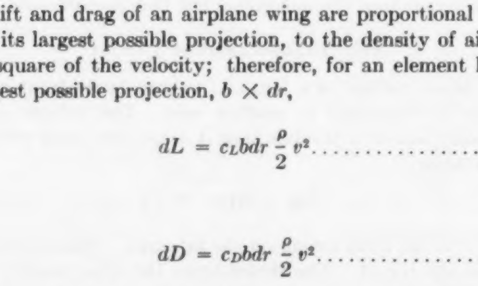

FIG. 13

The lift and drag of an airplane wing are proportional to the area of its largest possible projection, to the density of air, and to the square of the velocity; therefore, for an element having the largest possible projection, $b \times dr$,

$$dL = c_L b dr \frac{\rho}{2} v^2 \quad [6]$$

and

$$dD = c_D b dr \frac{\rho}{2} v^2 \quad [7]$$

The coefficients of lift and drag, c_L and c_D, which depend on the airfoil shape and on the angle of attack, have been obtained by wind-tunnel tests for numerous shapes of airfoils. Fig. 14 shows for a particular airfoil the coefficient of lift as a function of the coefficient of drag, with the angle of attack as parameter.

Due to the fact that the lift is some 15 to 20 times larger than the drag for reasonable angles of attack (α about 3 deg.) and that the angle β is always smaller than 45 deg. (usually around 25 deg.) we may, as a first approximation, neglect the drag entirely. Thus, for an element of an n-bladed fan,

$$\frac{dT}{n} = dL \cos \beta = c_L b dr \frac{\rho}{2} v^2$$

hence the total thrust of a fan having a hub radius equal to r_1, and a fan radius equal to r_2 will be

$$T = n \frac{\rho}{2} \int_{r_1}^{r_2} c_L v b v \cos \beta dr \quad [8]$$

or, since $v \cos \beta = \omega r$,

$$T = n \frac{\rho}{2} \omega \int_{r_1}^{r_2} c_L v b r dr$$

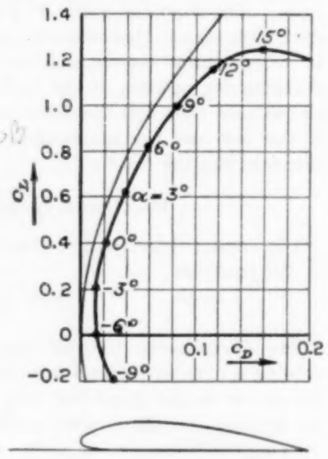

FIG. 14

The relative velocity of the blade element v varies with the radius r. For lightly loaded fans, where the rotational velocity back of the fan can be neglected as compared with the axial velocity, it is desirable to vary b and c_L (by varying the angle of attack along the radius) in such a way that the product $c_L v b$ is constant over the radius. The reason for doing so is given later. Assuming $c_L v b$ = const.,

$$T = \frac{n}{4} \rho \omega c_L v b \, (r_2^2 - r_1^2) \quad [9]$$

This value is somewhat too large since the drag has been neglected.

Due to the fact that the thrust is equal to the power output divided by the axial velocity, or $T = Vp_t/w$, Equation [9] enables us to determine the principal data of a fan, as, for instance, its size and speed, and the number, width, and airfoil section of the blades, if the power output is given.

The tangential speed ωr of the fan being usually several times larger than the axial speed w, we may neglect w^2 as compared to $(\omega r)^2$, writing in [9] ωr instead of v. Further, taking into account the fact that c_L is about 0.5, if we assume a sufficiently large lift/drag ratio to justify neglecting the drag, and that the average density of air is equal to 6.49×10^{-7} lb. min./ft.^{4} we have instead of Equation [9]:

$$\frac{Vp_t}{w} = T = n/4 \times 6.49 \times 10^{-7} \times \omega^2 \times \frac{1}{2} \times b_2 r_2 (r_2^2 - r_1^2)$$

or, with ω = r.p.m. $\times 2\pi$,

$$\frac{Vp_t}{w} = T = 3.2n \left(\frac{\text{r.p.m.}}{1000}\right)^2 b_2 r_2 (r_2^2 - r_1^2) \quad [10]$$

Example. Let V = 22,500 cu. ft. per min. and p_t = 2 in. of water = 10.4 lb. per sq. ft. For a fan radius of 18 in. = $1^1/_2$ ft., and a hub radius of 6 in. = $^1/_2$ ft.,

$$T = Ap_t = (1.5^2 - 0.5^2) \times \pi \times 10.4 = 65.2 \text{ lb.}$$

Assuming 6 blades and a speed of 1750 r.p.m., the width b_2 of the blade at the tip is given by [10] as 0.37 ft. = 4.5 in. The variation of b with the radius is then determined by the condition that $c_L v b$ = const.

The same power output, i.e., the same volume per minute, and the same total pressure, can be obtained also from a fan of a different size and speed and having a different number of blades. What fan, in a particular case, will be the most suitable depends on various factors. Sometimes, in addition to the power output, the r.p.m. is given and the other variables have to be so chosen that Equation [10] will be satisfied; and in the case where the kinetic energy of the air discharged by the fan has to be considered a loss, it is advisable to use a fan of larger diameter, which means a smaller axial velocity for a given volume per minute. Within a certain range all these different factors can be varied for a given volume per minute and for a given static pressure. How far we can go in this direction is governed mainly by the fact that a satisfactory efficiency must be obtained.

Fan losses by which the efficiency η is determined consists of:

(1) Loss due to the fact that each blade element, in producing a lift, has to overcome a certain drag; and

(2) Loss due to the rotational-velocity component of the air discharged by the fan.

The latter loss, which in some cases is the larger, can very often be considerably diminished by using stationary guide vanes back of the fan.

IV—LOSS DUE TO THE DRAG OF THE BLADE ELEMENT

Besides the component dT of the air force which if multiplied by the axial velocity represents the power output of the element, there is another component which acts on the element in the direction opposite to its motions, and which has to be overcome by the motive power. The product of this component and the radius, called the torque, represents, if multiplied by the angular velocity, the power input of the element.

The efficiency of a blade element is therefore

$$\eta = \frac{w dT}{\omega dQ} \quad [11]$$

According to Fig. 13,

$$dQ = r(dL \sin\beta + dD \cos\beta)$$

Thus, in connection with [6] and [7], we have for the efficiency of a blade element at a certain distance r from the axis of the fan

$$\eta_{(r)} = \frac{w}{\omega r} \times \frac{c_L \cos\beta - c_D \sin\beta}{c_L \sin\beta + c_D \cos\beta}$$

or, since $w/\omega r = \tan\beta$,

$$\eta_{(r)} = \frac{\dfrac{c_L}{c_D}\cot\beta - 1}{\dfrac{c_L}{c_D}\cot\beta + \cot^2\beta} = \frac{\dfrac{c_L}{c_D} \times \dfrac{\omega r}{w} - 1}{\dfrac{c_L}{c_D} \times \dfrac{\omega r}{w} + \left(\dfrac{\omega r}{w}\right)^2} \quad [12]$$

In this equation the efficiency of a blade element is expressed as a function of the two variables, c_L/c_D and $\omega r/w$. Fig. 15 shows the efficiency of a blade element as a function of $\omega r/w$ for a number of values of c_L/c_D. It is seen that the efficiency is a maximum for $\omega r/w \approx 1$, and that it decreases at first slowly and then more rapidly as $\omega r/w$ increases. For large values of $\omega r/w$ it is particularly important to use the best possible airfoil section with a large c_L/c_D value.

In order to obtain an expression for the efficiency of the whole fan corresponding to what has just been developed for a blade element, it is necessary to consider the expression

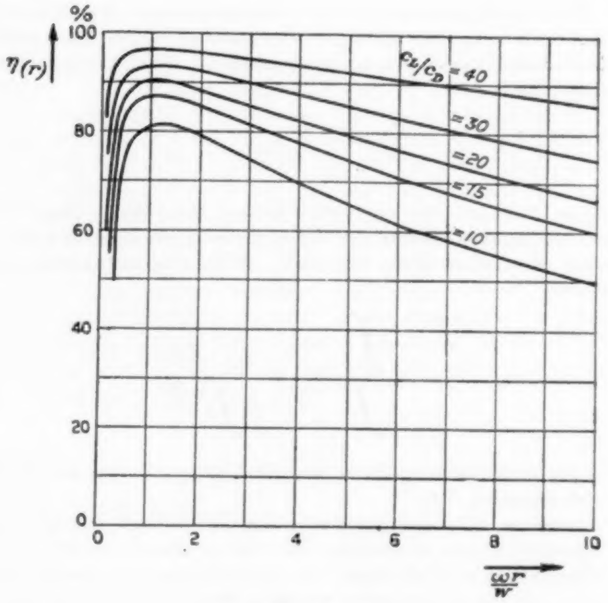

FIG. 15

$$\eta_F = \frac{w \displaystyle\int_{r_1}^{r_2} dT}{\omega \displaystyle\int_{r_1}^{r_2} r dQ}$$

or, since $\omega r dQ = w dT/\eta_{(r)}$

$$\eta_F = \frac{\displaystyle\int_{r_1}^{r_2} dT}{\displaystyle\int_{r_1}^{r_2} \frac{dT}{\eta_{(r)}}} \quad [13]$$

where $\eta_{(r)}$ is the efficiency of the blade element.

If the design of the fan is given, and if a particular working condition is assumed, which means a particular value of $p_d/(p_d + p_s) = p_d/p_t$, the efficiency η_F can be determined, although it is a fairly tedious calculation. For this purpose a certain but arbitrary value of the axial velocity has to be assumed, with which the angle of attack of each blade element is then determined. From these angles of attack and the c_L, c_D curves of the airfoils used at different radii, the thrust of each element can be calculated according to Equation [5] and integrated over the radius from the hub to the tip. If the total thrust calculated in this way is the same as that determined by the equation

$$T = A p_t = A \frac{\rho}{2} w^2 \frac{p_t}{p_d}$$

the axial velocity assumed was the right one; otherwise the calculation has to be repeated, using another value of w. Having in this way determined the axial velocity, the efficiency of each blade element can be calculated by [12], using the same angular velocity as assumed in calculating w. Finally the efficiency η_F can be found by a graphical integration of Equation [13].

More important, however, than the calculation of the efficiency of a fan of given design is the problem designing a fan that will have the highest efficiency possible. According to [13], the efficiency of the fan depends not only on the efficiency of the blade elements, but also on the variation of the thrust along the blades.

The simple assumption of a constant pressure over the fan area leads to the conclusion that the variation of the thrust with the radius of the blade is proportional to r. From the propeller theory we have

$$\frac{dT}{dr} = \rho \Gamma r \omega \qquad [14]$$

where Γ denotes the circulation around the blade. Therefore our assumption relating the thrust distribution involves a constant circulation along the blade. With this assumption we have

$$\eta_F = \frac{\int_{r_1}^{r_2} rdr}{\int_{r_1}^{r_2} \frac{rdr}{\eta_{(r)}}} = \frac{r_2^2 - r_1^2}{2\int_{r_1}^{r_2} \frac{rdr}{\eta_{(r)}}}$$

which can be solved easily by graphical integration in connection with Equation [12].

However, this assumption of a constant-pressure distribution over the fan area necessitates that the rotational velocity components shall be fairly large near the hub, causing a considerable loss according to the kinetic energy of the air because of its high rotational velocity.

Therefore if we do not use stationary guide vanes back of the fan in order to straighten out the air, in this way converting, at least partly, the kinetic energy due to rotational velocity into pressure, it is advisable to distribute the thrust over the blades in such a way that dT/dr will decrease more rapidly with decreasing r than it would if dT/dr were proportional to r. In other words, the circulation does not have to be constant over the blade length, but must decrease in the direction of the hub.

Although the assumptions on which the propeller theory, developed by Prandtl[2] and Betz,[3] is based do not strictly hold for all types of fans, particularly those of high pressure and low axial velocity, i.e., for a low value of φ^2/ψ, a distribution of circulation such as that developed by Prandtl will give better results than a constant circulation along the blade. For a propeller of n blades, the expression of the circulation as a function of the radius is, according to Prandtl,

$$\Gamma = \frac{2\pi r' w}{n} \times \frac{r^2}{r'^2 + r^2}$$

r' being that distance from the axis where $\tan \beta = 1$, or $r' = w/\omega$.

The influence of a finite number of blades, which necessitates a decrease of the circulation near the tips of the propeller blades, can be neglected in the case of a fan, since the fan runs in a housing, and there is but a small clearance space between the blades and the housing.

Assuming such a distribution of circulation, we obtain for Equation [13], making use of [14],

$$\eta_F = \frac{\frac{2\pi r'^1 w}{n}\rho\omega \int_{r_1}^{r_2} \frac{r^2}{r'^2 + r^2} rdr}{\frac{2\pi r' w}{n}\rho\omega \int_{r_1}^{r_2} \frac{r^2}{r'^2 + r^2}\frac{1}{\eta_{(r)}} rdr}$$

$$= \frac{\int_{r_1}^{r_2} \frac{rdr}{\left(\frac{r'}{r}\right)^2 + 1}}{\int_{r_1}^{r_2} \frac{rdr}{\left(\frac{r'}{r}\right)^2 + 1}\frac{1}{\eta_{(r)}}}$$

Substituting the new variable $x = r/r' = r\omega/w$,

$$\eta_F = \frac{1 + x^2 - \log_e(1 + x^2)\Big]_{x_1}^{x_2}}{2\int_{x_1}^{x^2} \frac{Cx^4 + x^5}{(1 + x^2)(Cx - 1)}dx} \qquad [15]$$

where C is equal to c_L/c_D.

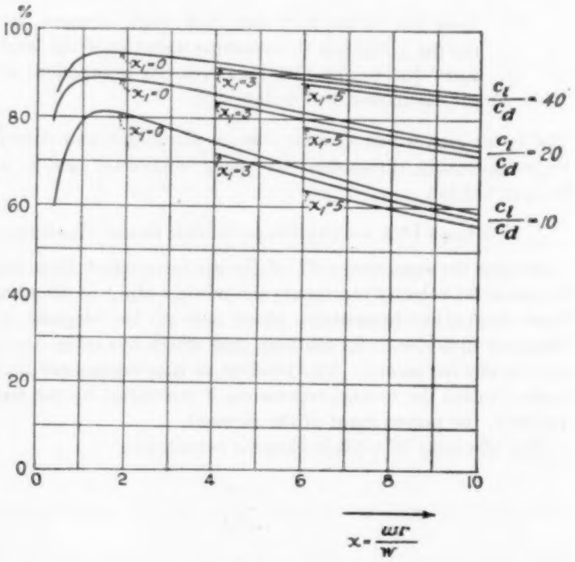

FIG. 16

Fig. 16 gives a solution of [15] for several values of C, which is assumed as constant along the blade, and for values of x_1 equal to 0, 3, and 5; the curve for $x_1 = 1$ is omitted because it practically coincides with the curve for $x_1 = 0$.

V—LOSS DUE TO THE TANGENTIAL VELOCITY COMPONENT OF THE AIR DISCHARGED BY THE FAN

In addition to the loss due to the drag of the blade element, there is still another source of loss which may, in some cases, be even larger. This is due to the rotational velocity of the air beyond the fan, being essentially connected with the pressure rise in the fan area.

In order to explain this, let us consider a two-dimensional flow of air moving with a velocity equal to w from left to right through a row of blades, which latter may move with a velocity u_1 at right angles to w. We assume this flow to be steady, the coordinate system being considered at rest with respect to the blades, and the velocity of flow sufficiently far ahead of the blades is then equal to $v_1 = \sqrt{w_1^2 + u_1^2}$. The pressure at this point may be p_1, and the pressure beyond the blades p_2, according to Fig. 17. Applying the Bernoulli equation to two particles, respectively, ahead of and beyond the blades on the same streamline, we see that a pressure increase must be connected with a velocity decrease:

$$p_1 + \frac{\rho}{2}v_1^2 = p_2 + \frac{\rho}{2}v_2^2$$

---

[2] Prandtl, L., "Application of Modern Hydrodynamics to Aeronautics," Rep. No. 116 of National Advisory Committee for Aeronautics.

[3] Betz, A., "Eine Erweiterung der Schraubenstrahltheorie," *Zeit. f. Flugtechnik u. Motorluftschiffahrt*, vol. 11 (1920), p. 105.

or

$$p_2 - p_1 = \frac{\rho}{2}(v_1^2 - v_2^2) = \frac{\rho}{2}[w_1^2 + u_1^2 - (w_2^2 + u_2^2)]$$

The axial velocity, however, being equal on both sides of the blades ($w_1 = w_2$),

$$p_2 - p_1 = \frac{\rho}{2}(u_1^2 - u_2^2) \ldots\ldots\ldots\ldots\ldots [16]$$

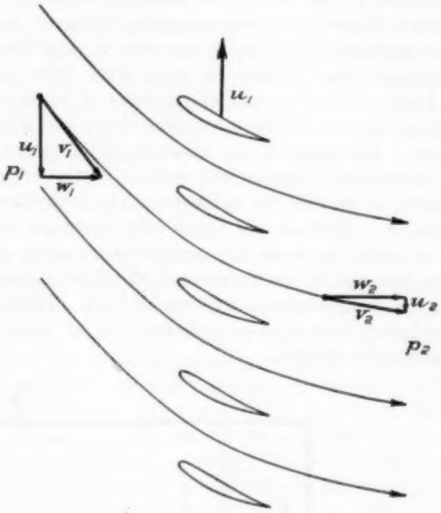

FIG. 17

Returning now to the first coordinate system in which the blades move with a speed equal to u_1 it is seen that the air beyond the blade has a component $u_1 - u_2$ perpendicular to w.

Applying this consideration to the flow through the fan area, it is seen that a pressure rise cannot be obtained without creating a rotational velocity. The kinetic energy due to this velocity must be considered as a loss, provided there are no stationary guide vanes beyond the fan. Assuming that the rotational component is sufficiently small to justify neglecting any centrifugal effects due to it, the loss due to the rotational velocity is

$$\int_{r_1}^{r_2} 2\pi r dr w \rho \frac{(u_1 - u_2)^2}{2} = \pi w \rho \int_{r_1}^{r_2} (\omega r - u_2)^2 r dr \ldots [17]$$

If the variation of the pressure difference on both sides of the fan is given as a function of the radius,

$$p_1 - p_2 = p_t = \frac{\rho}{2}(\omega^2 r^2 - u_2^2) = f(r) \ldots\ldots\ldots [18]$$

Equation [17] can be solved for a certain axial velocity and for a certain fan speed.

It can easily be shown by Equations [17] and [18] that for a constant pressure difference over the fan area corresponding to a constant circulation along the blade, the region near the hub contributes a much larger share of kinetic energy due to rotational velocities than the region near the blade tip. For this reason it is advisable, as mentioned before, to base the design of a fan upon a distribution of circulation which decreases with decreasing distance from the hub.

VI—RESTRICTIONS WITH REGARD TO THE VALIDITY OF THE ASSUMPTIONS PREVIOUSLY MADE

At the very outset it should be emphasized that the considerations regarding the blade-element theory and the formula expressing the efficiency no longer hold when the ratio of dynamic pressure to total pressure, i.e., φ^2/ψ, becomes too small. Particularly is it necessary to exercise care in the case of fans of large power output per unit area. Generally we may say that from about $\varphi^2/\psi = 0.3$ the centrifugal forces acting upon the boundary layer of the blades become more and more important, until finally for values in the neighborhood of $\varphi^2/\psi = 0.1$ the flow around the blades is entirely changed.

Another important question is whether the assumption holds that the performance of an element of a fan blade is the same as it is if considered an element of an air wing. In other words, can we apply the c_L, c_D curves of airfoils, determined by wind-tunnel tests, in designing a fan and calculating its efficiency? Generally speaking, it may be said that this assumption is the more justified the larger the ratio

$$\frac{w}{\omega r_2} = \varphi \ldots\ldots\ldots\ldots\ldots\ldots [19]$$

and the smaller ratio

$$\frac{T}{A\frac{\rho}{2}w^2} \ldots\ldots\ldots\ldots\ldots\ldots [20]$$

These, it may be noted, are the same restrictions made in the propeller theory—with the difference, however, that for a propeller the requirements are usually fulfilled in a high degree due to the large axial velocity w. For a theoretical treatment, therefore, the conditions are more favorable for a propeller than for a fan. Substituting Ap_t for T in [20] and considering that $p_t = \psi \frac{\rho}{2}(\omega r_2)^2$, we have, from [19],

$$\frac{T}{A\frac{\rho}{2}w^2} = \frac{\psi \omega^2 r_2^2}{w^2} = \frac{\psi}{\varphi^2} \ldots\ldots\ldots\ldots [20a]$$

The reciprocal of [20], or [20*a*], represents the ratio of dynamic pressure to total pressure, and it has been previously shown that in a set-up such as that shown in Fig. 3 this value is always less than unity, and the expression [20*a*] is thus greater than unity. However, if there is a diffuser beyond the fan, converting a part of the kinetic energy of the air into pressure, as shown in Fig. 18, φ^2/ψ can become considerably greater than unity, and hence the ratio [20*a*] very small. Following the variation of pressure along a streamline as shown in Fig. 18, and assuming a diffuser which converts 80 per cent of the kinetic energy of the air directly beyond the fan into pressure, we obtain

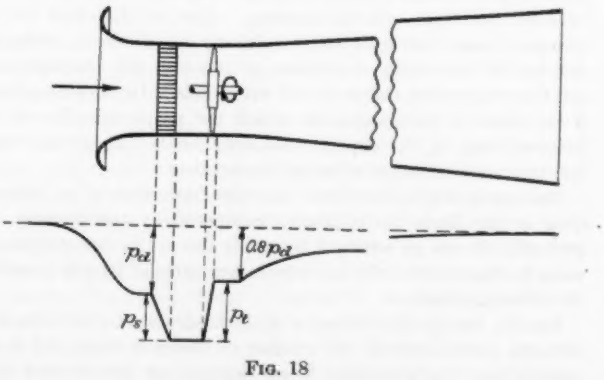

FIG. 18

$$\frac{p_d}{p_t} = \frac{\frac{\rho}{2} w^2}{\frac{\rho}{2} w^2 + p_s - 0.8 \frac{\rho}{2} w^2}$$

If p_s is negligible, we have $p_d/p_t = 5$, or

$$\frac{T}{A \frac{\rho}{2} w^2} = \frac{\psi}{\varphi^2} = \frac{p_t}{p_d} = \frac{1}{5}$$

Tests recently made with different fans, using a test equipment described later, have shown that for a value of $\varphi = 0.2$, the c_L, c_D curves can be used fairly well down to a value of $\psi/\varphi^2 = 0.3$. For larger values of φ this limit probably can be somewhat increased.

There is, however, still another difficulty regarding the application of the c_L, c_D curves. It is well known that for a certain angle of attack the lift and especially the drag of an air wing depend largely on the aspect ratio, i.e., on the ratio of the width of a wing to its length. In addition to the profile drag caused by air friction along the airfoil, there is the so-called induced drag, caused by air flowing around the ends of the wing, due to the pressure drop at these points from the region of higher pressure below the wing to the region of lower pressure above the wing. This flow around the ends of the wing, producing two vortices starting at each end, means an additional drag according to the kinetic energy of these vortices. As shown in the so-called Prandtl wing theory, such vortices are not only produced at the end of the wing but at all points along the trailing edge of the wing where the amount of the circulation varies or, where $d\Gamma/dx \gtrless 0$, if x is parallel to the length of the wing. This induced drag, which is very often the greater portion of the total drag, depends largely on the aspect ratio. Not each arbitrary distribution of the circulation along the wing produces the same induced drag for a given lift and wing area, but it has been proved that a certain distribution can be considered the best one, giving the minimum of drag. In the present case, the circulation has to vary like the ordinates of an ellipse, having its principal axis as the axis of abscissas. For this elliptical distribution of the circulation the induced drag is proportional to the aspect ratio and to the square of the lift.

Applying these considerations to the induced drag of a fan blade, we have to bear in mind that the flow around the blade tip is very restricted due to the small clearance space between the blade and the housing. Also, at the other end of the blade near the hub, the conditions are different, although due to the decreasing circulation at the hub the circumstances are here more like those at the wing ends. In addition, there is no elliptical circulation, for which the proportionality of the induced drag to the aspect ratio only holds. However, these last two arguments are of minor importance.

Bearing in mind, therefore, that the formation of an induced drag at the blade tip is largely hampered by the housing, we probably do not go wrong if we apply the c_L, c_D curve of an air wing having about a 50 per cent larger ratio of length to width than the fan blade.

Finally, the mutual influence of the blades has to be taken into account, particularly if the number of blades is large and if the ratio $w/\omega r_2 = \varphi$ is small. It all depends on the product $d \times w/\omega r_2$, where d is the distance between the blades; the smaller this product the larger the mutual influence of the blades. The effect of this influence is a decreasing lift and an increasing induced drag for a given angle of attack, in accordance with the multiplane wing theory. Therefore the thrust does not increase in exact proportion to the increase of number of blades as assumed in [8], but somewhat less. Here again the influence is more pronounced for a low value of φ^2/ψ than for a high one, making also in this respect a theoretical treatment more difficult for lower values of φ^2/ψ. The results so far obtained, however, do not give a sufficiently clear picture to enable us to see in what manner the blades interfere with each other.

VII—EXPERIMENTAL SET-UP FOR FAN TESTS

A few words may now be said about the test equipment which was built about a year ago at the Research Laboratories of the Westinghouse Electric & Manufacturing Company in order to study systematically the whole question of propeller-type vs. centrifugal-type fans. Numerous tests have been made with different kinds of fans, varying the number of blades from 2 to 32, and using blades of different aspect ratios and different airfoil sections. Furthermore the influence of the clearance space between blades and housing with respect to the efficiency has been studied, as well as the influence of the smoothness of the blade surfaces. All these and many other tests are very useful not only in order to obtain the performance curves of actually built fans, but also in order to check the various assumptions on which the designs of the fans were based. These tests are being continued, and after completion will be described in a later paper on the subject.

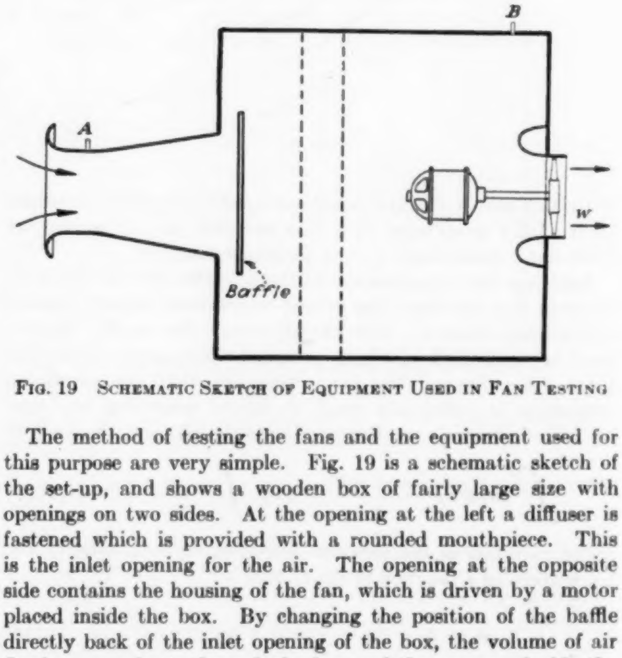

FIG. 19 SCHEMATIC SKETCH OF EQUIPMENT USED IN FAN TESTING

The method of testing the fans and the equipment used for this purpose are very simple. Fig. 19 is a schematic sketch of the set-up, and shows a wooden box of fairly large size with openings on two sides. At the opening at the left a diffuser is fastened which is provided with a rounded mouthpiece. This is the inlet opening for the air. The opening at the opposite side contains the housing of the fan, which is driven by a motor placed inside the box. By changing the position of the baffle directly back of the inlet opening of the box, the volume of air flowing per minute through the box and the pressure inside the box can be varied. A position of the baffle close to the wall represents the condition of a low value of φ^2/ψ, and one far from the wall a high value. In some cases it may be advisable to place screens between the baffle and the fan in order to diminish the kinetic energy of the air flowing at high velocity through the passage between the wall opening and baffle.

The volume of air flowing per unit time through the inlet opening, which volume of course is equal to the volume discharged by the fan, is determined by measuring the pressure difference at point A close to the rounded mouthpiece against atmospheric pressure. The increase of static pressure produced by the fan is measured directly by measuring the pressure at point B against atmospheric pressure. In addition to these two readings, the r.p.m. has to be determined, and also the power input to the shaft of the fan, which latter can be done best by using the motive power as a dynamometer. These readings, carried out for different baffle positions, provide sufficient data with which to calculate the φ, ψ, and η curves, and to obtain thereby a complete knowledge of the performance of the fan being tested.

VIII—Conclusions

In this paper a first attempt has been made to make use of more advanced aerodynamic theory in fan design. While such theory is applied with great success to airplane propellers, it requires considerable modification when applied to fans. This is due chiefly to the fact that the thrust of a propeller is caused by a velocity increase in the axial direction, whereas the pressure rise of a fan is essentially combined with an acceleration of air in a tangential direction. In addition, we may say that, generally speaking, the performance of a propeller is more susceptible to a theoretical treatment than is that of a fan, due to the high axial velocity of the propeller.

However, it may be emphasized that the assumptions on which the theory presented in this paper is based are well founded for that range of applications where the propeller-type fan can be considered superior as compared with the centrifugal type. Only for those working conditions (small volume and large pressure rise) where the propeller-type fan on the whole begins to be less suitable does the theoretical treatment become uncertain. Here further experiments are necessary, showing in what way the assumptions have to be modified for this case.

The propeller-type fan, working under normal conditions, however, can be designed in a rational way according to the outline given in this paper, and the power output as well as the efficiency can be predicted with reasonable accuracy.

Discussion

Th. Troller.[4] The author considers a propeller-type fan of the simplest form; namely, a propeller rotating in a closed tunnel, with no vanes or similar device for straightening the flow. Naturally this propeller has a special significance because of its simplicity and low cost. For many purposes, however, a small improvement of this construction—i.e., the installation of rigid guiding vanes before or behind the propeller—is quite helpful. Such an addition increases but little the cost of construction, but on the other hand makes possible a greater efficiency and pressure rise than obtainable with propeller alone. The calculation of such a fan is similar to the method used by Mr. Tietjens and is even somewhat simpler, for the reason that one assumption of the author may be left out of consideration; namely, the condition of small power loading or small ψ.

The writer wishes to omit the details of the calculation itself, but refers instead to the complete treatment of the question in Heft 10, Aachener Abhandlungen aus dem Aerodynamischen Institut, "Zur Berechnung von Schraubenventilatoren" (The Design of Propeller Fans), by Th. Troller. In this article the writer has discussed fully the principles of the design and calculation of propeller-type fans from an aerodynamical standpoint.

The writer will limit himself to several comments on the physical phenomena in the operation of propeller fans and the special conditions which lead to the consideration of the fans equipped with guiding vanes as an ideal type.

The general problem of the fan is as follows: It is desired to set a certain amount of air in motion against a certain static pressure. The energy required by the fan is equal to the quantity of air times (increase of static pressure plus increase of dynamic pressure of the flow), or more exactly, the integral over the single particles of air. Now, in general, for a given quantity of air and static pressure head this energy is smallest when longitudinal motion of all the fluid particles is constant. That follows from the fact that for a certain sum of the first power of a function (in this case a velocity distribution over the surface, which gives the quantity of air) the sum of the second powers (in this case the dynamic pressures) are smallest for a constant value of the variables. The consideration of the energy imparted to the air without taking into consideration other factors which influence the efficiency of the fan leads, therefore, to the condition that the flow produced by the fan has a uniform axial velocity over the whole cross-section. Calculation of the conditions at the fan shows further that when the author's ψ has greater values than about one, the energy of the air has a greater significance for the efficiency and the construction than all other factors such as friction, etc.

Now it is in general not possible to obtain the necessary condition for higher values of ψ without rigid guiding vanes or a second propeller rotating in the opposite direction. The propeller without vanes sets the air into rotation about the axis. This rotation gives rise to a loss of pressure toward the axis due to the centrifugal force. Since the static pressure against which the air must flow acts uniformly over the whole surface, the air will then flow more slowly or will perhaps even flow backward in this region. In order to prevent this, one must increase the pressure caused by the propeller by giving the propeller a larger working surface toward the axis. From this a new increase of rotation is caused. There results a further increase of under-pressure and further losses through the energy of rotation. This dilemma can be solved only by the use of a guiding vane.

Another point is the operation of the fan under varying conditions: in other words, the taking into account of the entire head-capacity curve instead of a single point on this line. If a fan is to be used under varying operating conditions (for instance, varying static pressures), it is necessary to design the propeller in such a way that the uniform velocity distribution is always obtained. In the aerodynamic construction of the fan there is a possibility of taking this point into consideration, since in the design for a certain operating condition only the product $b \cdot c_1$ is determined. In the Aachen article, the writer has developed the formula which gives the desired expression through which both factors can be determined for the entire propeller. These formulas are of a simple nature and make possible the complete fan design with little labor. Propellers designed on the basis of this formula in this manner have proved themselves always practical.

V. Nekrassoff.[5] The writer would like to take issue with one of the opening statements of the author which says, "Despite the importance of the propeller-type fan, there is, as contrasted with the aeroplane propeller, no theory for it." As far back as 1919 there was published in this country Report 29 of the National Advisory Committee for Aeronautics containing Dr. G. Bothezat's memoir on the general theory of blade screws (including propellers, fans, heliocopter screws, helicoidal pumps, turbo motors).

Even this first memoir, almost exclusively devoted to the problems of aeroplane propellers, has a sufficient amount of data for practical handling of the problems of rational propeller-fan design.

Using this memoir as a basis during research work for the Proctor & Schwartz Company in Philadelphia (1921–1926), the writer made quite a number of tests and theoretical investigations of the disk or propeller type of fans. All these researches finally were condensed in one hexagonal nomogram giving a solution at a glance of all seven fundamental problems of disk fan design. Not long ago the writer was told that this nomogram was still successfully used by the Proctor & Schwartz Company.

[5] Bell Telephone Laboratories, New York, N. Y.

In mentioning these facts, the writer would like to emphasize only the following: The theory of the propeller-type fan does exist already; its author, Dr. G. Bothezat, is still living in this country; the United States Navy has adopted as a standard type ventilators (propeller fans) designed by Dr. Bothezat himself; these fans are on the market manufactured by the Bothezat Company, and their performance is the very best one as compared with all other existing propeller fans.

With such purely historical correction, the paper certainly fully preserves all its excellent qualities of usefulness, but hardly can it be accepted as "a first attempt to make use of more advanced aerodynamic theory in fan design," as the author says in the concluding part of his paper.

AUTHOR'S CLOSURE

It may be regarded as a proof of the timeliness of this paper on propeller-type fans that almost at the same time another paper on this subject has been published in Germany by Mr. Th. Troller.

In his paper, the performance of a fan is discussed exclusively in connection with stationary guide vanes in front or behind the fan, and it is pointed out that a constant axial air velocity over the whole cross-section, corresponding to a constant circulation along the blade, will give the highest efficiency. This is particularly true if the total pressure produced by the fan is large. However, if this pressure is comparatively small, the loss of energy due to surface friction of the guide vanes may be larger than the gain of energy due to the conversion of rotational velocity into pressure. In this case, the use of guide vanes will bring practically no increase of the efficiency.

In addition, it happens quite often that there is no space for any guide vanes, as, for instance, for a fan on top of a Diesel locomotive or for a fan mounted on a rotor of a generator. Taking no account of these cases, the author agrees with Mr. Troller that a fan with guide vanes should be preferred if the cost of the fan is not of essential importance.

With respect to the historical remarks of Mr. V. Nekrassoff regarding Dr. G. Bothezat's work on propeller theory, which was outstanding at that time, the modern propeller theory is entirely based on the aerofoil theory as it was developed in 1918 by L. Prandtl. Although Dr. Bothezat realized the importance of the tip vortices of an aerofoil regarding its resistance, he tried in vain to develop a formula for the induced drag. It was shown by Dr. A. Betz in 1914 that the assumption of a constant circulation along the aerofoil and two concentrated tip vortices can be used quite well if one wants to determine the mutual influence of the wing of a biplane or the influence of the neighborhood of the ground. However, this assumption of two concentrated tip vortices, as it was made by Dr. Bothezat, is not sufficiently accurate for a determination of the drag of the aerofoil induced by the "vortex ribbon" behind the aerofoil. This is shown on page 20 of L. Prandtl's Aerofoil Theory.[6] Therefore, the results based on the assumption of only two tip vortices of finite value are in error.

On the other hand, it may be noted that the Report No. 29 of the N.A.C.A. by Dr. Bothezat contains only the first memoir on the propeller, and not the study on fans, although announced in the title. The performance of a propeller at a fixed point, however, cannot be considered equal to the performance of a fan working in a housing with small clearance space at the tip. The distribution of the circulation along the blades (highest efficiency assumed) is quite different in both cases. Dr. Bothezat says on page 166 of his report:

> This first memoir thus contains, besides a general summary of the whole screw problem, a detailed study of the propulsion screw—that is, the propeller—and the different questions in connection with it. A second memoir, directly continuing this one, will contain a special study of screws at a fixed point in their different application principally when used as fans and as helicopters as well as a detailed study of the turbo-motor screws, especiallly as aeroturbines; that is to say, as windmills.

This second memoir, however, containing the study of fans, has not yet been published.

The Use of Models in Vibration Research

By J. P. DEN HARTOG,[1] EAST PITTSBURGH, PA.

In this paper the theory of dynamic similarity as applied to vibration problems in mechanical engineering is discussed, and a number of specific examples are given.

THE use of models in research of any sort is intimately connected with the science of "dimensional analysis" or "dynamical similarity." At least this has become more and more so since Osborne Reynolds in 1883 published the results of a series of experiments on water flow through pipes in which the pressure drop was expressed not in the velocity of flow V, nor in the diameter of the pipe d, nor the viscosity ν, but in terms of a non-dimensional combination Vd/ν afterward called the Reynolds number.

Reynolds' fundamental work and the subsequent applications and extensions by a great number of scientists, among whom Rayleigh stands foremost, have dealt primarily with hydrodynamic problems. In fact it is no exaggeration to state that most of the great advance made in that science during the last thirty years is due to, or at least has been greatly influenced by, the theory of dynamic similarity.

But the method is by no means restricted to hydrodynamics alone. The whole domain of physics in its broadest sense has been affected by it. In this paper it is intended to discuss some cases in vibration engineering where model tests, mostly in conjunction with some similarity considerations, have led to useful results.

The Theory of Similarity Applied to the Classical Vibration Problem

Consider the simplest case of a single-degree-of-freedom system with viscous damping and a harmonic exciting force (Fig. 1). The equation of motion is usually written as:

$$m\frac{d^2x}{dt^2} + c\frac{dx}{dt} + kx = P \sin \omega t \ldots\ldots\ldots\ldots [1]$$
